W. W. Norton & Company has been independent since its founding in 1923, when William Warder Norton and Mary D. Herter Norton first published lectures delivered at the People's Institute, the adult education division of New York City's Cooper Union. The firm soon expanded its program beyond the Institute, publishing books by celebrated academics from America and abroad. By midcentury, the two major pillars of Norton's publishing program—trade books and college texts—were firmly established. In the 1950s, the Norton family transferred control of the company to its employees, and today—with a staff of five hundred and hundreds of trade, college, and professional titles published each year—W. W. Norton & Company stands as the largest and oldest publishing house owned wholly by its employees.

Preface

Why a cell biology textbook? What is its value in a world of online resources so vast that any information you might want about cells is, in principle, freely available a few taps away?

The answer is that a textbook provides what open-ended Internet searches cannot—a curation of knowledge and an expert, accurate guide to the beauty and complexities of cells. Our book provides a narrative that leads the reader logically and progressively through the key concepts, components, and experiments in such a way that readers can build for themselves a memorable, conceptual framework for cell biology—a framework that will allow them to understand and critically evaluate the exciting rush of new discoveries. That is what we have tried to do in *Molecular Biology of the Cell* for each of its seven editions.

This edition was completed during the COVID-19 pandemic. Many of the questions that this global crisis generated are cell biological questions—including how the virus gets into our cells, how it replicates, how our immune system responds, how vaccines are developed, and how scientists produce the molecular details of virus structure. Required for the rapid development of safe and effective COVID-19 vaccines, answers to all of these questions can be found in this textbook. To make room for them, as well as for many other major recent advances in our knowledge, much previous content had to be removed.

Understanding the inner workings of cells requires more than words. Our book contains more than 1500 illustrations that create a parallel narrative, closely interwoven with the text. Each figure has been designed to highlight a key concept. The unique clarity, simplicity, and consistency of the figures across chapters, achieved by use of a common set of icon designs and colors (for example, DNA red and proteins green), enables students to scan them as chapter overviews. In this edition, important protein structures are depicted and their Protein Data Bank (PDB) codes provided; these codes link to tools on the RCSB PDB website (www.rcsb.org), where students can more fully explore the proteins that lie at the core of cell biology. In addition, more than 180 narrated movies have been produced for the book, each linked to the text to provide additional insights.

John Wilson and Tim Hunt have again contributed their distinctive and imaginative problems to help students gain a more active understanding of the text. The end-of-chapter problems emphasize experiments and quantitative approaches in order to encourage critical thinking. Their Digital Problems Book in Smartwork greatly expands on these self-assessment problems and includes data analysis and video review questions that are based on the movie links in the textbook.

Many millions of scientific papers are relevant to cell biology, and many important new ones are published daily. The challenge for textbook writers is to sort through this overwhelming wealth of information to produce a clear and accurate conceptual platform for understanding how cells work. We have aimed high, seeking primarily to support the education of cell biology students, including the next generation of bioscientists, but also to support active scientists pursuing new fundamental research and the search for practical advances to improve the human condition.

So, why read a textbook? We live in a world that presents humanity with many challenging problems related to cell biology, including declining biodiversity, climate change, food insecurity, environmental degradation, resource depletion, and animal and plant diseases. We hope that this new edition of our textbook will help the reader to better understand these problems and—for many—to contribute to solving them.

MBOC7_ptr_ch00_fm_i-xxxviii.indd 5 08/12/21 11:23 AM

Note to the Reader

What's New in the Seventh Edition?

Every chapter in the Seventh Edition has been significantly updated with information on new discoveries in the field of cell biology. Examples of this new content include:

- Updated information on the continuing impact of human genome research, including what has been learned from sequencing hundreds of thousands of human genomes (Chapter 4), and updated coverage of tumor genomes (Chapter 20).
- New research on pathogens, diseases, and methods of combating them, including discussion of COVID-19 (Chapters 1, 5, and 23) and mRNA vaccines (Chapter 24).
- Updated research on cellular organization, including new information on biomolecular condensates (Chapters 3, 6, 7, 12, and 14) and on chromosome organization by DNA loop extrusion (Chapters 4, 7, and 17).
- Expanded coverage of new microscope technologies, including superresolution light microscopy and atomic resolution electron microscopy (Chapter 9), and new research breakthroughs from cryo-electron microscopy, such as stretch-activated Piezo channels (Chapter 11).
- New coverage of evolution, including a new discussion on the diversity of life (Chapter 1), plus updates on both human (Chapter 4) and HIV (Chapter 23) evolution

In addition, a quarter of the book's illustrations are either completely new or significantly updated for accuracy, clarity, and visual appeal.

Finally, we are thrilled to offer online assessment, for the first time, with the Digital Problems Book in Smartwork—reimagining the classic companion text, *The Problems Book*, for twenty-first century instructors and students.

Structure of the Book

Although the chapters of this book can be read independently of one another, they are arranged in a logical sequence of five parts. The first three chapters of Part I cover elementary principles and basic biochemistry. They can serve either as an introduction for those who have not studied biochemistry or as a refresher course for those who have. Part II deals with the storage, expression, and transmission of genetic information. Part III presents the principles of the main experimental methods for investigating and analyzing cells; here, a section titled "Mathematical Analysis of Cell Function" in Chapter 8 provides an extra dimension in our understanding of cell regulation and function. Part IV describes the internal organization of the cell. Part V follows the behavior of cells in multicellular systems, starting with how cells become attached to each other and concluding with chapters on pathogens and infection and on the innate and adaptive immune systems.

End-of-Chapter Problems

A selection of problems, written by John Wilson and Tim Hunt, appears in the text at the end of each chapter. Solutions to these problems are available on the Norton Teaching Tools site.

MBOC7_ptr_ch00_fm_i-xxxviii.indd 6 08/12/21 11:23 AM

References

A concise list of selected references is included at the end of each chapter. These are arranged in alphabetical order by author surname under the main chapter section headings. These references often include the original papers in which the most critical discoveries were first reported. The ebook also includes the DOI identifier for the references, making it easy for students to access the articles.

Glossary Terms

Throughout the book, boldface type has been used to highlight key terms at the point in a chapter where the main discussion occurs. Italic type is used to set off important terms with a lesser degree of emphasis. At the end of the book is an expanded glossary, covering all the major terms common to cell biology; it should be the first resort for a reader who encounters an unfamiliar technical word.

Website for Students

Resources for students are available at **digital.wwnorton.com/mboc7**. The complete glossary as well as a set of flashcards are available on this student website.

MBOC7_ptr_ch00_fm_i-xxxviii.indd 7 08/12/21 11:23 AM

Nomenclature for Genes and Proteins

Each species has its own conventions for naming genes; the only common feature is that they are always set in italics. In some species (such as humans), gene names are spelled out all in capital letters; in other species (such as zebrafish), all in lowercase; in yet others (most mouse genes), with the first letter in uppercase and the rest in lowercase; or (as in *Drosophila*) with different combinations of uppercase and lowercase, according to whether the first mutant allele to be discovered produced a dominant or recessive phenotype. Conventions for naming protein products are equally varied.

This typographical chaos drives everyone crazy. Moreover, there are many occasions, especially in a book such as this, where we need to refer to a gene generically—without specifying the mouse version, the human version, the chick version, or the hippopotamus version—because the gene variants across species are all equivalent for the purposes of our discussion. What convention then should we use?

We have decided in this book to follow a uniform rule. We write all gene names with the first letter in uppercase and the rest in lowercase, and all in italics, thus: *Bazooka, Cdc2, Dishevelled, Egl1*. The corresponding protein, where it is named after the gene, will be written in the same way, but in roman rather than italic letters: Bazooka, Cdc2, Dishevelled, Egl1. When it is necessary to specify the organism, this can be done with a prefix to the gene name.

For completeness, we list a few further details of naming rules that we shall follow. In some instances, an added letter in the gene name is traditionally used to distinguish between genes that are related by function or evolution; for those genes, we put that letter in uppercase if it is usual to do so (*LacZ*, *RecA*, *HoxA4*). Proteins are more of a problem. Many of them have names in their own right, assigned to them before the gene was named. Such protein names take many forms, although most of them traditionally begin with a lowercase letter (actin, hemoglobin, catalase); others are acronyms (such as GFP, for green fluorescent protein, or BMP4, for bone morphogenetic protein 4). To force all such protein names into a uniform style would do too much violence to established usages, and we shall simply write them in the traditional way. For the corresponding gene names in all these cases, we shall nevertheless follow our standard rule: *Actin, Hemoglobin, Catalase, Bmp4, Gfp*.

For those who wish to know them, the table shows some of the official conventions for individual species—conventions that we shall mostly violate in this book, in the manner shown.

Resources for Instructors

digital.wwnorton.com/mboc7

Designed to enrich the classroom experience, Instructor Resources are available at **digital.wwnorton.com/mboc7**. Adopting instructors can obtain access to the site from their sales representative, who can be identified by visiting wwnorton .com/educator and clicking the "Find My Rep" button.

The Digital Problems Book in Smartwork

For the first time, the popular print supplement *Molecular Biology of the Cell: The Problems Book* is now available in Smartwork. Easier for instructors to assign and more helpful to students because of each question's pedagogical scaffolding, the Digital Problems Book in Smartwork features the questions authored by Tim Hunt and John Wilson adapted for digital delivery. An enormous library of almost 3500 questions that include critical thinking questions, data analysis questions, and animation and video questions, allows instructors to deliver the exact type of assessment that their students need. The Digital Problems Book in Smartwork comes at no additional cost with all new copies of *Molecular Biology of the Cell*.

MBOC7_ptr_ch00_fm_i-xxxviii.indd 10 08/12/21 11:23 AM

Norton Teaching Tools

The Norton Teaching Tools site for *Molecular Biology of the Cell* provides creative and engaging resources to refresh a syllabus or to design a new one. Dynamic, experienced instructors have created primary literature suggestions, active learning activities, lecture PowerPoint files, descriptions of all of the animations and videos, and much more. All of the teaching tools are aligned with chapter topics and organized by activity type, making it easily sortable. The site also features tips for assigning Norton's digital learning tools and addressing the most common course challenges.

Animations and Videos

Under the authorial direction of Michele M. McDonough and Thomas A. Volpe, both of Northwestern University, the animations and video library has been thoroughly updated and expanded. The more than 180 animations and videos are integrated into the ebook and also available to students and instructors at digital .wwnorton.com/mboc7. Instructors can view descriptions of each on the Norton Teaching Tools site.

Norton Ebook

The purchase of any new print copy of the Seventh Edition of *Molecular Biology of the Cell* includes access to the Norton Ebook version of the text at no additional cost. The Norton Ebook can be purchased as an affordable stand-alone option that provides an active reading experience, enabling students to take notes, bookmark, search, highlight, and read offline. All of the videos and animations appear directly in the ebook, and instructors can add notes that students can see as they are reading the text.

Art of Molecular Biology of the Cell, Seventh Edition

The images from the book are available in two convenient formats: PowerPoint and JPEG, and in both labeled and unlabeled versions.

Figure-integrated Lecture Outlines

The section headings, concept headings, and figures from the text have been integrated into PowerPoint presentations and can be customized. For example, the content of these presentations can be combined with videos, questions from the book, or activities in the Norton Teaching Tools site, in order to create unique lectures that facilitate interactive learning.

Test Bank

Updated for the Seventh Edition, the test bank includes a variety of question formats: multiple choice, short answer, fill-in-the-blank, true-false, and matching. The test bank was created with the philosophy that a good exam should require students to reflect upon and integrate information as a part of a sound understanding. Questions are classified by section and difficulty, making it easy to construct tests and quizzes. The test bank question library includes about 70 questions per chapter, ensuring instructors can find the right questions for their exams. It will be delivered through Norton Testmaker, which brings the high-quality questions in the test bank online. Create assessments for your course without downloading files or installing specialized software, customize test bank questions, and easily export your tests to Microsoft Word or Common Cartridge files for your learning management system (LMS).

MBOC7_ptr_ch00_fm_i-xxxviii.indd 11 08/12/21 11:23 AM

About the Authors

Bruce Alberts received his PhD from Harvard University and is the Chancellor's Leadership Chair in Biochemistry and Biophysics for Science and Education, University of California, San Francisco. He was the editor-in-chief of *Science* magazine from 2008 until 2013, and for twelve years he served as president of the U.S. National Academy of Sciences (1993–2005).

Rebecca Heald received her PhD from Harvard University and is professor of molecular and cell biology at the University of California, Berkeley. She also serves as the co-chair of that department.

Alexander Johnson received his PhD from Harvard University and is professor of microbiology and immunology at the University of California, San Francisco. He is also director of the Program in Biological Sciences (PIBS) at UCSF.

David Morgan received his PhD from the University of California, San Francisco, and is professor of the Department of Physiology there as well as vice dean for research in the School of Medicine.

Martin Raff received his MD from McGill University and is an emeritus professor of biology and an affiliated member of the Medical Research Council Laboratory for Molecular Cell Biology at University College London.

Keith Roberts received his PhD from the University of Cambridge and was deputy director of the John Innes Centre, Norwich. He is emeritus professor at the University of East Anglia.

Peter Walter received his PhD from the Rockefeller University in New York and is professor of the Department of Biochemistry and Biophysics at the University of California, San Francisco, and an investigator at the Howard Hughes Medical Institute.

John Wilson received his PhD from the California Institute of Technology. He is Distinguished Emeritus Professor of Biochemistry and Molecular Biology at Baylor College of Medicine in Houston.

Tim Hunt received his PhD from the University of Cambridge, where he taught biochemistry and cell biology for more than 20 years. He worked at Cancer Research UK from 1990 to 2010. He shared the 2001 Nobel Prize in Physiology or Medicine with Lee Hartwell and Paul Nurse. He moved to Okinawa in 2016.

MBOC7_ptr_ch00_fm_i-xxxviii.indd 12 08/12/21 11:23 AM

Acknowledgments

We once again thank our spouses, partners, families, friends, and colleagues for their continuing patience and support, without which the writing of this new edition of our textbook would not have been possible. As always, we are also indebted to a large number of scientists whose generous help has been essential for making the text as clear, up-to-date, and accurate as possible.

Deserving special credit are the following five outstanding scientists who accepted the task of re-drafting chapters in their areas of expertise: Chapters 12 and 13, Ramanujan Hegde (MRC Laboratory of Molecular Biology and Cambridge University, United Kingdom); Chapter 14, Jared Rutter (University of Utah); Chapter 21, David Bilder (University of California, Berkeley); Chapter 22, Yukiko Yamashita (Whitehead Institute, Massachusetts Institute of Technology); Chapter 23, Matthew Welch (University of California, Berkeley).

In what follows, we acknowledge and thank all of the scientists whose suggestions have helped us to prepare this edition. (A combined list of those who helped with our first, second, third, fourth, fifth, and sixth editions is also provided.)

General: Joseph Ahlander (Northeastern State University), Buzz Baum (Molecular Research Institute, United Kingdom), Michael Burns (Loyola University Chicago), Silvia C. Finnemann (Fordham University), Nora Goosen (Leiden University, The Netherlands), Harold Hoops (State University of New York, Buffalo), Joanna Norris (University of Rhode Island), Mark V. Reedy (Creighton University), Jeff Singer (Portland State University), Amy Springer (University of Massachusetts), Andreas Wodarz (University of Cologne, Germany). In addition, Tiago Barros produced new molecular models for the Seventh Edition.

Chapter 1: Sage Arbor (Marian University Indianapolis), Stephen E. Asmus (Centre College), Jill Banfield (University of Colifornia, Porkoley), Zoë Burke (University of Both

Stephen E. Asmus (Centre College), Jill Banfield (Universit of California, Berkeley), Zoë Burke (University of Bath, United Kingdom), Elizabeth Good (University of Illinois, Urbana-Champaign), Julian Guttman (Simon Fraser University, Canada), Sudhir Kuman (Temple University), Sue Hum-Musser (Western Illinois University), Brad Mehrtens (University of Illinois, Urbana-Champaign), Inaki Ruiz-Trillo (University of Barcelona, Spain), David Stern (Janelia Research Campus), Andrew Wood (Southern Illinois University), Lidan You (University of Toronto, Canada).

Chapter 2: Sage Arbor (Marian University Indianapolis), Stephen E. Kingdom) Mike Chao (California State University, San Bernardino), Edward B. Cluett (Ithaca College), Elizabeth Good (University of Illinois, Urbana-Champaign), Yun Hyun Huh (Gwangju Institute of Science and Technology, South Korea), Tim Levine (University College London, United Kingdom), Sue Hum-Musser (Western Illinois University), Wendy Innis-Whitehouse (University of Texas, Rio Grande Valley), Mack Ivey (University of Arkansas), Stephen Rogers (University of North Carolina), Michael Silverman (Simon Fraser University, Canada), Gina Voeltz (University of Colorado, Boulder), Graham Warren (University College London, United Kingdom), Weiliang Xia (Shanghai Jiao Tong University, China), Ge Yang (Carnegie Mellon University).

Chapter 13: Major contributor Ramanujan Hegde (MRC Laboratory of Molecular Biology and Cambridge University, United Kingdom). Swapna Bhat (University of North Georgia, Gainesville), Pete Cullen (University of Bristol, United Kingdom), Zheng Fan (The University of Tennessee Health Science Center), Adam Frost (University of California, San Francisco), Wendy Innis-Whitehouse (University of Texas, Rio Grande Valley), Reinhard Jahn (Max Planck Institute for Biophysical Chemistry, Germany), Elizabeth Miller (MRC Laboratory of Molecular Biology, United Kingdom), Sean Munro (MRC Laboratory of Molecular Biology, United Kingdom), Michael Silverman (Simon Fraser University, Canada), Susan Spencer (Saint Louis University), Christine Suetterlin (University of California, Irvine), Graham Warren (University College London, United Kingdom).

Chapter 14: Major contributor Jared Rutter (University of Utah). Cedric Asensio (University of Denver), Alice Barkan (University of Oregon), Tessa Burch-Smith (University of Tennessee, Knoxville), Navdeep Chandel (Northwestern University), Elizabeth Good (University of Illinois, Urbana-Champaign), Mark Grimes (University of Montana), Yun Hyun Huh (Gwangju Institute of Science and Technology, South Korea), Sue Hum-Musser (Western Illinois University), Mack Ivey (University of Arkansas), Werner Kühlbrandt (Max Planck Institute of Biophysics, Germany), Dario Leister (University of Munich, Germany), Song-Tao Liu (University of Toledo), Amit Singh (University of Dayton), Jonathan Snow (Barnard College), Amy Sprowles (Humboldt State University), Dennis Winge (University of Utah).

Chapter 15: Josefino Castillo (University of Santo Tomas, Philippines), Elizabeth Good (University of Illinois, Urbana-Champaign), Mark Grimes (University of Montana), Sue Hum-Musser (Western Illinois University), Natalia Jura (University of California, San Francisco), In Hye Lee (Ewha Womans University, South Korea), Song-Tao Liu (University of Toledo), Bruce Mayer (University of Connecticut), Alexandra Newton (University of California, San Diego), Roeland Nusse (Stanford University), Amit Singh (University of Dayton), Jonathan Snow (Barnard College), Amy Sprowles (Humboldt State University). Chapter 16: Anna Akhmanova (Utrecht University, The Netherlands), Alexander Bershadsky (National University of Singapore, Singapore), David Bilder (University of California, Berkeley), Josefino Castillo (University of Santo Tomas, Philippines), Ann Cavanaugh (Creighton University), Andrew Carter (Medical Research Council, United Kingdom), Roger Craig (University of Massachusetts Medical School), Lillian Fritz-Laylin (University of Massachusetts), Elizabeth Good (University of Illinois, Urbana-Champaign), Julian Guttman (Simon Fraser University, Canada), Sue Hum-Musser (Western Illinois University), Yulia Komarova (University of Illinois, Chicago), Arash Komeili (University of California, Berkeley), Chao Liu (Stanford University), Richard McIntosh (University of Colorado), Dyche Mullins (University of California, San Francisco), Maxence Nachury (University of California, San Francisco), Daniela Nicastro (University of Texas Southwestern), Sam Reck-Peterson (University of California, San Diego), Luke Rice (University of Texas Southwestern), Stephen Rogers (University of North Carolina), Trina Schroer (Johns Hopkins University), Michael Sixt (IST, Austria), Thomas Surrey (The Francis Crick Institute, United Kingdom), Tatyana Svitkina (University of Pennsylvania), Katherine Warpeha (University of Illinois, Chicago), Matthew Welch (University of California, Berkeley), Lidan You (University of Toronto, Canada).

Chapter 17: Michael W. Black (California Polytechnic State University), Ann Cavanaugh (Creighton University), Yu Chen (University of Massachusetts), Frederick Dick (University of Western Ontario, Canada), Bruce Edgar (University of Utah), Michael Glotzer (University of Chicago), Elizabeth Good (University of Illinois, Urbana-Champaign), Greg Hermann (Lewis and Clark College), Sue Hum-Musser (Western Illinois University), Peter Mayinger (Oregon Health and Science University), Mindy McCarville (Dalhousie University, Canada), Jennifer McDonough (Kent State University), Yuko Miyamoto (Elon University), Jonathon Pines (Institute of Cancer Research, United Kingdom), Stephen Rogers (University of North Carolina), Frank Uhlmann (The Francis Crick Institute, United Kingdom), Johannes Walter (Harvard Medical School), Katherine Warpeha (University of Illinois, Chicago), Christina Zito (University of New Haven). Chapter 18: Stephen E. Asmus (Centre College), Yu Chen (University of Massachusetts), Elizabeth Good (University of Illinois, Urbana-Champaign), Douglas R. Green (St. Jude's Children's Research Hospital), Mindy McCarville (Dalhousie University, Canada), Sue Hum-Musser (Western Illinois University), Yuko Miyamoto (Elon University), Mark Running (University of Louisville), Christina Zito (University of New Haven).

Chapter 19: Stephen E. Asmus (Centre College), Zoë Burke (University of Bath, United Kingdom), John Couchman (University of Copenhagen, Denmark), Elizabeth Good (University of Illinois, Urbana-Champaign), Tony J.C. Harris (University of Toronto), Sue Hum-Musser (Western Illinois University), Yulia Komarova (University of Illinois, Chicago), Zhengchang Liu (University of New Orleans), Mark Running (University of Louisville), Kara Sawarynski (Oakland University), Masatoshi Takeichi (RIKEN Center for Developmental Biology, Japan), Zena Werb (formerly of University of California, San Francisco), Alpha Yap (University of Queensland, Australia), Christina Zito (University of New Haven).

Chapter 20: Alan Ashworth (University of California, San Francisco), Anton Berns (Netherlands Cancer Institute, The Netherlands), David Bilder (University of California, Berkeley), Fred Bunz (Johns Hopkins University), Venugopalan Cheriyath (Texas A&M University,

MBOC7_ptr_ch00_fm_i-xxxviii.indd 15 08/12/21 11:23 AM

Commerce), Michel DuPage (University of California, Berkeley), Paul Edwards (University of Cambridge, United Kingdom), Elizabeth Good (University of Illinois, Urbana-Champaign), Jeff Hadwiger (Oklahoma State University), Monika Haoui (University of California, Berkeley), Lin He (University of California, Berkeley), Dirk Hockemeyer (University of California, Berkeley), Sue Hum-Musser (Western Illinois University), Doug Kellogg (University of California, Santa Cruz), Maria Krasilnikova (Pennsylvania State University), Christopher Lassiter (Roanoke College), Kunxin Luo (University of California, Berkeley), Adam G. Matthews (Wellesley College), Mike Misamore (Texas Christian University) Alexander K. Murashov (East Carolina University), Kristina Pazehoski (Grove City College), David Pellman (Dana Farber Cancer Institute), Jody Rosenblatt (University of Utah), Peter Savage (University of Chicago), Kara Sawarynski (Oakland University), Timothy Shannon (Francis Marion University), Frederick Sproull (LaRoche University), Robert A. Weinberg (Massachusetts Institute of Technology), Harold Varmus (Weill Cornell Medicine), Kenneth Yip (University of Toronto, Canada), Christina Zito (University of New Haven).

Chapter 21: Major contributor David Bilder (University of California, Berkeley). Paul Cullen (State University of New York, Buffalo), Claude Desplan (New York University), Bruce Edgar (University of Utah), Stephen Jesch (Cornell University), Christopher Lassiter (Roanoke College), Laura Mathies (Virginia Commonwealth University), Mike Misamore (Texas Christian University), Alexander K. Murashov (East Carolina University), Nipam Patel (Marine Biological Laboratory), Ruth Phillips (Syracuse University), Olivier Pourquié (Harvard University), Joshua Sanes (Harvard University), Ramaswamy Sharma (University of Texas Health Science Center at San Antonio), Jan Skotheim (Stanford University), David Somers (The Ohio State University), Didier Stanier (Max Planck Institute for Heart and Lung Research, Germany), Shannon Stevenson (University of Minnesota, Duluth), Nancy Toffolo (University of Florida), Jean-Paul Vincent (The Francis Crick Institute, United Kingdom), John Wallingford (University of Texas, Austin), Neal Williams (University of California, Davis).

Chapter 22: Major contributor Yukiko Yamashita (Whitehead Institute, Massachusetts Institute of Technology). Stefano Biressi (University of Trento, Italy), Steven Clark (University of Michigan), Elizabeth Good (University of Illinois, Urbana-Champaign), Konrad Hocheldinger (Harvard University), Shagun Khera (University of Plymouth, United Kingdom), Carien Niessen (University of Cologne, Germany), Jenean O'Brien (The College of St. Scholastica), Peter Reddien (Massachusetts Institute of Technology), Edward Seto (George Washington University), Arianna Smith (Kenyon College), Elly Tanaka (Imperial College London, United Kingdom) Chapter 23: Major contributor Matthew Welch (University of California, Berkeley). Steven Clark (University of Michigan), Ding Jeak Ling (National University of Singapore, Singapore), Stefan Fischer (Deggendorf Institute of Technology, Germany), Elizabeth Good (University of Illinois, Urbana-Champaign), Karen Guillemin (University of Oregon), Julian Guttman (Simon Fraser University, Canada), Jenean O'Brien (The College

of St. Scholastica), Daniel A. Portnoy (University of California, Berkeley), David Sibley (Washington University in Saint Louis), Michael Way (The Francis Crick Institute, United Kingdom)

Chapter 24: Steven Clark (University of Michigan), Elizabeth Good (University of Illinois, Urbana-Champaign), Jenean O'Brien (The College of St. Scholastica), Peter Parham (Stanford University), Shamith Samarajiwa (University of Cambridge, United Kingdom), Phoebe Stavride (University of Nicosia, Greece), Hariharan Subramanian (Michigan State University), Colin Watts (University of Dundee, United Kingdom), Donald Very (Duquesne University), Debby Walser-Kuntz (Carleton College).

REVIEWERS OF PREVIOUS EDITIONS

Jerry Adams (The Walter and Eliza Hall Institute of Medical Research, Australia), Ralf Adams (London Research Institute, United Kingdom), Markus Affolter (University of Basel, Switzerland), David Agard (University of California, San Francisco), Julie Ahringer (The Gurdon Institute, United Kingdom), John Aitchison (Institute for System Biology, Seattle), Michael Akam (University of Cambridge, United Kingdom), Anna Akhmanova (Utrecht University, The Netherlands), David Allis (The Rockefeller University), Wolfhard Almers (Oregon Health and Science University), Fred Alt (CBR Institute for Biomedical Research, Boston), Victor Ambros (University of Massachusetts, Worcester), Linda Amos (MRC Laboratory of Molecular Biology, United Kingdom), Raul Andino (University of California, San Francisco), Oscar Aparicio (University of Southern California), Clay Armstrong (University of Pennsylvania), Martha Arnaud (University of California, San Francisco), Najla Arshad (Indian Institute of Science, India), Spyros Artavanis-Tsakonas (Harvard Medical School), Michael Ashburner (University of Cambridge, United Kingdom), Jonathan Ashmore (University College London, United Kingdom), Laura Attardi (Stanford University), Tayna Awabdy (University of California, San Francisco), Jeffrey Axelrod (Stanford University Medical Center), Peter Baker (deceased), David Baldwin (Stanford University), Michael Banda (University of California, San Francisco), Cornelia Bargmann (The Rockefeller University), Ben Barres (Stanford University), David Bartel (Massachusetts Institute of Technology), Konrad Basler (University of Zurich, Switzerland), Wolfgang Baumeister (Max Planck Institute of Biochemistry, Germany), Michael Bennett (Albert Einstein College of Medicine), Darwin Berg (University of California, San Diego), Anton Berns (Netherlands Cancer Institute, The Netherlands), Bradley E. Bernstein (Harvard Medical School), Merton Bernfield (Harvard Medical School), Michael Berridge (The Babraham Institute, United Kingdom), Wendy Bickmore (MRC Human Genetics Unit, United Kingdom), Walter Birchmeier (Max Delbrück Center for Molecular Medicine, Germany), Adrian Bird (Wellcome Trust Centre, United Kingdom), David Birk (UMDNJ-Robert Wood Johnson Medical School), Michael Bishop (University of California, San Francisco), Trever Bivona (University of California, San Francisco), Elizabeth Blackburn (University of California, San Francisco), Tim Bliss (National Institute for Medical Research, United Kingdom), Hans Bode (University of California, Irvine), Piet Borst (Jan Swammerdam Institute, University of

Amsterdam, The Netherlands), Henry Bourne (University of California, San Francisco), Alan Boyde (University College London, United Kingdom), Donita Brady (Duke University), Martin Brand (University of Cambridge, United Kingdom), Carl Branden (deceased), Andre Brandli (Swiss Federal Institute of Technology, Zurich, Switzerland), Dennis Bray (University of Cambridge, United Kingdom), Mark Bretscher (MRC Laboratory of Molecular Biology, United Kingdom), Douglas J. Briant (University of Victoria, Canada), Jason Brickner (Northwestern University), James Briscoe (National Institute for Medical Research, United Kingdom), Neil Brockdorff (University of Oxford, United Kingdom), Marianne Bronner-Fraser (California Institute of Technology), Robert Brooks (King's College London, United Kingdom), Barry Brown (King's College London, United Kingdom), Donald Brown (Carnegie Institution for Science, Baltimore), Michael Brown (University of Oxford, United Kingdom), Michael Bulger (University of Rochester Medical Center), Fred Bunz (Johns Hopkins University), Steve Burden (New York University School of Medicine), Max Burger (University of Basel, Switzerland), Stephen Burley (SGX Pharmaceuticals), Briana Burton (Harvard University), Keith Burridge (University of North Carolina, Chapel Hill), John Cairns (Radcliffe Infirmary, United Kingdom), Patricia Calarco (University of California, San Francisco), Zacheus Cande (University of California, Berkeley), Lewis Cantley (Harvard Medical School), Charles Cantor (Columbia University), Roderick Capaldi (University of Oregon), Mario Capecchi (University of Utah), Michael Carey (University of California, Los Angeles), Adelaide Carpenter (University of California, San Diego), John Carroll (University College London, United Kingdom), Tom Cavalier-Smith (King's College London, United Kingdom), Pierre Chambon (University of Strasbourg, France), Moses Chao (New York University School of Medicine), Venice Chiueh (University of California, Berkeley), Hans Clevers (Hubrecht Institute, The Netherlands), Enrico Coen (John Innes Institute, United Kingdom), Philip Cohen (University of Dundee, United Kingdom), Robert Cohen (University of California, San Francisco), Stephen Cohen (EMBL Heidelberg, Germany), Roger Cooke (University of California, San Francisco), Steven Cook (Imperial College London, United Kingdom), John Cooper (Washington University School of Medicine, St. Louis), Julie P. Cooper (National Cancer Institute), John Couchman (University of Copenhagen, Denmark), Jose A. Costova (Universidade de Santiago de Compostela, Spain), Michael Cox (University of Wisconsin, Madison), Nancy Craig (Johns Hopkins University), Emily D. Crawford (University of California, San Francisco), James Crow (University of Wisconsin, Madison), Stuart Cull-Candy (University College London, United Kingdom), Leslie Dale (University College London, United Kingdom), Caroline Damsky (University of California, San Francisco), Graeme Davis (University of California, San Francisco), Caroline Dean (John Innes Centre, United Kingdom), Johann De Bono (The Institute of Cancer Research, United Kingdom), Anthony DeFranco (University of California, San Francisco), Abby Dernburg (University of California, Berkeley), Johan de Rooij (The Hubrecht Institute, The Netherlands), Arshad Desai (University of California, San Diego), Michael Dexter (The Wellcome Trust, United Kingdom), John Dick (University of Toronto, Canada), Christopher Dobson (University of Cambridge,

United Kingdom), Chris Doe (University of Oregon, Eugene), Russell Doolittle (University of California, San Diego), W. Ford Doolittle (Dalhousie University, Canada), Julian Downward (Cancer Research UK, United Kingdom), Uwe Drescher (King's College London, United Kingdom), Keith Dudley (King's College London, United Kingdom), Graham Dunn (MRC Cell Biophysics Unit, United Kingdom), Jim Dunwell (John Innes Institute, United Kingdom), Susan K. Dutcher (Washington University in St. Louis), Richard H. Ebright (Rutgers University), Bruce Edgar (Fred Hutchinson Cancer Research Center), Paul Edwards (University of Cambridge, United Kingdom), Robert Edwards (University of California, San Francisco), David Eisenberg (University of California, Los Angeles), Sarah Elgin (Washington University in St. Louis), Ruth Ellman (Institute of Cancer Research, United Kingdom), Michael Elowitz (California Institute of Technology), Hana El-Samad (University of California, San Francisco), Beverly Emerson (The Salk Institute), Charles Emerson (University of Virginia), Scott D. Emr (Cornell University), Sharyn Endow (Duke University), Amber English (University of Colorado at Boulder), Lynn Enquist (Princeton University), Tariq Enver (Institute of Cancer Research, United Kingdom), David Epel (Stanford University), Ralf Erdmann (Ruhr University of Bochum, Germany), Gerard Evan (University of California, Comprehensive Cancer Center), Ray Evert (University of Wisconsin, Madison), Matthias Falk (Lehigh University), Stanley Falkow (Stanford University), Douglas Fearon (University of Cambridge, United Kingdom), Gary Felsenfeld (National Institutes of Health), Stuart Ferguson (University of Oxford, United Kingdom), James Ferrell (Stanford University), Christine Field (Harvard Medical School), Daniel Finley (Harvard University), Gary Firestone (University of California, Berkeley), Gerald Fischbach (Columbia University), Gordon Fishell (New York University School of Medicine), Robert Fletterick (University of California, San Francisco), Harvey Florman (Tufts University), Judah Folkman (Harvard Medical School), Larry Fowke (University of Saskatchewan, Canada), Velia Fowler (The Scripps Research Institute), Thomas D. Fox (Cornell University), Jennifer Frazier (Exploratorium, San Francisco), Matthew Freeman (Laboratory of Molecular Biology, United Kingdom), Daniel Friend (University of California, San Francisco), Elaine Fuchs (University of Chicago), Joseph Gall (Carnegie Institution of Washington), Richard Gardner (University of Oxford, United Kingdom), Anthony Gardner-Medwin (University College London, United Kingdom), Peter Garland (Institute of Cancer Research, United Kingdom), David Garrod (University of Manchester, United Kingdom), Susan M. Gasser (University of Basel, Switzerland), Walter Gehring (Biozentrum, University of Basel, Switzerland), Benny Geiger (Weizmann Institute of Science, Rehovot, Israel), Vladimir Gelfand (Northwestern University), Larry Gerace (The Scripps Research Institute), Holger Gerhardt (London Research Institute, United Kingdom), John Gerhart (University of California, Berkeley), Günther Gerisch (Max Planck Institute of Biochemistry, Germany), Frank Gertler (Massachusetts Institute of Technology), Sankar Ghosh (Yale University School of Medicine), Alfred Gilman (The University of Texas Southwestern Medical Center), Andrew P. Gilmore (University of Manchester, United Kingdom), Reid Gilmore (University of

Yaffe (California Institute for Regenerative Medicine), Kenneth M. Yamada (National Institutes of Health), Keith Yamamoto (University of California, San Francisco), Shinya Yamanaka (Kyoto University, Japan), Alpha Yap (The University of Queensland, Australia), Charles Yocum (University of Michigan, Ann Arbor), Peter Yurchenco (UMDNJ-Robert Wood Johnson Medical School), Rosalind Zalin (University College London, United Kingdom), Patricia Zambryski (University of California, Berkeley), Marino Zerial (Max Planck Institute of Molecular Cell Biology and Genetics, Germany).

OUR PUBLISHER

We thank the dozens of people whose dedication brought this project to fruition. Special thanks go to our editor, Betsy Twitchell, whose talents and personality kept everyone focused. As for previous editions, Denise Schanck directed operations, displaying unflagging patience, insight, tact, and energy throughout the entire journey. Once again, we are in debt to our talented artist, Nigel Orme, who-with author Keith Roberts-produced the captivating art and design that grace the covers, as well as the hundreds of distinctive, highly informative figures throughout the text. Carla Talmadge, our tireless project editor, juggled the many moving parts of this textbook and ushered it gracefully into the book you hold in your hands today. In addition, we are immensely grateful to our copyeditor, Christopher Curioli, who carefully read every page. We also thank Danny Vargo, our assistant editor who tracked the countless emails, chapter drafts, and Excel files that constantly zipped back and forth between editors, authors, and reviewers. And production manager Jane Searle adeptly managed the process of translating our raw material into the polished final product.

An absolutely tireless team at Norton created the print and digital supplementary resources for our book. Media editor Todd Pearson, associate editor Jasmine Ribeaux, and media assistant editor Lindsey Heale worked on every element of the package as a team. Chris Rapp's dedicated and focused efforts on the Smartwork course have produced an

xxii ACKNOWLEDGMENTS

invaluable resource for students and instructors. Megan Schindel, Patricia Wong, and Tommy Persano handled the permissions for this edition, and Kim Yi's media project editorial group, specifically Jesse Newkirk, skillfully shepherded the content through its many stages of development.

Marketing manager Ruth Bolster's expertise in direct marketing has helped ensure that this book makes it into the hands of as many instructors and students as possible. We thank her and everyone involved in Norton's sales, marketing, and management teams for their unflagging support of our book, including Erik Fahlgren, Michael Wright, Ann Shin, and Julia Reidhead.

Brief Contents

PART I	INTRODUCTION TO THE CELL	
Chapter 1	Cells, Genomes, and the Diversity of Life	1
Chapter 2	Cell Chemistry and Bioenergetics	49
Chapter 3	Proteins	115
PART II	BASIC GENETIC MECHANISMS	
Chapter 4	DNA, Chromosomes, and Genomes	183
Chapter 5	DNA Replication, Repair, and Recombination	253
Chapter 6	How Cells Read the Genome: From DNA to Protein	321
Chapter 7	Control of Gene Expression	397
PART III	WAYS OF WORKING WITH CELLS	
Chapter 8	Analyzing Cells, Molecules, and Systems	475
Chapter 9	Visualizing Cells and Their Molecules	563
PART IV	INTERNAL ORGANIZATION OF THE CELL	
Chapter 10	Membrane Structure	603
Chapter 11	Small-Molecule Transport and Electrical Properties of Membranes	637
Chapter 12	Intracellular Organization and Protein Sorting	683
Chapter 13	Intracellular Membrane Traffic	749
Chapter 14	Energy Conversion and Metabolic Compartmentation: Mitochondria and Chloroplasts	811
Chapter 15	Cell Signaling	873
Chapter 16	The Cytoskeleton	949
Chapter 17	The Cell Cycle	1027
Chapter 18	Cell Death	1089
PART V	CELLS IN THEIR SOCIAL CONTEXT	
Chapter 19	Cell Junctions and the Extracellular Matrix	1105
Chapter 20	Cancer	1163
Chapter 21	Development of Multicellular Organisms	1217
Chapter 22	Stem Cells in Tissue Homeostasis and Regeneration	1279
Chapter 23	Pathogens and Infection	1313
Chapter 24	The Innate and Adaptive Immune Systems	1353

GENOME DIVERSIFICATION AND THE TREE OF LIFE	10		
The Tree of Life Has Three Major Domains: Eukaryotes,		Chapter 2 Cell Chemistry and Bioenergetics	49
Bacteria, and Archaea	11	THE CHEMICAL COMPONENTS OF A CELL	49
Eukaryotes Make Up the Domain of Life That Is Most		Water Is Held Together by Hydrogen Bonds	50
Familiar to Us	13	Four Types of Noncovalent Attractions Help Bring Molecules	00
On the Basis of Genome Analysis, Bacteria Are the Most		Together in Cells	51
Diverse Group of Organisms on the Planet	13	Some Polar Molecules Form Acids and Bases in Water	52
Archaea: The Most Mysterious Domain of Life	15	A Cell Is Formed from Carbon Compounds	53
Organisms Occupy Most of Our Planet	15	Cells Contain Four Major Families of Small Organic Molecules	53
Cells Can Be Powered by a Wide Variety of Free-Energy Sources	15	The Chemistry of Cells Is Dominated by Macromolecules	
Some Cells Fix Nitrogen and Carbon Dioxide for Other Cells	17	with Remarkable Properties	54
Genomes Diversify Over Evolutionary Time, Producing		Noncovalent Bonds Specify Both the Precise Shape of a	
New Types of Organisms	18	Macromolecule and Its Binding to Other Molecules	55
New Genes Are Generated from Preexisting Genes	19	Summary	56
Gene Duplications Give Rise to Families of Related Genes	00	CATALYSIS AND THE USE OF ENERGY BY CELLS	57
Within a Single Genome	20	Cell Metabolism Is Organized by Enzymes	57
The Function of a Gene Can Often Be Deduced from	20	Biological Order Is Made Possible by the Release of	0.
Its Nucleotide Sequence More Than 200 Gene Families Are Common to All	20	Heat Energy from Cells	58
Three Domains of Life	21	Cells Obtain Energy by the Oxidation of Organic Molecules	6
Summary	21	Oxidation and Reduction Involve Electron Transfers	62
•		Enzymes Lower the Activation-Energy Barriers That Block	
EUKARYOTES AND THE ORIGIN OF THE EUKARYOTIC CELL	22	Chemical Reactions	63
Eukaryotic Cells Contain a Variety of Organelles	23	Enzymes Can Drive Substrate Molecules Along Specific	
Mitochondria Evolved from a Symbiotic Bacterium	0.5	Reaction Pathways	64
Captured by an Ancient Archaeon	25	How Enzymes Find Their Substrates: The Enormous	
Chloroplasts Evolved from a Symbiotic Photosynthetic	26	Rapidity of Molecular Motions	65
Bacterium Engulfed by an Ancient Eukaryotic Cell Eukaryotes Have Hybrid Genomes	27	The Free-Energy Change for a Reaction, ΔG , Determines	
Eukaryotic Genomes Are Big	28	Whether It Can Occur Spontaneously	66
Eukaryotic Genomes Are Rich in Regulatory DNA	28	The Concentration of Reactants Influences the Free-Energy	
Eukaryotic Genomes Define the Program of Multicellular	20	Change and a Reaction's Direction	67
Development Development	29	The Standard Free-Energy Change, ΔG°, Makes It Possible	0-
Many Eukaryotes Live as Solitary Cells	30	to Compare the Energetics of Different Reactions	67
Summary	31	The Equilibrium Constant and ΔG° Are Readily Derived from	00
	31	Each Other The Free Free Changes of Counted Beactions Are Additive	68
MODEL ORGANISMS Mutations Power the Europians of Coppe	32	The Free-Energy Changes of Coupled Reactions Are Additive	69
Mutations Reveal the Functions of Genes Molocular Richard Rogan with a Spetlight on One Ractorium	32	Activated Carrier Molecules Are Essential for Biosynthesis	69
Molecular Biology Began with a Spotlight on One Bacterium and Its Viruses	33	The Formation of an Activated Carrier Is Coupled to an Energetically Favorable Reaction	70
The Focus on <i>E. coli</i> as a Model Organism Has Accelerated	00	ATP Is the Most Widely Used Activated Carrier Molecule	71
Many Subsequent Discoveries	35	Energy Stored in ATP Is Often Harnessed to Join	1
A Yeast Serves as a Minimal Model Eukaryote	36	Two Molecules Together	72

xxvi CONTENTS

NADH and NADPH Are Important Electron Carriers	73	Enzymes Speed Reactions by Selectively Stabilizing	
There Are Many Other Activated Carrier Molecules in Cells The Synthesis of Biological Polymers Is Driven by	75	Transition States Enzymes Can Use Simultaneous Acid and Base Catalysis	148 148
ATP Hydrolysis	76	Lysozyme Illustrates How an Enzyme Works	149
Summary	78	Tightly Bound Small Molecules Add Extra Functions to Proteins	152
HOW CELLS OBTAIN ENERGY FROM FOOD	80	The Cell Regulates the Catalytic Activities of Its Enzymes	155
Glycolysis Is a Central ATP-producing Pathway Glycolysis Illustrates How Enzymes Couple Oxidation	80	Allosteric Enzymes Have Two or More Binding Sites That Interact Two Ligands Whose Binding Sites Are Coupled Must Reciprocally	
to Energy Storage	83	Affect Each Other's Binding	157
Fermentations Produce ATP in the Absence of Oxygen	84	Symmetrical Protein Assemblies Produce Cooperative Allosteric Transitions	158
Organisms Store Food Molecules in Special Reservoirs Between Meals, Most Animal Cells Derive Their Energy	85	Many Changes in Proteins Are Driven by Protein Phosphorylation A Eukaryotic Cell Contains a Large Collection of Protein Kinases	159
from Fatty Acids Obtained from Fat Sugars and Fats Are Both Degraded to Acetyl CoA	86	and Protein Phosphatases The Regulation of the Src Protein Kinase Reveals How a	159
in Mitochondria The Citric Acid Cycle Generates NADH by Oxidizing	87	Protein Can Function as a Microprocessor Regulatory GTP-binding Proteins Are Switched On and	161
Acetyl Groups to CO ₂ Electron Transport Drives the Synthesis of the Majority	88	Off by the Gain and Loss of a Phosphate Group	162
of the ATP in Most Cells	90	Proteins Can Be Regulated by the Covalent Addition	
Many Biosynthetic Pathways Begin with Glycolysis		of Other Proteins	162
or the Citric Acid Cycle	90	An Elaborate Ubiquitin-conjugating System Is Used	100
Animals Must Obtain All the Nitrogen and Sulfur	04	to Mark Proteins Protein Complexes with Interchangeable Parts Make	163
They Need from Food Metabolism Is Highly Organized and Regulated	91 92	Efficient Use of Genetic Information	164
Summary	93	A GTP-binding Protein Shows How Large Protein	
Problems	112	Movements Can Be Generated from Small Ones	166
References	114	Motor Proteins Produce Directional Movement in Cells	167
		Proteins Often Form Large Complexes That Function as Protein Machines	167
Chapter 3 Proteins	115	The Disordered Regions in Proteins Are Critical for a	107
· ·	445	Set of Different Functions	168
THE ATOMIC STRUCTURE OF PROTEINS The Structure of a Protein Is Specified by Its Amino	115	Scaffolds Bring Sets of Interacting Macromolecules Together and Concentrate Them in Selected Regions of a Cell	170
Acid Sequence Proteins Fold into a Conformation of Lowest Energy	115 121	Macromolecules Can Self-assemble to Form Biomolecular	
The α Helix and the β Sheet Are Common Folding Motifs	121	Condensates Classical Studies of Phase Separation Have Relevance	171
Four Levels of Organization Are Considered to Contribute	400	for Biomolecular Condensates	173
to Protein Structure Protein Domains Are the Modular Units from Which Larger	123	A Comparison of Three Important Types of Large Biological	
Proteins Are Built	124	Assemblies Many Proteins Are Controlled by Covalent Modifications	174
Proteins Also Contain Unstructured Regions	126	That Direct Them to Specific Sites Inside the Cell	175
All Protein Structures Are Dynamic, Interconverting Rapidly		A Complex Network of Protein Interactions Underlies	
Between an Ensemble of Closely Related Conformations	126	Cell Function	176
Because of Thermal Energy Function Has Selected for a Tiny Fraction of the Many	120	Protein Structures Can Be Predicted and New Proteins	470
Possible Polypeptide Chains	126	Designed Summary	178 179
Proteins Can Be Classified into Many Families	127	Problems	179
Some Protein Domains Are Found in Many Different Proteins	129	References	181
The Human Genome Encodes a Complex Set of Proteins, Revealing That Much Remains Unknown	130		
Protein Molecules Often Contain More Than One	100	Chapter 4 DNA, Chromosomes, and Genomes	183
Polypeptide Chain	130		
Some Globular Proteins Form Long Helical Filaments	131	THE STRUCTURE AND FUNCTION OF DNA	185
Protein Molecules Can Have Elongated, Fibrous Shapes Covalent Cross-Linkages Stabilize Extracellular Proteins	132 133	A DNA Molecule Consists of Two Complementary Chains of Nucleotides	185
Protein Molecules Often Serve as Subunits for the Assembly	100	The Structure of DNA Provides a Mechanism for Heredity	187
of Large Structures	134	In Eukaryotes, DNA Is Enclosed in a Cell Nucleus	189
Many Structures in Cells Are Capable of Self-Assembly	136	Summary	189
Assembly Factors Often Aid the Formation of Complex	100	CHROMOSOMAL DNA AND ITS PACKAGING	
Biological Structures When Assembly Processes Go Wrong: The Case of	136	IN THE CHROMATIN FIBER	189
Amyloid Fibrils	137	Eukaryotic DNA Is Packaged into a Set of Chromosomes Chromosomes Contain Long Strings of Genes	190
Amyloid Structures Can Also Perform Useful Functions in Cells	139	The Nucleotide Sequence of the Human Genome Shows	191
Summary	140	How Our Genes Are Arranged	193
PROTEIN FUNCTION	140	Each DNA Molecule That Forms a Linear Chromosome	
All Proteins Bind to Other Molecules The Surface Conformation of a Protein Patermines Ita Chemistry	140	Must Contain a Centromere, Two Telomeres,	407
The Surface Conformation of a Protein Determines Its Chemistry Sequence Comparisons Between Protein Family Members	142	and Replication Origins DNA Molecules Are Highly Condensed in Chromosomes	195 197
Highlight Crucial Ligand-binding Sites	142	Nucleosomes Are a Basic Unit of Eukaryotic Chromosome	197
Proteins Bind to Other Proteins Through Several Types		Structure	197
of Interfaces	143	The Structure of the Nucleosome Core Particle Reveals	
Antibody Binding Sites Are Especially Versatile The Equilibrium Constant Measures Binding Strength	144	How DNA is Packaged	198
The Equilibrium Constant Measures Binding Strength Enzymes Are Powerful and Highly Specific Catalysts	145 146	Nucleosomes Have a Dynamic Structure and Are Frequently Subjected to Changes Catalyzed by	
Substrate Binding Is the First Step in Enzyme Catalysis	146	ATP-dependent Chromatin-remodeling Complexes	200

Some Forms of Chromatin Can Be Directly Inherited	215	The DNA Replication Fork Is Asymmetrical The High Fidelity of DNA Replication Requires Several	256
The Abnormal Perturbations of Heterochromatin That Arise During Tumor Progression Contribute to Many Cancers	215	Proofreading Mechanisms	258
Summary	217	DNA Replication in the 5'-to-3' Direction Allows Efficient Error Correction	260
THE GLOBAL STRUCTURE OF CHROMOSOMES Chromosomes Are Folded into Large Loops of Chromatin	217 217	A Special Nucleotide-polymerizing Enzyme Synthesizes	200
Polytene Chromosomes Are Uniquely Useful for Visualizing		Short RNA Primer Molecules Special Proteins Help to Open Up the DNA Double Helix	260
Chromatin Structures Chromosome Loops Decondense When the Genes Within	218	in Front of the Replication Fork	261
Them Are Expressed	220	A Sliding Ring Holds a Moving DNA Polymerase onto the DNA The Proteins at a Replication Fork Cooperate to Form	262
Mammalian Interphase Chromosomes Occupy Discrete Territories in the Nucleus, with Their Heterochromatin		a Replication Machine	263
and Euchromatin Distributed Differently	220	DNA Replication Is Fundamentally Similar in Eukaryotes and Bacteria	265
A Biochemical Technique Called Hi-C Reveals Details of Chromosome Organization	221	A Strand-directed Mismatch Repair System Removes	
Chromosomal DNA Is Organized into Loops by Large Protein Rings	223	Replication Errors That Remain in the Wake of the Replication Machine	267
Euchromatin and Heterochromatin Separate Spatially in the Nucleus	225	The Accidental Incorporation of Ribonucleotides During	000
Mitotic Chromosomes Are Highly Condensed	227	DNA Replication Is Corrected DNA Topoisomerases Prevent DNA Tangling During	269
Summary HOW GENOMES EVOLVE	228	Replication	269
Genome Comparisons Reveal Functional DNA Sequences	229	Summary	272
by Their Conservation Throughout Evolution	230	THE INITIATION AND COMPLETION OF DNA REPLICATION IN CHROMOSOMES	272
Genome Alterations Are Caused by Failures of the Normal Mechanisms for Copying and Maintaining		DNA Synthesis Begins at Replication Origins	272
DNA, as Well as by Transposable DNA Elements	231	Bacterial Chromosomes Typically Have a Single Origin of DNA Replication	273
The Genome Sequences of Two Species Differ in Proportion to the Length of Time Since They Have Separately Evolved	232	Eukaryotic Chromosomes Contain Multiple Origins	
Phylogenetic Trees Constructed from a Comparison of	000	of Replication In Eukaryotes, DNA Replication Takes Place During	273
DNA Sequences Trace the Relationships of All Organisms A Comparison of Human and Mouse Chromosomes	233	Only One Part of the Cell Cycle	276
Shows How the Structures of Genomes Diverge The Size of a Vertebrate Genome Reflects the Relative	234	Eukaryotic Origins of Replication Are "Licensed" for Replication by the Assembly of an Origin Recognition Complex	276
Rates of DNA Addition and DNA Loss in a Lineage	236	Features of the Human Genome That Specify Origins	
Multispecies Sequence Comparisons Identify Many	237	of Replication Remain to Be Fully Understood Properties of the ORC Ensure That Each Region of the	277
Conserved DNA Sequences of Unknown Function Changes in Previously Conserved Sequences Can	231	DNA Is Replicated Once and Only Once in Each S Phase	277
Help Decipher Critical Steps in Evolution	238	New Nucleosomes Are Assembled Behind the Replication Fork Termination of DNA Replication Occurs Through the Ordered	279
Mutations in the DNA Sequences That Control Gene Expression Have Driven Many of the Evolutionary		Disassembly of the Replication Fork	280
Changes in Vertebrates	239	Telomerase Replicates the Ends of Chromosomes Telomeres Are Packaged into Specialized Structures	281
Gene Duplication Also Provides an Important Source of Genetic Novelty During Evolution	240	That Protect the Ends of Chromosomes	282
Duplicated Genes Diverge	240	Telomere Length Is Regulated by Cells and Organisms	282
The Evolution of the Globin Gene Family Shows How		Summary	284
DNA Duplications Contribute to the Evolution of Organisms	241	DNA REPAIR Without DNA Repair, Spontaneous DNA Damage Would	284
Genes Encoding New Proteins Can Be Created by the Recombination of Exons	242	Rapidly Change DNA Sequences	286
Neutral Mutations Often Spread to Become Fixed in a Population,		The DNA Double Helix Is Readily Repaired	288
with a Probability That Depends on Population Size	243	DNA Damage Can Be Removed by More Than One Pathway	288

Coupling Nucleotide Excision Repair to Transcription Ensures	000	In Eukaryotes, Transcription Initiation Also Requires Activator,	00.4
That the Cell's Most Important DNA Is Efficiently Repaired The Chemistry of the DNA Bases Facilitates Damage Detection	290 290	Mediator, and Chromatin-modifying Proteins Transcription Florgation in Fukanyotas Requires Accessory	334
Special Translesion DNA Polymerases Are Used in Emergencies	292	Transcription Elongation in Eukaryotes Requires Accessory Proteins	335
Double-Strand Breaks Are Efficiently Repaired	292	Transcription Creates Superhelical Tension	335
DNA Damage Delays Progression of the Cell Cycle	295	Transcription Elongation in Eukaryotes Is Tightly Coupled	
Summary	295	to RNA Processing	337
HOMOLOGOUS RECOMBINATION	296	RNA Capping Is the First Modification of Eukaryotic	
Homologous Recombination Has Common Features in All Cells	296	Pre-mRNAs	338
DNA Base-pairing Guides Homologous Recombination	296	RNA Splicing Removes Intron Sequences from Newly	000
Homologous Recombination Can Flawlessly Repair Double-Strand		Transcribed Pre-mRNAs Nucleotide Sequences Signal Where Splicing Occurs	339 341
Breaks in DNA	297	RNA Splicing Is Performed by the Spliceosome	341
Specialized Processing of Double-Strand Breaks Commits Repair to Homologous Recombination	298	The Spliceosome Uses ATP Hydrolysis to Produce a Complex	011
Strand Exchange Is Directed by the RecA/Rad51 Protein	298	Series of RNA-RNA Rearrangements	343
Homologous Recombination Can Rescue Broken and Stalled	200	Other Properties of Pre-mRNA and Its Synthesis Help to	
DNA Replication Forks	299	Explain the Choice of Proper Splice Sites	345
DNA Repair by Homologous Recombination Entails Risks		RNA Splicing Has Remarkable Plasticity	346
to the Cell	300	Spliceosome-catalyzed RNA Splicing Evolved from RNA Self-splicing Mechanisms	347
Homologous Recombination Is Crucial for Meiosis	301	RNA-processing Enzymes Generate the 3' End of Eukaryotic	041
Meiotic Recombination Begins with a Programmed Double-Strand Break	202	mRNAs	348
Holliday Junctions Are Recognized by Enzymes That Drive	302	Mature Eukaryotic mRNAs Are Selectively Exported from	
Branch Migration	302	the Nucleus	349
Homologous Recombination Produces Crossovers Between		Noncoding RNAs Are Also Synthesized and Processed in	
Maternal and Paternal Chromosomes During Meiosis	304	the Nucleus	351
Homologous Recombination Often Results in Gene Conversion	305	The Nucleolus Is a Ribosome-producing Factory The Nucleus Contains a Variety of Subnuclear Biomolecular	353
Summary	306	Condensates	355
TRANSPOSITION AND CONSERVATIVE SITE-SPECIFIC		Summary	357
RECOMBINATION	306	•	
Through Transposition, Mobile Genetic Elements Can Insert	007	FROM RNA TO PROTEIN	358
into Any DNA Sequence DNA-only Transposons Can Move by a Cut-and-Paste	307	An mRNA Sequence Is Decoded in Sets of Three Nucleotides tRNA Molecules Match Amino Acids to Codons in mRNA	358 359
Mechanism	307	tRNAs Are Covalently Modified Before They Exit from the Nucleus	361
Some DNA-only Transposons Move by Replicating	00.	Specific Enzymes Couple Each Amino Acid to Its Appropriate	001
Themselves	309	tRNA Molecule	361
Some Viruses Use a Transposition Mechanism to Move		Editing by tRNA Synthetases Ensures Accuracy	363
Themselves into Host-Cell Chromosomes	309	Amino Acids Are Added to the C-terminal End of a Growing	
Some RNA Viruses Replicate and Express Their Genomes	044	Polypeptide Chain	364
Without Using DNA as an Intermediate Retroviral-like Retrotransposons Resemble Retroviruses,	311	The RNA Message Is Decoded in Ribosomes Elongation Factors Drive Translation Forward and Improve	365
but Cannot Move from Cell to Cell	313	Its Accuracy	368
A Large Fraction of the Human Genome Is Composed	010	Induced Fit and Kinetic Proofreading Help Biological Processes	000
of Nonretroviral Retrotransposons	313	Overcome the Inherent Limitations of Complementary	
Different Transposable Elements Predominate in		Base-Pairing	369
Different Organisms	314	Accuracy in Translation Requires a Large Expenditure of	
Genome Sequences Reveal the Approximate Times at Which	014	Free Energy	370
Transposable Elements Have Moved Conservative Site-specific Recombination Can Reversibly	314	The Ribosome Is a Ribozyme Nucleotide Sequences in mRNA Signal Where to Start Protein	371
Rearrange DNA	315	Synthesis	373
Conservative Site-specific Recombination Can Be Used to	0.0	Stop Codons Mark the End of Translation	374
Turn Genes On or Off	316	Proteins Are Made on Polyribosomes	375
Bacterial Conservative Site-specific Recombinases Have Become		There Are Minor Variations in the Standard Genetic Code	375
Powerful Tools for Cell and Developmental Biologists	317	Inhibitors of Prokaryotic Protein Synthesis Are Useful	070
Summary Problems	317	as Antibiotics	376
References	318 320	Quality-Control Mechanisms Act to Prevent Translation of Damaged mRNAs	378
Tioloronoco	020	Stalled Ribosomes Can Be Rescued	379
		The Ribosome Coordinates the Folding, Enzymatic Modification,	
Chapter 6 How Cells Read the Genome:		and Assembly of Newly Synthesized Proteins	380
From DNA to Protein	321	Molecular Chaperones Help Guide the Folding of Most Proteins	380
FROM DNA TO RNA	323	Proper Folding of Newly Synthesized Proteins Is Also Aided by	000
RNA Molecules Are Single-Stranded	324	Translation Speed and Subunit Assembly Proteins That Ultimately Fail to Fold Correctly Are Marked	383
Transcription Produces RNA Complementary to One Strand		Proteins That Ultimately Fail to Fold Correctly Are Marked for Destruction by Polyubiquitin	384
of DNA	325	The Proteasome Is a Compartmentalized Protease with	504
RNA Polymerases Carry Out DNA Transcription	325	Sequestered Active Sites	384
Cells Produce Different Categories of RNA Molecules	327	Many Proteins Are Controlled by Regulated Destruction	386
Signals Encoded in DNA Tell RNA Polymerase Where to Start and Stop	328	There Are Many Steps from DNA to Protein	387
Bacterial Transcription Start and Stop Signals Are Heterogeneous	020	Summary	388
in Nucleotide Sequence	329	THE RNA WORLD AND THE ORIGINS OF LIFE	389
Transcription Initiation in Eukaryotes Requires Many Proteins	331	Single-Strand RNA Molecules Can Fold into Highly	
To Initiate Transcription, RNA Polymerase II Requires a Set		Elaborate Structures	390
of General Transcription Factors	332	Ribozymes Can Be Produced in the Laboratory	390

MBOC7_ptr_ch00_fm_i-xxxxviii.indd 28 08/12/21 11:23 AM

RNA Can Both Store Information and Catalyze Chemical Reactions	391	Transcription Circuits Allow the Cell to Carry Out Logic Operations Summary	433 434
How Did Protein Synthesis Evolve?	392	MECHANISMS THAT REINFORCE CELL MEMORY	
All Present-Day Cells Use DNA as Their Hereditary Material	393	IN PLANTS AND ANIMALS Patterns of DNA Methylation Can Be Inherited When Vertebrate	435
Summary	393	Cells Divide	435
Problems	394	CG-Rich Islands Are Associated with Many Genes in Mammals	436
References	395	Genomic Imprinting Is Based on DNA Methylation A Chromosome-wide Alteration in Chromatin Structure Can Be	438
Chapter 7 Control of Gene Expression	397	Inherited The Mammalian X-Inactivation in Females Is Triggered by	440
AN OVERVIEW OF GENE CONTROL	397	the Synthesis of a Long Noncoding RNA Stable Patterns of Gene Expression Can Be Transmitted	442
The Different Cell Types of a Multicellular Organism Contain		to Daughter Cells	443
the Same DNA	397	Summary	445
Different Cell Types Synthesize Different Sets of RNAs and Proteins The Spectrum of mRNAs Present in a Cell Can Be Used	398	POST-TRANSCRIPTIONAL CONTROLS Transcription Attenuation Causes the Premature Termination	445
to Accurately Identify the Cell Type	400	of Some RNA Molecules	445
External Signals Can Cause a Cell to Change the Expression of Its Genes	400	Riboswitches Probably Represent Ancient Forms of Gene	
Gene Expression Can Be Regulated at Many of the Steps		Control Alternative RNA Splicing Can Produce Different Forms of	446
in the Pathway from DNA to RNA to Protein Summary	401 402	a Protein from the Same Gene	446
CONTROL OF TRANSCRIPTION BY SEQUENCE-SPECIFIC	702	The Definition of a Gene Has Been Modified Since the Discovery	448
DNA-BINDING PROTEINS	402	of Alternative RNA Splicing Back Splicing Can Produce Circular RNA Molecules	449
The Sequence of Nucleotides in the DNA Double Helix Can	402	A Change in the Site of RNA Transcript Cleavage and Poly-A	440
Be Read by Proteins	402	Addition Can Change the C-terminus of a Protein	449
Transcription Regulators Contain Structural Motifs That Can		Nucleotides in mRNA Can Be Covalently Modified	450
Read DNA Sequences	403	RNA Editing Can Change the Meaning of the RNA Message	451
Dimerization of Transcription Regulators Increases Their	400	The Human AIDS Virus Illustrates How RNA Transport from	450
Affinity and Specificity for DNA Many Transprintion Populators Rind Cooperatively to DNA	406 407	the Nucleus Can Be Regulated mRNAs Can Be Localized to Specific Regions of the Cytosol	452 453
Many Transcription Regulators Bind Cooperatively to DNA Nucleosome Structure Promotes Cooperative Binding		Untranslated Regions of mRNAs Control Their Translation	456
of Transcription Regulators	408 409	The Phosphorylation of an Initiation Factor Regulates Protein Synthesis Globally	457
DNA-Binding by Transcription Regulators Is Dynamic Summary	410	Initiation at AUG Codons Upstream of the Translation	437
TRANSCRIPTION REGULATORS SWITCH GENES		Start Can Regulate Eukaryotic Translation Initiation	458
ON AND OFF	410	Internal Ribosome Entry Sites Also Provide Opportunities	
The Tryptophan Repressor Switches Genes Off	410	for Translational Control	458
Repressors Turn Genes Off and Activators Turn Them On	411	Changes in mRNA Stability Can Control Gene Expression	459
Both an Activator and a Repressor Control the Lac Operon	412	Regulation of mRNA Stability Involves P-bodies and	401
DNA Looping Can Occur During Bacterial Gene Regulation	412	Stress Granules Summary	461 462
Complex Switches Control Gene Transcription in Eukaryotes	414		
A Eukaryotic Gene Control Region Includes Many <i>cis</i> -Regulatory Sequences	414	REGULATION OF GENE EXPRESSION BY NONCODING RNAs Small Noncoding RNA Transcripts Regulate Many Animal	462
Eukaryotic Transcription Regulators Work in Groups	415	and Plant Genes Through RNA Interference	462
Activator Proteins Promote the Assembly of RNA Polymerase		miRNAs Regulate mRNA Translation and Stability	463
at the Start Point of Transcription	416	RNA Interference Also Serves as a Cell Defense Mechanism	464
Eukaryotic Transcription Activators Direct the Modification		RNA Interference Can Direct Heterochromatin Formation	465
of Local Chromatin Structure	417	piRNAs Protect the Germ Line from Transposable Elements	466
Some Transcription Activators Work by Releasing Paused	440	RNA Interference Has Become a Powerful Experimental Tool	467
RNA Polymerase Transcription Activators Work Synergistically	418 419	Cells Have Additional Mechanisms to Hold Transposons and Integrated Viral Genomes in Check	467
Condensate Formation Likely Increases the Efficiency	419	Bacteria Use Small Noncoding RNAs to Protect Themselves	407
of Transcription Initiation	420	from Viruses	468
Eukaryotic Transcription Repressors Can Inhibit Transcription		Long Noncoding RNAs Have Diverse Functions in the Cell	469
in Several Ways	420	Summary	471
Insulator DNA Sequences Prevent Eukaryotic Transcription		Problems	472
Regulators from Influencing Distant Genes Summary	422 422	References	474
MOLECULAR GENETIC MECHANISMS THAT CREATE	722		
AND MAINTAIN SPECIALIZED CELL TYPES	423	Chapter 8 Analyzing Cells, Molecules, and Systems	475
Complex Genetic Switches That Regulate Drosophila Development		ISOLATING CELLS AND GROWING THEM IN CULTURE	476
Are Built Up from Smaller Modules The Presentile Fig Cons le Regulated by Combinatorial Controls	423	Cells Can Be Isolated from Tissues and Grown in Culture	476
The <i>Drosophila Eve</i> Gene Is Regulated by Combinatorial Controls Transcription Regulators Are Brought into Play by	424	Eukaryotic Cell Lines Are a Widely Used Source of	
Extracellular Signals	426	Homogeneous Cells	478
Combinatorial Gene Control Creates Many Different Cell Types	427	Hybridoma Cell Lines Are Factories That Produce Monoclonal	
Specialized Cell Types Can Be Experimentally Reprogrammed to		Antibodies	478
Become Pluripotent Stem Cells	428	Summary	480
Combinations of Master Transcription Regulators Specify Cell	100	PURIFYING PROTEINS	480
Types by Controlling the Expression of Many Genes Specialized Calle Must Papidly Turn Some Genes On and Off	429	Cells Can Be Separated into Their Component Fractions	480
Specialized Cells Must Rapidly Turn Some Genes On and Off Differentiated Cells Maintain Their Identity	430 431	Cell Extracts Provide Accessible Systems to Study Cell Functions Proteins Can Be Separated by Chromatography	482 483

xxx CONTENTS

Immunoprecipitation Is a Rapid Affinity Purification Method Genetically Engineered Tags Provide an Easy Way to Purify	486	Expression of Individual Genes Can Be Measured Using Quantitative RT-PCR	536
Proteins	486	Global Analysis of mRNAs by RNA-seq Provides a Snapshot	
Purified Cell-free Systems Are Required for the Precise Dissection	400	of Gene Expression	536
of Molecular Functions	486 487	Genome-wide Chromatin Immunoprecipitation Identifies Sites on the Genome Occupied by Transcription Regulators	538
Summary		Ribosome Profiling Reveals Which mRNAs Are Being	550
ANALYZING PROTEINS	487	Translated in the Cell	538
Proteins Can Be Separated by SDS Polyacrylamide-Gel	107	Recombinant DNA Methods Have Revolutionized Human Health	539
Electrophoresis Two dimensional Cal Floatrophoresis Provides Greater Protein	487	Transgenic Plants Are Important for Agriculture	540
Two-dimensional Gel Electrophoresis Provides Greater Protein Separation	489	Summary	542
Specific Proteins Can Be Detected by Blotting with Antibodies	490	MATHEMATICAL ANALYSIS OF CELL FUNCTION	542
Hydrodynamic Measurements Reveal the Size and Shape	100	Regulatory Networks Depend on Molecular Interactions	543
of a Protein Complex	490	Differential Equations Help Us Predict Transient Behavior	545
Mass Spectrometry Provides a Highly Sensitive Method		Promoter Activity and Protein Degradation Affect the Rate	
for Identifying Unknown Proteins	491	of Change of Protein Concentration	546
Sets of Interacting Proteins Can Be Identified by		The Time Required to Reach Steady State Depends on	
Biochemical Methods	493	Protein Lifetime	547
Optical Methods Can Monitor Protein Interactions	493	Quantitative Methods Are Similar for Transcription Repressors	
Protein Structure Can Be Determined Using X-ray Diffraction	494	and Activators	548
NMR Can Be Used to Determine Protein Structure in Solution	496	Negative Feedback Is a Powerful Strategy in Cell Regulation	549
Protein Sequence and Structure Provide Clues About	407	Delayed Negative Feedback Can Induce Oscillations	549
Protein Function	497 498	DNA Binding by a Repressor or an Activator Can Be	551
Summary		Cooperative Positive Feedback Is Important for Switchlike Responses	551
ANALYZING AND MANIPULATING DNA	498	and Bistability	551
Restriction Nucleases Cut Large DNA Molecules into	400	Robustness Is an Important Characteristic of Biological	001
Specific Fragments	498	Networks	553
Gel Electrophoresis Separates DNA Molecules of Different Sizes Purified DNA Molecules Can Be Specifically Labeled	499	Two Transcription Regulators That Bind to the Same Gene	
with Radioisotopes or Chemical Markers in Vitro	501	Promoter Can Exert Combinatorial Control	554
Genes Can Be Cloned Using Bacteria	501	An Incoherent Feed-forward Interaction Generates Pulses	555
An Entire Genome Can Be Represented in a DNA Library	503	A Coherent Feed-forward Interaction Detects Persistent Inputs	556
Hybridization Provides a Powerful but Simple Way to Detect		The Same Network Can Behave Differently in Different	
Specific Nucleotide Sequences	505	Cells Because of Stochastic Effects	557
Genes Can Be Cloned in Vitro Using PCR	506	Several Computational Approaches Can Be Used to Model	
PCR Is Also Used for Diagnostic and Forensic Applications	507	the Reactions in Cells	557
PCR and Synthetic DNA Are Ideal Sources of Specific		Statistical Methods Are Critical for the Analysis of Biological Data	558
Gene Sequences for Cloning	510	Summary	558
DNA Cloning Allows Any Protein to Be Produced in Large		Problems	559
Amounts	511	References	561
DNA Can Be Sequenced Rapidly by Dideoxy Sequencing Next Congretion Sequencing Methods Have Revolutionized	512	1.0.0.0.1000	
Next-Generation Sequencing Methods Have Revolutionized DNA and RNA Analysis	514	Chapter 9 Visualizing Cells and Their Molecules	563
To Be Useful, Genome Sequences Must Be Annotated	516		000
Summary	518	LOOKING AT CELLS AND MOLECULES IN THE LIGHT	
•		MICROSCOPE	563
STUDYING GENE FUNCTION AND EXPRESSION	518	The Conventional Light Microscope Can Resolve Details	EC.4
Classical Genetic Screens Identify Random Mutants with Specific	E40	0.2 µm Apart Photon Noise Creates Additional Limits to Recolution	564
Abnormalities Mutations Con Course Loss or Coin of Protein Function	519	Photon Noise Creates Additional Limits to Resolution When Light Levels Are Low	567
Mutations Can Cause Loss or Gain of Protein Function Complementation Tests Reveal Whether Two Mutations Are in the	522	Living Cells Are Seen Clearly in a Phase-Contrast or a	307
Same Gene or Different Genes	523	Differential-Interference-Contrast Microscope	567
Gene Products Can Be Ordered in Pathways by Epistasis	020	Images Can Be Enhanced and Analyzed by Digital Techniques	568
Analysis	523	Intact Tissues Are Usually Fixed and Sectioned Before Microscopy	569
Mutations Responsible for a Phenotype Can Be Identified		Specific Molecules Can Be Located in Cells by Fluorescence	
Through DNA Analysis	524	Microscopy	570
Rapid and Cheap DNA Sequencing Has Revolutionized		Antibodies Can Be Used to Detect Specific Proteins	572
Human Genetic Studies	524	Individual Proteins Can Be Fluorescently Tagged in Living Cells	
Linked Blocks of Polymorphisms Have Been Passed Down		and Organisms	573
from Our Ancestors		Protein Dynamics Can Be Followed in Living Cells	575
Sequence Variants Can Aid the Search for Mutations	525	Fluerescent Discourses Can Maniter Call Cignaling	576
Associated with Disease		Fluorescent Biosensors Can Monitor Cell Signaling	
Conomica la Accoloratina the Discovery of Para Mutationa	526	Imaging of Complex Three-dimensional Objects Is Possible

		Mechanosensitive Channels Allow Cells to Sense Their Physical	
THE LIPID BILAYER Characheanhallaide Sphingelinide and Storale Are	604	Environment	659
Glycerophospholipids, Sphingolipids, and Sterols Are the Major Lipids in Cell Membranes	605	The Function of a Neuron Depends on Its Elongated Structure	661
Phospholipids Spontaneously Form Bilayers	606	Voltage-gated Cation Channels Generate Action Potentials	000
The Lipid Bilayer Is a Two-dimensional Fluid	608	in Electrically Excitable Cells Myelination Increases the Speed and Efficiency of Action	662
The Fluidity of a Lipid Bilayer Depends on Its Composition	609	Potential Propagation in Nerve Cells	666
Despite Their Fluidity, Lipid Bilayers Can Form Domains		Patch-Clamp Recording Indicates That Individual Ion Channels	000
of Different Compositions	610	Open in an All-or-Nothing Fashion	666
Lipid Droplets Are Surrounded by a Phospholipid Monolayer	611	Voltage-gated Cation Channels Are Evolutionarily and Structurally	
The Asymmetry of the Lipid Bilayer Is Functionally Important	612	Related	668
Glycolipids Are Found on the Surface of All Eukaryotic Plasma Membranes	613	Different Neuron Types Display Characteristic Stable Firing	000
Summary	614	Properties Transmitter geted for Channels Convert Chamical Signals	668
MEMBRANE PROTEINS	615	Transmitter-gated Ion Channels Convert Chemical Signals into Electrical Ones at Chemical Synapses	669
Membrane Proteins Can Be Associated with the Lipid Bilayer	0.10	Chemical Synapses Can Be Excitatory or Inhibitory	670
in Various Ways	615	The Acetylcholine Receptors at the Neuromuscular Junction	
Lipid Anchors Control the Membrane Localization of Some		Are Excitatory Transmitter-gated Cation Channels	671
Signaling Proteins	616	Neurons Contain Many Types of Transmitter-gated Channels	672
In Most Transmembrane Proteins, the Polypeptide Chain	0.17	Many Psychoactive Drugs Act at Synapses	673
Crosses the Lipid Bilayer in an α-Helical Conformation	617	Neuromuscular Transmission Involves the Sequential Activation	673
Transmembrane α Helices Often Interact with One Another Some β Barrels Form Large Channels	619 619	of Five Different Sets of Ion Channels Single Neurons Are Complex Computation Devices	674
Many Membrane Proteins Are Glycosylated	621	Neuronal Computation Requires a Combination of at Least	014
Membrane Proteins Can Be Solubilized and Purified in Detergents		Three Kinds of K ⁺ Channels	675
Bacteriorhodopsin Is a Light-driven Proton (H+) Pump That		Long-term Potentiation in the Mammalian Hippocampus	
Traverses the Lipid Bilayer as Seven α Helices	625	Depends on Ca ²⁺ Entry Through NMDA-Receptor Channels	677
Membrane Proteins Often Function as Large Complexes	627	The Use of Channelrhodopsins Has Revolutionized	070
Many Membrane Proteins Diffuse in the Plane of the Membrane	627	the Study of Neural Circuits Summary	678 679
Cells Can Confine Proteins and Lipids to Specific Domains Within a Membrane	629	Problems	680
The Cortical Cytoskeleton Gives Membranes Mechanical Strength		References	681
and Restricts Membrane Protein Diffusion	630

THE ENDOPLASMIC RETICULUM	698	The Assembly of a Clathrin Coat Drives Vesicle Formation	752
The ER Is Structurally and Functionally Diverse	698	Adaptor Proteins Select Cargo into Clathrin-coated Vesicles	753
Signal Sequences Were First Discovered in Proteins Imported into the Rough ER	701	Phosphoinositides Mark Organelles and Membrane Domains Membrane-bending Proteins Help Deform the Membrane	754
A Signal-Recognition Particle (SRP) Directs the ER Signal	701	During Vesicle Formation	755
Sequence to a Specific Receptor at the ER	702	Cytoplasmic Proteins Regulate the Pinching off and Uncoating	
The Polypeptide Chain Passes Through a Signal Sequence–gated		of Coated Vesicles	756
Aqueous Channel in the Translocator	705	Monomeric GTPases Control Coat Assembly	756
Translocation Across the ER Membrane Does Not Always		Coat-recruitment GTPases Participate in Coat Disassembly	758
Require Ongoing Polypeptide Chain Elongation	707	The Shape and Size of Transport Vesicles Are Diverse	759
Transmembrane Proteins Contain Hydrophobic Segments That Are Recognized Like Signal Sequences	709	Rab Proteins Guide Transport Vesicles to Their Target Membrane	760
Hydrophobic Segments of Multipass Transmembrane Proteins	100	Rab Proteins Create and Change the Identity of an Organelle	761
Are Interpreted Contextually to Determine Their Orientation	710	SNAREs Mediate Membrane Fusion	762
Some Proteins Are Integrated into the ER Membrane by a		Interacting SNAREs Need to Be Pried Apart Before They Can	
Post-translational Mechanism	711	Function Again	763
Some Membrane Proteins Acquire a Covalently Attached	740	Viruses Encode Specialized Membrane Fusion Proteins Needed	704
Glycosylphosphatidylinositol (GPI) Anchor Translocated Polypeptide Chains Fold and Assemble in the	712	for Cell Entry Summary	764 764
Lumen of the Rough ER	712		704
Most Proteins Synthesized in the Rough ER Are Glycosylated by	7 12	TRANSPORT FROM THE ENDOPLASMIC RETICULUM THROUGH THE GOLGI APPARATUS	765
the Addition of a Common N-Linked Oligosaccharide	714	Proteins Leave the ER in COPII-coated Transport Vesicles	765
Oligosaccharides Are Used as Tags to Mark the State of		Only Proteins That Are Properly Folded and Assembled Can	700
Protein Folding	715	Leave the ER	766
Improperly Folded Proteins Are Exported from the ER and Degraded in the Cytosol	716	Vesicular Tubular Clusters Mediate Transport from the ER to	
Misfolded Proteins in the ER Activate an Unfolded Protein Response	717	the Golgi Apparatus	766
The ER Assembles Most Lipid Bilayers	720	The Retrieval Pathway to the ER Uses Sorting Signals Many Proteins Are Selectively Retained in the Compartments	768
Membrane Contact Sites Between the ER and Other Organelles		in Which They Function	768
Facilitate Selective Lipid Transfer	722	The Golgi Apparatus Consists of an Ordered Series	7 00
Summary	723	of Compartments	769
PEROXISOMES	723	Oligosaccharide Chains Are Processed in the Golgi Apparatus	771
Peroxisomes Use Molecular Oxygen and Hydrogen Peroxide	704	Proteoglycans Are Assembled in the Golgi Apparatus	772
to Perform Oxidation Reactions Short Signal Sequences Direct the Import of Proteins	724	What Is the Purpose of Glycosylation? Transport Through the Golgi Apparatus Occurs by Multiple	773
into Peroxisomes	724	Mechanisms	774
Summary	726	Golgi Matrix Proteins Help Organize the Stack	775
THE TRANSPORT OF PROTEINS INTO MITOCHONDRIA		Summary	776
AND CHLOROPLASTS	726	TRANSPORT FROM THE TRANS GOLGI NETWORK	
Translocation into Mitochondria Depends on Signal Sequences		TO THE CELL EXTERIOR AND ENDOSOMES	776
and Protein Translocators	727	Many Proteins and Lipids Are Carried Automatically from	
Mitochondrial Proteins Are Imported Post-translationally as	700	the <i>Trans</i> Golgi Network to the Cell Surface	777
Unfolded Polypeptide Chains Protein Import Is Powered by ATP Hydrolysis, a Membrane	728	A Mannose 6-Phosphate Receptor Sorts Lysosomal Hydrolases in the <i>Trans</i> Golgi Network	777
Potential, and Redox Potential	730	Defects in the GlcNAc Phosphotransferase Cause a Lysosomal	,,,
Transport into the Inner Mitochondrial Membrane Occurs Via		Storage Disease in Humans	779
Several Routes	731	Secretory Vesicles Bud from the Trans Golgi Network	780
Bacteria and Mitochondria Use Similar Mechanisms to Insert	700	Precursors of Secretory Proteins Are Proteolytically Processed	704
β Barrels into Their Outer Membrane Two Signal Sequences Direct Proteins to the Thylokoid Membrane	733	During the Formation of Secretory Vesicles Secretory Vesicles Wait Near the Plasma Membrane Until	781
Two Signal Sequences Direct Proteins to the Thylakoid Membrane in Chloroplasts	733	Signaled to Release Their Contents	782
Summary	735	For Rapid Exocytosis, Synaptic Vesicles Are Primed at the	102
THE TRANSPORT OF MOLECULES BETWEEN THE NUCLEUS		Presynaptic Plasma Membrane	782
AND THE CYTOSOL	735	Synaptic Vesicles Can Be Recycled Locally After Exocytosis	783
Nuclear Pore Complexes Perforate the Nuclear Envelope	736	Secretory Vesicle Membrane Components Are Quickly Removed	
Nuclear Localization Signals Direct Proteins to the Nucleus	738	from the Plasma Membrane	784
Nuclear Import Receptors Bind to Both Nuclear Localization	700	Some Regulated Exocytosis Events Serve to Enlarge the Plasma Membrane	785
Signals and NPC Proteins The Pen CTPens Impages Directionality on Nuclear Impart	739	Polarized Cells Direct Proteins from the <i>Trans</i> Golgi Network	700
The Ran GTPase Imposes Directionality on Nuclear Import Through NPCs	740	to the Appropriate Domain of the Plasma Membrane	786
Nuclear Export Works Like Nuclear Import, but in Reverse	741	Summary	787
Transport Through NPCs Can Be Regulated by Controlling Access		TRANSPORT INTO THE CELL FROM THE PLASMA	
to the Transport Machinery	742	MEMBRANE: ENDOCYTOSIS	788
The Nuclear Envelope Disassembles and Reassembles	740	Pinocytic Vesicles Form from Coated Pits in the Plasma	
During Mitosis	743 745	Membrane	789
Summary Problems	745	Not All Membrane Invaginations and Pinocytic Vesicles	700
References	748	Are Clathrin Coated Cells Use Receptor-mediated Endocytosis to Import Selected	789
		Extracellular Macromolecules	791
Chapter 13 Intracellular Membrane Traffic	749	Specific Proteins Are Retrieved from Early Endosomes	
		and Returned to the Plasma Membrane	792
MECHANISMS OF MEMBRANE TRANSPORT	754	Recycling Endosomes Regulate Plasma Membrane Composition	793
AND COMPARTMENT IDENTITY There Are Verigue Types of Costed Verigles	751 751	Plasma Membrane Signaling Receptors Are Down-regulated by	70.4
There Are Various Types of Coated Vesicles	751	Degradation in Lysosomes	794

MBOC7_ptr_ch00_fm_i-xxxxviii.indd 32 08/12/21 11:23 AM

Early Endosomes Mature into Late Endosomes ESCRT Protein Complexes Mediate the Formation of Intralumenal	795	CHLOROPLASTS AND PHOTOSYNTHESIS Chloroplasts Resemble Mitochondria but Have a Separate	843
Vesicles in Multivesicular Bodies Summary	796 798	Thylakoid Compartment Chloroplasts Capture Energy from Sunlight and Use It	843
THE DEGRADATION AND RECYCLING OF	700	to Fix Carbon Carbon Fixation Uses ATP and NADPH to Convert CO ₂	844
MACROMOLECULES IN LYSOSOMES Lysosomes Are the Principal Sites of Intracellular Digestion	798 798	into Sugars	845
Lysosomes Are Heterogeneous Plant and Fungal Vacuoles Are Remarkably Versatile Lysosomes	799 800	Carbon Fixation in Some Plants Is Compartmentalized to Facilitate Growth at Low CO ₂ Concentrations	846
Multiple Pathways Deliver Materials to Lysosomes Cells Can Acquire Nutrients from the Extracellular Fluid by	801	The Sugars Generated by Carbon Fixation Can Be Stored as Starch or Consumed to Produce ATP	849
Macropinocytosis Specialized Phagocytic Cells Can Ingest Large Particles	802 802	The Thylakoid Membranes of Chloroplasts Contain the Protein Complexes Required for Photosynthesis and ATP Generation	849
Cargo Recognition by Cell-surface Receptors Initiates Phagocytosis	803	Chlorophyll–Protein Complexes Can Transfer Either Excitation Energy or Electrons	850
Autophagy Degrades Unwanted Proteins and Organelles The Rate of Nonselective Autophagy Is Regulated by Nutrient	804	A Photosystem Contains Chlorophylls in Antennae and a Reaction Center	851
Availability A Family of Cargo-specific Receptors Mediates Selective	805	The Thylakoid Membrane Contains Two Different Photosystems Working in Series	852
Autophagy	806	Photosystem II Uses a Manganese Cluster to Withdraw Electrons from Water	853
Some Lysosomes and Multivesicular Bodies Undergo Exocytosis Summary	807 807	The Cytochrome b_6 - f Complex Connects Photosystem II to	000
Problems	808	Photosystem I	854
References	810	Photosystem I Carries Out the Second Charge-Separation Step in the Z Scheme	855
Chapter 14 Energy Conversion and Metabolic		The Chloroplast ATP Synthase Uses the Proton Gradient	
Compartmentation: Mitochondria and		Generated by the Photosynthetic Light Reactions to Produce ATP	855
	811	The Proton-Motive Force for ATP Production in Mitochondria	000
THE MITOCHONDRION	813	and Chloroplasts Is Essentially the Same	856
The Mitochondrion Has an Outer Membrane and an Inner	010	Chemiosmotic Mechanisms Evolved in Stages By Providing an Inexhaustible Source of Reducing Power,	856
Membrane	814	Photosynthetic Bacteria Overcame a Major Evolutionary	
Fission, Fusion, Distribution, and Degradation of Mitochondria	815	Obstacle	857
The Inner Membrane Cristae Contain the Machinery for Electron Transport and ATP Synthesis	817	The Photosynthetic Electron-Transport Chains of	
The Citric Acid Cycle in the Matrix Produces NADH	817	Cyanobacteria Produced Atmospheric Oxygen and Permitted New Life-Forms	857
Mitochondria Have Many Essential Roles in Cellular Metabolism	818	Summary	860
A Chemiosmotic Process Couples Oxidation Energy to ATP Production	821	THE GENETIC SYSTEMS OF MITOCHONDRIA	
The Energy Derived from Oxidation Is Stored as an	021	AND CHLOROPLASTS	861
Electrochemical Gradient	822	The Genetic Systems of Mitochondria and Chloroplasts Resemble Those of Prokaryotes	861
Summary	823	Over Time, Mitochondria and Chloroplasts Have Exported	001
THE PROTON PUMPS OF THE ELECTRON-TRANSPORT CHAIN The Redox Potential Is a Measure of Electron Affinities	823 823	Most of Their Genes to the Nucleus by Gene Transfer	862
Electron Transfers Release Large Amounts of Energy	824	Mitochondria Have a Relaxed Codon Usage and Can Have a Variant Genetic Code	864
Transition Metal Ions and Quinones Accept and Release Electrons		Chloroplasts and Bacteria Share Many Striking Similarities	865
Readily NADH Transfers Its Electrons to Oxygen Through Three Large	824	Organellar Genes Are Maternally Inherited in Animals and Plants	866
Enzyme Complexes Embedded in the Inner Membrane	827	Mutations in Mitochondrial DNA Can Cause Severe	866
The NADH Dehydrogenase Complex Contains Separate Modules		Inherited Diseases Why Do Mitochondria and Chloroplasts Maintain a Costly	000
for Electron Transport and Proton Pumping	828	Separate System for DNA Transcription and Translation?	867
Cytochrome c Reductase Takes Up and Releases Protons on Opposite Sides of the Crista Membrane, Thereby		Summary	868
Pumping Protons	829	Problems References	869 871
The Cytochrome c Oxidase Complex Pumps Protons	004	Holdronoco	011
and Reduces O ₂ Using a Catalytic Iron–Copper Center Succinate Dehydrogenase Acts in Both the Electron-Transport	831	Chapter 15 Cell Signaling	873
Chain and the Citric Acid Cycle The Respiratory Chain Forms a Supercomplex in the	832	PRINCIPLES OF CELL SIGNALING	873
The Respiratory Chain Forms a Supercomplex in the Crista Membrane	833	Extracellular Signals Can Act Over Short or Long Distances Extracellular Signal Molecules Bind to Specific Receptors	874 875
Protons Can Move Rapidly Through Proteins Along Predefined		Each Cell Is Programmed to Respond to Specific Combinations of	013
Pathways	834	Extracellular Signals	876
Summary ATR PRODUCTION IN MITOCHONDRIA	835 835	There Are Three Major Classes of Cell-Surface Receptor Proteins Cell-Surface Receptors Relay Signals Via Intracellular Signaling	878
ATP PRODUCTION IN MITOCHONDRIA The Large Negative Value of △G for ATP Hydrolysis Makes ATP		Molecules	879
Useful to the Cell The ATP Synthase Is a Nanomachine That Produces ATP by	835	Intracellular Signals Must Be Specific and Robust in a Noisy Cytoplasm Intracellular Signaling Complexes Form at Activated Cell Surface	881
Rotary Catalysis Proton-driven Turbines Are Ancient and Critical for Energy	837	Intracellular Signaling Complexes Form at Activated Cell-Surface Receptors Madular Intracellular Signaling Complexes Form at Activated Cell-Surface Receptors	882
Conversion Mitochondrial Cristae Help to Make ATP Synthesis Efficient	839 840	Modular Interaction Domains Mediate Interactions Between Intracellular Signaling Proteins	883
Special Transport Proteins Move Solutes Through the Inner		The Relationship Between Signal and Response Varies in Different	
Membrane Chemiosmotic Mechanisms First Arose in Bacteria	841 842	Signaling Pathways The Speed of a Response Depends on the Turnover of Signaling	885
Summary	842	Molecules	886

Cells Can Respond Abruptly to a Gradually Increasing Signal	887	Chapter 16 The Cytoskeleton	949
Positive Feedback Can Generate an All-or-None Response Negative Feedback Is a Common Feature of Intracellular Signaling Systems	888 890	FUNCTION AND DYNAMICS OF THE CYTOSKELETON Cytoskeletal Filaments Are Dynamic, but Can Nevertheless	949
Cells Can Adjust Their Sensitivity to a Signal Summary	890 892	Form Stable Structures The Cytoskeleton Determines Cellular Organization and Polarity	951 952
SIGNALING THROUGH G-PROTEIN-COUPLED		Filaments Assemble from Protein Subunits That Impart Specific Physical and Dynamic Properties	953
RECEPTORS Heterotrimeric G Proteins Relay Signals from GPCRs	892 893	Accessory Proteins and Motors Act on Cytoskeletal Filaments Molecular Motors Operate in a Cellular Environment	955
Some G Proteins Regulate the Production of Cyclic AMP Cyclic-AMP-dependent Protein Kinase (PKA) Mediates Most	895	Dominated by Brownian Motion	956
of the Effects of Cyclic AMP	896	Summary	957 957
Some G Proteins Signal Via Phospholipids Ca ²⁺ Functions as a Ubiquitous Intracellular Mediator	898 899	ACTIN Actin Subunits Assemble Head-to-Tail to Create Flexible,	957
Feedback Generates Ca ²⁺ Waves and Oscillations	900	Polar Filaments	958
Ca ²⁺ /Calmodulin-dependent Protein Kinases Mediate	000	Nucleation Is the Rate-limiting Step in the Formation of Actin Filaments	958
Many Responses to Ca ²⁺ Signals Some G Proteins Directly Regulate Ion Channels	902 904	Actin Filaments Have Two Distinct Ends That Grow at Different Rates	
Smell and Vision Depend on GPCRs That Regulate Ion Channels	905	ATP Hydrolysis Within Actin Filaments Leads to Treadmilling	
Nitric Oxide Gas Can Mediate Signaling Between Cells	908 909	at Steady State The Functions of Actin Filaments Are Inhibited by Both	962
Second Messengers and Enzymatic Cascades Amplify Signals GPCR Desensitization Depends on Receptor Phosphorylation	909	Polymer-stabilizing and Polymer-destabilizing Chemicals	963
Summary	910	Actin-binding Proteins Influence Filament Dynamics	004
SIGNALING THROUGH ENZYME-COUPLED RECEPTORS	911	and Organization Actin Nucleation Is Tightly Regulated and Generates Branched	964
Activated Receptor Tyrosine Kinases (RTKs) Phosphorylate Themselves	911	or Straight Filaments	964
Phosphorylated Tyrosines on RTKs Serve as Docking Sites	911	Actin Filament Elongation Is Regulated by Monomer-binding	007
for Intracellular Signaling Proteins	913	Proteins Actin Filament-binding Proteins Alter Filament Dynamics and	967
Proteins with SH2 Domains Bind to Phosphorylated Tyrosines The Monomeric GTPase Ras Mediates Signaling by Most RTKs	913 915	Organization	968
Ras Activates a MAP Kinase Signaling Module	916	Severing Proteins Regulate Actin Filament Depolymerization	970
Scaffold Proteins Reduce Cross-Talk Between Different MAP	040	Bacteria Can Hijack the Host Actin Cytoskeleton Actin at the Cell Cortex Determines Cell Shape	971 971
Kinase Modules Rho Family GTPases Functionally Couple Cell-Surface	918	Distinct Modes of Cell Migration Rely on the Actin Cytoskeleton	972
Receptors to the Cytoskeleton	919	Cells Migrating in Three Dimensions Can Navigate Around Barriers Summary	974 975
PI 3-Kinase Produces Lipid Docking Sites in the Plasma	020		
Membrane The PI-3-Kinase–Akt Signaling Pathway Stimulates Animal	920	MYOSIN AND ACTIN Actin-based Motor Proteins Are Members of the	976
Cells to Survive and Grow	921	Myosin Superfamily	976
RTKs and GPCRs Activate Overlapping Signaling Pathways Some Enzyme-coupled Receptors Associate with Cytoplasmic	923	Myosin Generates Force by Coupling ATP Hydrolysis to Conformational Changes	977
Tyrosine Kinases	923	Sliding of Myosin II Along Actin Filaments Causes Muscles	911
Cytokine Receptors Activate the JAK-STAT Signaling Pathway	924	to Contract	977
Extracellular Signal Proteins of the TGFβ Superfamily Act Through Receptor Serine/Threonine Kinases and Smads	926	A Sudden Rise in Cytosolic Ca ²⁺ Concentration Initiates Muscle Contraction	981
Summary	927	Heart Muscle Is a Precisely Engineered Machine	984
ALTERNATIVE SIGNALING ROUTES IN GENE REGULATION	928	Actin and Myosin Perform a Variety of Functions in Non-Muscle Cells	984
The Receptor Notch Is a Latent Transcription Regulator Wat Proteins Activate Frizzled and Thereby Inhibit & Category	928	Summary MICROTUBULES	986 987
What Proteins Activate Frizzled and Thereby Inhibit β-Catenin Degradation	930	Microtubules Are Hollow Tubes Made of Protofilaments	988
Hedgehog Proteins Initiate a Complex Signaling Pathway		Microtubules Undergo a Process Called Dynamic Instability	988
in the Primary Cilium Many Inflammatory and Stress Signals Act Through an	932	Microtubule Functions Are Inhibited by Both Polymer-stabilizing and Polymer-destabilizing Drugs	991
NFκB-dependent Signaling Pathway	934	A Protein Complex Containing γ-Tubulin Nucleates Microtubules	991
Nuclear Receptors Are Ligand-modulated Transcription	005	The Centrosome Is a Prominent Microtubule Nucleation Site	991
Regulators Circadian Clocks Use Negative Feedback Loops to	935	Microtubule Organization Varies Widely Among Cell Types Microtubule-binding Proteins Modulate Filament Dynamics and	993
Control Gene Expression	937	Organization	995
Three Purified Proteins Can Reconstitute a Cyanobacterial Circadian Clock in a Test Tube	938	Microtubule Plus End-binding Proteins Modulate Microtubule	996
Summary	939	Dynamics and Attachments Tubulin-sequestering and Microtubule-severing Proteins Modulate	990
SIGNALING IN PLANTS	940	Microtubule Dynamics	998
Multicellularity and Cell Communication Evolved Independently	0.40	Two Types of Motor Proteins Move Along Microtubules Microtubules and Motors Move Organelles and Vesicles	999
in Plants and Animals Receptor Serine/Threonine Kinases Are the Largest Class of	940	Motile Cilia and Flagella Are Built from Microtubules and Dyneins	1004
Cell-Surface Receptors in Plants	941	Primary Cilia Perform Important Signaling Functions in Animal Cells	
Ethylene Blocks the Degradation of Specific Transcription	041	Summary	1006
Regulatory Proteins in the Nucleus Regulated Positioning of Auxin Transporters Patterns	941	INTERMEDIATE FILAMENTS AND OTHER CYTOSKELETAL POLYMERS	1007
Plant Growth	943	Intermediate Filament Structure Depends on the Lateral Bundling	
Phytochromes Detect Red Light, and Cryptochromes Detect Blue Light	944	and Twisting of Coiled-Coils Intermediate Filaments Impart Mechanical Stability to	1007
Summary	945	Animal Cells	1009
Problems Petersona	946	Linker Proteins Connect Cytoskeletal Filaments and Bridge

Septins Form Filaments That Contribute to Subcellular Organization	1012	Actin and Myosin II in the Contractile Ring Guide the Process of	1005
Bacterial Cell Shape and Division Depend on Homologs	1013	Cytokinesis	1065
of Eukaryotic Cytoskeletal Proteins Summary	1013	Local Activation of RhoA Triggers Assembly and Contraction of the Contractile Ring	1065
	1010	The Microtubules of the Mitotic Spindle Determine the Plane	1005
CELL POLARITY AND COORDINATION OF	1016	of Animal Cell Division	1066
THE CYTOSKELETON Cell Polarity Is Governed by Small GTPases in Budding Yeast	1016	The Phragmoplast Guides Cytokinesis in Higher Plants	1068
PAR Proteins Generate Anterior—Posterior Polarity	1010	Membrane-enclosed Organelles Must Be Distributed to	
in Embryos	1018	Daughter Cells During Cytokinesis	1069
Conserved Complexes Polarize Epithelial Cells and Control	.0.0	Some Cells Reposition Their Spindle to Divide Asymmetrically	1069
Their Growth	1019	Mitosis Can Occur Without Cytokinesis	1070
Cell Migration Requires Dynamic Cell Polarity	1020	Summary	1070
External Signals Can Dictate the Direction of Cell Migration	1022	MEIOSIS	1071
Communication Among Cytoskeletal Elements Supports		Meiosis Includes Two Rounds of Chromosome Segregation	1071
Whole-Cell Polarity and Locomotion	1023	Duplicated Homologs Pair During Meiotic Prophase	1073
Summary	1023	Homolog Pairing Culminates in the Formation of a Synaptonemal	
Problems	1024	Complex	1073
References	1025	Homolog Segregation Depends on Several Unique	1075
		Features of Meiosis I Crossing-Over Is Highly Regulated	1075 1076
Chapter 17 The Cell Cycle	1027	Meiosis Frequently Goes Wrong	1076
OVERVIEW OF THE CELL CYCLE	1027	Summary	1077
The Eukaryotic Cell Cycle Usually Consists of Four Phases	1027		
Cell-Cycle Control Is Similar in All Eukaryotes	1030	CONTROL OF CELL DIVISION AND CELL GROWTH Mitogens Stimulate Cell Division	1077 1078
Cell-Cycle Progression Can Be Studied in Various Ways	1030	9	1078
Summary	1031	Cells Can Enter a Specialized Nondividing State Mitogens Stimulate G ₁ -Cdk and G ₁ /S-Cdk Activities	1078
THE CELL-CYCLE CONTROL SYSTEM	1031	DNA Damage Blocks Cell Division	1080
The Cell-Cycle Control System Triggers the Major Events of	1001	Many Human Cells Have a Built-In Limitation on the Number	1000
the Cell Cycle	1032	of Times They Can Divide	1082
The Cell-Cycle Control System Depends on Cyclically Activated		Cell Proliferation Is Accompanied by Cell Growth	1083
Cyclin-dependent Protein Kinases	1033	Proliferating Cells Usually Coordinate Their Growth and Division	1084
Protein Phosphatases Reverse the Effects of Cdks	1035	Summary	1084
Hundreds of Cdk Substrates Are Phosphorylated in a Defined		Problems	1085
Order	1035	References	1087
Positive Feedback Generates the Switchlike Behavior of			
Cell-Cycle Transitions	1036	Chapter 18 Cell Death	1089
The Anaphase-promoting Complex/Cyclosome (APC/C) Triggers	1000	Apoptosis Eliminates Unwanted Cells	1090
the Metaphase-to-Anaphase Transition	1038 1040	Apoptosis Depends on an Intracellular Proteolytic Cascade	.000
The G ₁ Phase Is a Stable State of Cdk Inactivity The Cell-Cycle Control System Functions as a Linked Series	1040	Mediated by Caspases	1091
of Biochemical Switches	1041	Activation of Cell-Surface Death Receptors Initiates the Extrinsic	
Summary	1042	Pathway of Apoptosis	1093
S PHASE	1042	The Intrinsic Pathway of Apoptosis Depends on Proteins	
S-Cdk Initiates DNA Replication Once Per Cell Cycle	1042	Released from Mitochondria	1094
Chromosome Duplication Requires Duplication of	1040	Bcl2 Proteins Are the Critical Controllers of the Intrinsic Pathway	
Chromatin Structure	1045	of Apoptosis	1095
Cohesins Hold Sister Chromatids Together	1045	An Inhibitor of Apoptosis (an IAP) and Two Anti-IAP Proteins	
Summary	1046	Help Control Caspase Activation in the Cytosol of Some Mammalian Cells	1098
MITOSIS	1046	Extracellular Survival Factors Inhibit Apoptosis in Various Ways	1098
M-Cdk and Other Protein Kinases Drive Entry into Mitosis	1047	Healthy Neighbors Phagocytose and Digest Apoptotic Cells	1100
Condensin Helps Configure Duplicated Chromosomes		Either Excessive or Insufficient Apoptosis Can Contribute	1100
for Separation	1047	to Disease	1100
The Mitotic Spindle Is a Dynamic Microtubule-based Machine	1050	Summary	1102
Microtubules Are Nucleated in Multiple Regions of the Spindle	1051	Problems	1103
Microtubule Instability Increases Greatly in Mitosis	1052	References	1104
Microtubule-based Motor Proteins Govern Spindle Assembly			
and Function	1052	Chapter 19 Cell Junctions and the	
Bipolar Spindle Assembly in Most Animal Cells Begins			1105
with Centrosome Duplication	1053		
Spindle Assembly in Animal Cells Requires Nuclear-Envelope Breakdown	1054	CELL-CELL JUNCTIONS	1108
Mitotic Chromosomes Promote Bipolar Spindle Assembly	1054 1055	Cadherins Form a Diverse Family of Adhesion Molecules	1108
Kinetochores Attach Sister Chromatids to the Spindle	1056	Cadherins Mediate Homophilic Adhesion	1108
Bi-orientation Is Achieved by Trial and Error	1057	Cadherin-dependent Cell-Cell Adhesion Guides the Organization	1110
Multiple Forces Act on Chromosomes in the Spindle	1059	of Developing Tissues Assembly of Strong Cell-Cell Adhesions Requires Changes in	1110
The APC/C Triggers Sister-Chromatid Separation and the		the Actin Cytoskeleton	1112
Completion of Mitosis	1060	Catenins Link Classical Cadherins to the Actin Cytoskeleton	1113
Unattached Chromosomes Block Sister-Chromatid Separation:		Adherens Junctions Respond to Tension from Inside and	
The Spindle Assembly Checkpoint	1062	Outside the Tissue	1113
Chromosomes Segregate in Anaphase A and B	1062	Tissue Remodeling Depends on the Coordination of	
Segregated Chromosomes Are Packaged in Daughter Nuclei	1000	Actin-mediated Contraction with Cell-Cell Adhesion	1114
at Telophase	1063	Desmosomes Give Epithelia Mechanical Strength	1116
Summary	1064	Tight Junctions Form a Seal Between Cells and a Fence	
CYTOKINESIS	1064	Between Plasma Membrane Domains	1116

INTRODUCTION TO THE CELL

Cells, Genomes, and the Diversity of Life

CHAPTER

1

The surface of our planet is populated by living things—organisms—curious, intricately organized chemical factories that take in matter from their surroundings and use these raw materials to generate copies of themselves. These organisms appear extraordinarily diverse. What could be more different than a tiger and a piece of seaweed or a butterfly and a tree? Yet our ancestors, knowing nothing of cells or DNA, saw that all these things had something in common. They called that something "life," marveled at it, struggled to define it, and despaired of explaining what it was or how it worked in terms that relate to non-living matter.

The remarkable discoveries of the past 100 years or so have not diminished the marvel—quite the contrary. But they have removed the central mystery regarding the nature of life. We can now see that all living things are made of cells: small, membrane-enclosed units filled with a concentrated aqueous solution of chemicals and endowed with the extraordinary ability to create copies of themselves by growing and then dividing in two.

Because cells are the fundamental units of life, it is to *cell biology*—the study of the structure, function, and behavior of cells—that we must look for answers to the questions of what life is and how it works. With a deeper understanding of cells and their evolution, we can begin to tackle the grand historical problems of life on Earth: its mysterious origins, its stunning diversity, and its invasion of every conceivable habitat. Indeed, as emphasized long ago by the pioneering cell biologist E. B. Wilson, "the key to every biological problem must finally be sought in the cell; for every living organism is, or at some time has been, a cell."

Despite their apparent diversity, living things are fundamentally similar inside. The whole of biology is thus a counterpoint between two themes: astonishing variety in individual particulars and astonishing constancy in fundamental mechanisms. In this chapter, we begin by outlining the universal features common to all life on our planet, along with some of the fundamental properties of their cells. We then discuss how an analysis of DNA *genomes* allows scientists to position the wide variety of organisms in an evolutionary "tree of life." This

IN THIS CHAPTER

The Universal Features of Life on Earth

Genome Diversification and the Tree of Life

Eukaryotes and the Origin of the Eukaryotic Cell

Model Organisms

1

approach, which quantifies how closely organisms are related to one another, allows us to identify the three major branches of life on Earth, *eukaryotes, bacteria*, and *archaea*—each with unique qualities. We shall see that the familiar world of plants and animals—the focus of scientists for many centuries—makes up only a small slice of the complete diversity of life, the vast majority of which is invisible to the unaided human eye.

After exploring some of the ways that genomes change over evolutionary times, we highlight the handful of *model organisms* that biologists have chosen to focus on to dissect the molecular mechanisms underlying life. A few specific viruses, including SARS-CoV-2, pose grave threats to humans, so they too have become objects of intensive study. For this reason, this section also includes an introduction to viruses, the ubiquitous parasites that have evolved to feed on cells. Viruses are now recognized to be the most abundant biological entities on the planet.

THE UNIVERSAL FEATURES OF LIFE ON EARTH

There are more than 2 million described species living on Earth today, but many, many more are yet to be discovered. Each species is different, and each reproduces itself faithfully, yielding progeny that are unique to that species. Thus, the parent organism hands down information specifying, in extraordinary detail, the characteristics that the offspring will have. This phenomenon of *heredity* is central to the definition of life: it distinguishes life from other processes, such as the growth of a crystal, or the burning of a candle, or the formation of waves on water, in which structures are generated without the same type of link between the peculiarities of parents and offspring. A living organism must consume free energy to exist, as does a candle flame. But life employs this *free energy* to drive a very complex system of chemical reactions that create and maintain the intricate organization of its cells, all as specified by the hereditary information in those cells.

Most living organisms are single cells. Others, such as us, are like vast multicellular cities in which groups of cells perform specialized functions that are linked by intricate systems of intercellular communication. But even for the aggregate of more than 10¹³ cells that makes up a human body, the whole organism has been generated by cell divisions from a single cell. The single cell therefore contains all of the hereditary information that defines a species (Figure 1-1). The cell must also contain all of the machinery needed to gather raw materials from the environment and to construct from them a new cell in its own image, complete with a new copy of the hereditary information of its parent. Every cell on Earth is truly amazing.

All Cells Store Their Hereditary Information in the Form of Double-Strand DNA Molecules

Computers have made us familiar with the concept of information as a measurable quantity— 10^6 bytes to record a few hundred pages of text or an image from a digital camera, 10^9 bytes for a 60-minute video streamed from the Internet, and so on. Computers have also made us well aware that the same information can be recorded in many different physical forms: the discs and tapes that we used 25 years ago for our electronic archives have become unreadable on present-day machines. Living cells, like computers, store information, and it is estimated that they have been evolving and diversifying for more than 3.5 billion years. One might not expect that they would all store their information in the same form or that the hereditary information carried by one type of cell should be readable by the information-handling machinery of another. And yet it is so. This fact provides compelling evidence that all living things on Earth have inherited the form of their genetic instructions, as well as how to use them, from a *universal common ancestral cell*. This ancestor is thought to have existed roughly 3.5–3.8 billion years ago.

MBOC7_ptr_ch01_001-048.indd 2 02/12/21 12:53 PM

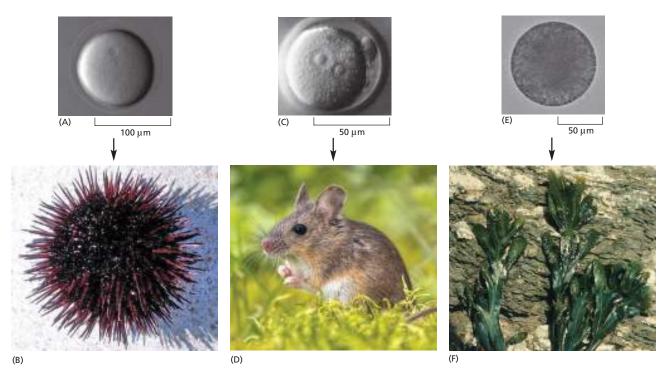

Figure 1–1 The hereditary information in the fertilized egg cell determines the nature of the whole multicellular organism that will develop from it. As indicated, although their starting cells look superficially similar, the egg of a sea urchin gives rise to a sea urchin (A and B), the egg of a mouse gives rise to a mouse (C and D), and the egg of the seaweed Fucus gives rise to a Fucus seaweed (E and F). (A, courtesy of David McClay; B, courtesy of Tim Hunt; C, courtesy of Patricia Calarco, from G. Martin, Science 209:768–776, 1980. With permission from AAAS; D, Rudmer Zwerver/Alamy Stock Photo; E and F, courtesy of Colin Brownlee.)

All cells on Earth today store their hereditary information in the form of double-strand molecules of DNA-long, unbranched, paired polymer chains, which are always composed of the same four types of *monomers*. These monomers, chemical compounds known as nucleotides, have nicknames drawn from a four-letter alphabet—A, T, C, G—and they are strung together in a long linear sequence that encodes the hereditary information, just as the sequence of 1's and 0's encodes the information in a computer file. We can take a piece of DNA from a human cell and insert it into a bacterium or a piece of bacterial DNA and insert it into a human cell, and, with only a few minor modifications, the information will be successfully read, interpreted, and copied. As we describe in Chapter 8, scientists can now rapidly read out the sequence of nucleotides in any DNA molecule and thereby determine the complete DNA sequence of any cell's genome—the totality of its hereditary information embodied in the linear sequence of nucleotides in its DNA. As a result, we now know the complete genome sequences for tens of thousands of species, ranging from the smallest bacterium to the largest plants and animals on Earth.

All Cells Replicate Their Hereditary Information by Templated Polymerization

The mechanisms that make life possible depend on the structure of the double-strand DNA molecule. We discuss this remarkable molecule in detail in Chapters 4 and 5; here we provide only an overview of its structure and means of reproduction. Each monomer in a single DNA strand—that is, each **nucleotide**—consists of two parts: a sugar (deoxyribose) with a phosphate group attached to it, and a *base*, which may be either adenine (A), guanine (G),

MBOC7_ptr_ch01_001-048.indd 3 02/12/21 12:53 PM

Chapter 1: Cells, Genomes, and the Diversity of Life

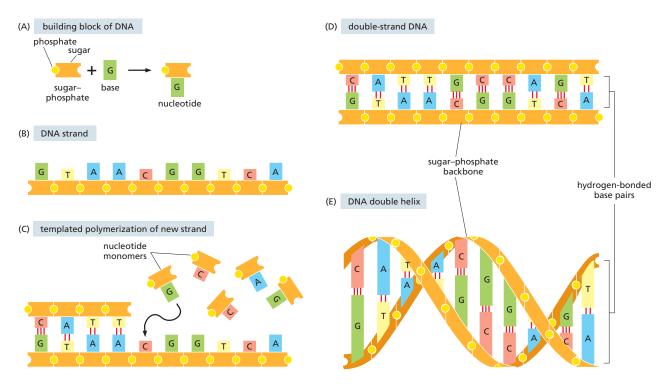

Figure 1–2 DNA and its building blocks. (A) DNA is made from simple subunits, called nucleotides. Each nucleotide consists of a specific arrangement of about 35 covalently linked atoms, forming a sugar–phosphate molecule with a nitrogen-containing side group, or base, attached to it. The bases are of four types (adenine, guanine, cytosine, and thymine), corresponding to four distinct nucleotides, labeled A, G, C, and T. (B) A single strand of DNA consists of nucleotides joined together by sugar–phosphate linkages. Note that the individual sugar–phosphate units are asymmetric, giving the backbone of the strand a definite directionality, or polarity. This directionality guides the molecular processes by which the information in DNA is both interpreted and copied (replicated) in cells: the information is always "read" in a consistent order, just as written English text is read from left to right. (C) Through templated polymerization, the sequence of nucleotides in an existing DNA strand controls the sequence in which nucleotides are joined together in a new DNA strand; T in one strand pairs with A in the other, and G in one strand with C in the other. The new strand therefore has a nucleotide sequence complementary to that of the old strand and a backbone with opposite directionality: thus, GTAA... in the original strand, is ...TTAC in the new strand. (D) A normal DNA molecule consists of two such complementary strands. The nucleotides within each strand are linked by strong (covalent) chemical bonds; the complementary nucleotides on opposite strands are held together more weakly, by hydrogen bonds. (E) The two strands twist around each other to form a double helix — a robust structure that can accommodate any sequence of nucleotides without altering its basic double-helical structure (see Movie 4.1).

cytosine (C), or thymine (T) (Figure 1-2). Each sugar is linked to the next via the phosphate group, creating a polymer chain composed of a repetitive sugarphosphate backbone with a series of bases protruding from it. The DNA polymer is extended by adding monomers at one end. For a single isolated strand, these monomers can, in principle, be added in any order, because each one links to the next in the same way, through the part of the molecule that is the same for all of them. In the living cell, however, DNA is not synthesized as a free strand in isolation, but on a template formed by a preexisting DNA strand. The bases that protrude from this template can bind to bases of the strand being synthesized, according to a strict rule defined by the complementary structures of the bases: A binds to T, and C binds to G. This base-pairing holds fresh monomers in place and thereby controls the selection of which one of the four monomers will next be added to a growing strand. In this way, a double-strand structure is created, consisting of two exactly complementary sequences of A's, C's, T's, and G's. These two strands twist around each other, forming a DNA double helix (see Figure 1-2E).

Compared with the covalent sugar-phosphate bonds, the hydrogen bonds between the base pairs are weak, which allows the two DNA strands to be

MBOC7_ptr_ch01_001-048.indd 4 02/12/21 12:53 PM

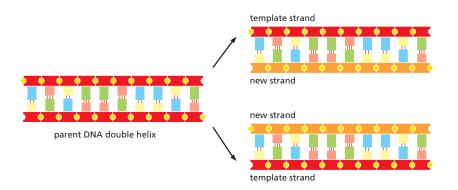

Figure 1–3 The copying of genetic information by DNA replication. In this process, the two strands of a DNA double helix are pulled apart, and each serves as a template for the synthesis of a new complementary strand. The end result is two daughter DNA double helices that are identical in sequence to the parent double helix.

pulled apart without breakage of their backbones. Each strand then can serve as a template, in the way just described, for the synthesis of a fresh DNA strand complementary to itself—a fresh copy, that is, of the hereditary information (Figure 1–3). In different types of cells, this process of DNA replication occurs at different rates, with different controls to start it or stop it, and with different auxiliary molecules to help the process along (discussed in Chapters 5 and 17). But the basics are universal: DNA is the information store for heredity, and *templated polymerization* is the way in which this information is copied throughout the living world.

All Cells Transcribe Portions of Their DNA into RNA Molecules

To carry out its information-bearing function, DNA must do more than copy itself. It must also *express* its information, by letting the information guide the synthesis of other molecules in the cell. This expression occurs by a mechanism that is the same in all living organisms, leading first and foremost to the production of two other crucial classes of biological polymers: RNA molecules and protein molecules. The process begins with a templated polymerization called **transcription**, in which segments of the DNA sequence are used as templates for the synthesis of shorter molecules of the closely related polymer **ribonucleic acid, or RNA**. Subsequently, in a process called **translation**, many of these RNA molecules direct the synthesis of polymers of a radically different chemical class—the *proteins* (**Figure 1–4**). The detailed chemical reactions involved are presented in Chapter 6; here they will only be briefly outlined.

The backbone of an RNA molecule is formed by a slightly different sugar from that in DNA—ribose instead of deoxyribose; in addition, one of the four bases is slightly different—uracil (U) replaces thymine (T). Most important, however, the other three bases—A, C, and G—are identical to those in DNA, and all four bases will pair with their complementary counterparts in DNA—the A, U, C, and G of RNA with the T, A, G, and C of DNA, respectively. During transcription, this pairing allows the RNA monomers to be lined up and selected for polymerization on a template strand of DNA, just as DNA monomers are selected during replication. The outcome is a single-strand polymer molecule whose sequence of nucleotides faithfully represents a portion of the cell's genetic information, even though it is written in a slightly different alphabet—consisting of the four RNA monomers instead of the four DNA monomers.

The same segment of DNA can be used repeatedly to guide the synthesis of many identical RNA molecules. Thus, whereas the cell's archive of genetic information in the form of DNA is fixed and sacrosanct, *RNA transcripts* are mass-produced and disposable. Most of these transcripts function as intermediates in the transfer of genetic information by serving as *messenger RNA (mRNA)* molecules that guide the synthesis of proteins according to the genetic instructions stored in the DNA. But as we discuss in Chapter 6, some RNA transcripts do not serve as information carriers; instead, they function directly in the cell to carry out a variety of other functions.

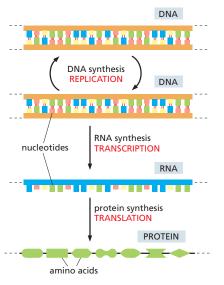

Figure 1–4 From DNA to protein. In addition to DNA replication (shown at the top of the figure), genetic information is read out and put to use through a two-step process: First, in transcription, segments of the DNA sequence are used to guide the synthesis of molecules of RNA. Then, in translation, RNA molecules are used to guide the synthesis of proteins, which are polymers made of amino acid subunits (discussed shortly).

MBOC7_ptr_ch01_001-048.indd 5 02/12/21 12:53 PM

All Cells Use Proteins as Catalysts

Like DNA and RNA molecules, **protein** molecules are long unbranched polymer chains, formed by stringing together monomeric building blocks (subunits) drawn from a standard repertoire that is the same for all living cells. Like DNA and RNA, proteins carry information in the form of a linear sequence of subunits in the same way as a human message written in an alphabetic script. There are many different protein molecules in each cell, and—if we ignore water molecules—they form the major portion of the cell's mass.

The subunits of proteins are the **amino acids**, which are quite different from the nucleotides of DNA and RNA, and there are 20 types instead of 4. Each amino acid is built around a core structure that allows it to be covalently linked in a standard way to any other amino acid in the set; attached to this core is a side group of atoms that gives each amino acid a distinctive chemical character. Each protein molecule is a *polypeptide* chain that is created by joining its amino acids in a particular sequence; this sequence determines how the polypeptide folds up, giving the protein its unique three-dimensional structure. Through several billion years of evolution, these sequences have been selected to give each protein a useful function.

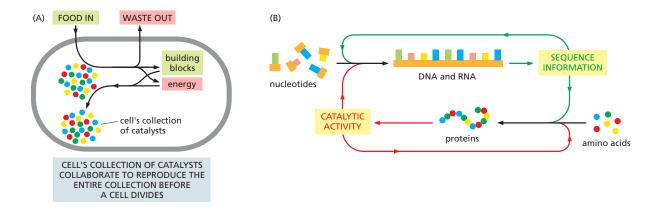

By folding into a precise structure that binds with high specificity to other molecules, each protein performs a specific function according to its genetically specified sequence of amino acids. Proteins form and maintain diverse cell and extracellular structures, generate movements, sense signals, and so on. Many have reactive sites on their surface, allowing them to act as *enzymes* that catalyze reactions that make or break specific covalent bonds. Proteins, above all, are the main molecules that put the cell's genetic information into action. Thus, polynucleotides (DNA and mRNAs) specify the amino acid sequences of proteins. Proteins, in turn, serve as *catalysts* to cause many different chemical reactions to occur, including those that synthesize new DNA and RNA molecules.

In everyday speech, a catalyst refers to "any agent that provokes or speeds significant change or action." But in chemistry, the term **catalyst** is defined more narrowly, being applied to any molecule that speeds up a specific chemical reaction without itself being changed. From the most fundamental point of view, a living cell is a self-replicating collection of catalysts that takes in food, processes this food to provide both the building blocks and energy needed to make more catalysts, and discards the materials left over as waste (**Figure 1–5A**). Together, these feedback loops that connect proteins and polynucleotides form the basis for this autocatalytic, self-reproducing behavior of all living organisms (**Figure 1–5B**).

All Cells Translate RNA into Protein in the Same Way

How the information in DNA specifies the production of proteins was a complete mystery in the 1950s when the double-strand structure of DNA was first revealed as the basis of heredity. But in subsequent years, scientists discovered the elegant

Figure 1-5 Life as an autocatalytic process. (A) The living cell is a selfreplicating collection of catalysts. (B) Life can be viewed as an autocatalytic process. DNA and RNA molecules provide the nucleotide sequence information (green arrows) that is used both to produce proteins and to copy themselves. Proteins, in turn, provide the catalytic activity (red arrows) needed to synthesize DNA, RNA, and proteins themselves. Together, these feedback loops create the self-replicating system that endows cells with the ability to reproduce. Although the great majority of the catalysts in the cell are proteins (known as enzymes), a few RNA molecules (known as ribozymes) also have this property, as we will see in Chapter 6.

MBOC7_ptr_ch01_001-048.indd 6 02/12/21 12:53 PM

mechanisms involved. The translation of genetic information from the 4-letter alphabet of polynucleotides into the 20-letter alphabet of proteins is a complex process. The rules of this translation seem in some respects neat and rational but in other respects strangely arbitrary, given that they are (with minor exceptions) identical in all living things. These arbitrary features, it is thought, reflect frozen accidents in the early history of life. They stem from the chance properties of the earliest organisms that were passed on by heredity and have become so deeply embedded in the constitution of all living cells that they cannot be changed without disastrous consequences.

It turns out that the information in the sequence of a messenger RNA (mRNA) molecule is read out in groups of three nucleotides at a time: each triplet of nucleotides, or codon, specifies (codes for, or encodes) a single amino acid in a corresponding protein. Because the number of distinct triplets that can be formed from four nucleotides is 4³, there are 64 possible codons, all of which occur in nature. However, there are only 20 naturally occurring amino acids, which means there are necessarily many cases in which several codons correspond to the same amino acid. This genetic code is read out by a special class of small RNA molecules, called transfer RNAs (tRNAs). Each type of tRNA becomes attached at one end to a specific amino acid and displays at its other end a specific sequence of three nucleotides—an anticodon—that enables it to recognize, through base-pairing, a particular codon or subset of codons in mRNA. The intricate chemistry that enables these tRNAs to translate a specific sequence of A, C, G, and U nucleotides in an mRNA molecule into a specific sequence of amino acids in a protein molecule occurs on a ribosome, a large multimolecular machine composed of both protein and *ribosomal RNA*. All of these processes will be described in detail in Chapter 6.

Each Protein Is Encoded by a Specific Gene

DNA molecules as a rule are very large, containing the specifications for thousands of proteins and RNA molecules. Special sequences in the DNA serve as punctuation, defining where the information for each RNA and protein begins and ends. And individual segments of the long DNA sequence are transcribed into separate mRNA molecules, coding for different proteins. Each such DNA segment represents one gene. As previously mentioned, some DNA segments—a smaller number—are transcribed into RNA molecules that are not translated into protein but have other functions in the cell; such DNA segments also count as genes. A **gene** therefore is defined as the segment of DNA sequence corresponding either to a single protein (but sometimes to a set of closely related, alternative protein variants) or to a single catalytic, regulatory, or structural RNA molecule.

In all cells, the *expression* of individual genes is regulated: instead of manufacturing its full repertoire of possible proteins and RNAs at full tilt all the time, the cell adjusts the rate of transcription and translation of different genes independently, according to need. As we shall see in Chapter 7, stretches of *regulatory DNA* are interspersed among the segments that code for protein, and these noncoding regions bind to special protein molecules that control the rate of transcription of individual genes. The organization of this regulatory DNA varies widely from one class of organisms to another, but the basic strategy is universal. In this way, the genome of the cell dictates not only the nature of the cell's proteins but also when and where they are to be made.

Life Requires a Continual Input of Free Energy

A living cell is a dynamic chemical system, operating far from chemical equilibrium. For a cell to grow or to make a new cell in its own image, it must take in *free energy* from the environment, as well as raw materials, to drive the necessary synthetic reactions. This consumption of free energy is fundamental to life. When this energy is not available, a cell decays toward chemical equilibrium and soon dies.

MBOC7_ptr_ch01_001-048.indd 7 02/12/21 12:53 PM

As one example, free energy is required for the propagation of genetic information. Picture the molecules in a cell as a swarm of objects endowed with thermal energy, moving around violently at random, buffeted by collisions with one another. To copy genetic information—in the form of a DNA sequence, for example—nucleotide molecules from this wild crowd must be captured, arranged in a specific order defined by a preexisting template, and linked together in a fixed relationship. The bonds that hold the nucleotides in their proper places on the template and join them together must be strong enough to resist the disordering effect of thermal motion, which we describe shortly. The joining process is driven forward by a consumption of free energy, which is needed to ensure that the correct bonds are made, and made robustly. As an analogy, the molecules might be compared with spring-loaded traps, ready to snap into a more stable, lower-energy attached state when they meet their proper partners. As they snap together into the bonded arrangement, their available stored energy—their free energy—like the energy of the spring in the trap, is released and dissipated as heat. In a cell, the chemical processes underlying information transfer are more complex, but the same basic principle applies: free energy must be spent for the creation of order.

To replicate its genetic information faithfully, and indeed to make all its complex molecules according to the correct specifications, the cell therefore requires free energy, which has to be imported somehow from the surroundings. As we will discuss in detail in Chapter 2, the free energy required by animal cells is derived from chemical bonds in food molecules that the animals eat, whereas plants get their free energy from sunlight.

All Cells Function as Biochemical Factories

Because all cells make DNA, RNA, and protein, they all have to contain and manipulate a similar collection of small organic (carbon-containing) molecules, including simple sugars, nucleotides, and amino acids, as well as other substances that are universally required. All cells, for example, require the phosphorylated nucleotide *ATP* (*adenosine triphosphate*), not only as a building block for the synthesis of DNA and RNA but also as a carrier of the free energy that is needed to drive a huge number of chemical reactions in the cell.

Although all cells function as biochemical factories of a broadly similar type, many of the details of their small-molecule transactions differ. Plants, for example, require only the simplest of nutrients because they harness the energy of sunlight to make all their own small organic molecules. Other organisms, such as animals and some bacteria, feed on living (or once living) organisms and must obtain many of their organic molecules ready-made. We return to this point later in the chapter.

All Cells Are Enclosed in a Plasma Membrane Across Which Nutrients and Waste Materials Must Pass

Each living cell is enclosed by a membrane—the **plasma membrane**. This membrane acts as a selective barrier that enables the cell to concentrate nutrients gathered from its environment and retain the products it synthesizes for its own use, while excreting its waste products. Without a plasma membrane, the cell could not maintain its integrity as a coordinated chemical system.

The molecules that form cell membranes have the simple physicochemical property of being *amphiphilic*; that is, they consist of one part that is hydrophilic (water-soluble) and another part that is hydrophobic (water-insoluble). Such molecules placed in water aggregate spontaneously, arranging their hydrophobic portions to be as much in contact with one another as possible to hide them from the water, while keeping their hydrophilic portions exposed. Amphiphilic molecules of appropriate shape, such as the *phospholipid* molecules that compose most of the molecules of the plasma membrane, spontaneously aggregate in water to create a *bilayer* that forms small closed vesicles (Figure 1–6).

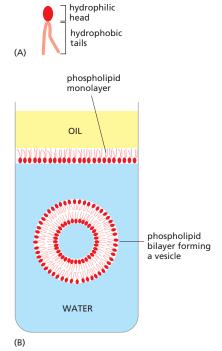

Figure 1–6 Behavior of phospholipid molecules in water. (A) A phospholipid molecule is amphiphilic, having a hydrophilic (water-loving) phosphate head group and a hydrophobic (water-avoiding) hydrocarbon tail. (B) At an interface between oil and water, phospholipids arrange themselves as a single sheet (a monolayer), with their head groups facing the water and their tail groups facing the oil. When immersed in water, however, phospholipids aggregate to form lipid bilayers that fold in on themselves to form sealed aqueous compartments known as vesicles.

MBOC7_ptr_ch01_001-048.indd 8 02/12/21 12:53 PM

Although the chemical details vary, the hydrophobic tails of the predominant lipid molecules in all cells are hydrocarbon polymers ($-CH_2-CH_2-CH_2-$), and their spontaneous assembly into a lipid bilayer is but one of many examples of an important general principle: cells produce molecules whose chemical properties cause them to *self-assemble* into the structures that a cell needs.

The cell boundary cannot be totally impermeable. If a cell is to grow and reproduce, it must be able to import raw materials and export waste across its plasma membrane. All cells therefore have specialized proteins embedded in their plasma membrane that transport specific molecules from one side to the other. Some of these *membrane transport proteins*, like some of the proteins that catalyze the fundamental small-molecule reactions inside the cell, have been so well conserved over the course of evolution that we can recognize the family resemblances between them when even the most distantly related organisms are compared.

The transport proteins in the plasma membrane largely determine which molecules enter the cell, while the catalytic proteins (enzymes) inside the cell determine the reactions that the entering molecules undergo. Thus, by specifying the RNAs and proteins that the cell produces, the genetic information recorded in the DNA sequence dictates the entire chemistry of the cell—in fact, not only its chemistry but also its form and its behavior, for these too are chiefly determined and controlled by the cell's proteins.

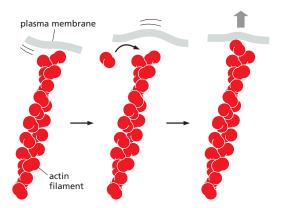

Cells Operate at a Microscopic Scale Dominated by Random Thermal Motion

Thus far we have described the cell as a self-replicating, membrane-bound bag of chemicals and macromolecules; but, as the unit of life, the cell is much more than the sum of its parts. Although not obvious from microscopy images, even the simplest cell is highly ordered internally: its individual components must self-assemble and become highly organized for the cell to function. And the cell contents are in perpetual motion. The most obvious movements are catalyzed by motor proteins, enzymes that use the energy of ATP hydrolysis for a wide variety of purposes; these include pumping ions across the plasma membrane, translocating large assemblies from one intracellular site to another, and propelling the cell through its environment. In addition, and as previously mentioned, random thermal motions of molecules (including water) are prominent at the scale of cells—whose dimensions can be as small as a micrometer (10⁻⁶ meters) in diameter. This type of spontaneous movement, called thermal or Brownian motion, was first observed by Robert Brown in 1827, while looking through a microscope at pollen grains immersed in water. Caused by random molecular collisions, the constant fluctuating movement has important repercussions. Brownian motion drives a process called diffusion, and it determines the rates of biochemical reactions as molecules collide with one another within the interior of a cell (described in Chapter 2; see Movie 2.4).

Even though random, the cell can harness Brownian motion for its own advantage. For example, during one step in the crawling migration of animal cells, the plasma membrane at the leading edge extends forward (see Chapter 16). This movement does not involve motor proteins. Instead, a cytoskeletal filament (an actin polymer) polymerizes adjacent to the inner membrane surface. When the membrane fluctuates in the forward direction, actin quickly fills in the gap so that the membrane cannot slip back to its original position. This phenomenon, in which random thermal motions are harnessed in a directed way, creates a *Brownian ratchet* (Figure 1–7).

Because an object at the micrometer scale is constantly buffeted by water molecules, its movement requires overcoming high viscous drag forces. As a result, the directed movement of a complex of molecules inside the cell (by a motor protein, for example) will stop immediately when the motor disengages, leaving the complex to be randomly buffeted by thermal motion. There is no "gliding" inside the cell.

MBOC7_ptr_ch01_001-048.indd 9 02/12/21 12:53 PM

A Living Cell Can Exist with 500 Genes

We have seen how genomes carry the information for all the proteins and RNA molecules of a cell, and how, through catalysis, all the other building blocks of the cell are made. But how complex are real living cells? In particular, what are the minimum requirements of a living cell? One measure of complexity is based on the total number of genes in an organism's genome. A species that has one of the smallest known genomes is the bacterium *Mycoplasma genitalium*, which causes a common, sexually transmitted, human disease (Figure 1–8). This organism lives as a parasite in mammals, where the environment provides it with many of the small molecules it needs ready-made. Nevertheless, it still has to make all the large molecules—DNA, RNAs, and proteins. It has 525 genes, most of which are essential. Its genome of 580,070 nucleotide pairs represents 145,018 bytes of information—about as much as it takes to record the text of one chapter of this book. Cell biology may be complicated, but it is not unimaginably so.

Summary

The individual cell is the minimal self-reproducing unit of life. A cell consists of a self-replicating collection of catalysts, enclosed in a plasma membrane. All cells operate as biochemical factories, driven by the free energy released in a complicated network of chemical reactions. Central to a cell's ability to reproduce is the transmission of its genetic information to its progeny cells when it divides. All cells store their genetic information in double-strand DNA, and the complete sequence of DNA nucleotides for each organism is known as its genome. The cell replicates this information by separating the paired DNA strands and using each as a template for polymerization to make a new DNA strand with a complementary sequence of nucleotide subunits. The same strategy of templated polymerization is used in the transcription of portions of the DNA into molecules of the closely related polynucleotide polymer, RNA. Most of these RNA molecules are mRNAs that in turn guide the synthesis of protein molecules by the process of translation. Proteins are polymers of amino acid subunits and are the catalysts for almost all the cell's chemical reactions. They are also responsible for the selective import and export of molecules across the plasma membrane that surrounds each cell. The specific shape and function of each protein depend on its amino acid sequence, which is specified by the nucleotide sequence of a corresponding segment of the DNA—the gene that codes for that protein. In this way, the DNA of the cell determines the cell's chemistry, which is fundamentally similar in all cells, reflecting their ultimate origin from a common ancestor cell that existed on Earth more than 3.5 billion years ago.

GENOME DIVERSIFICATION AND THE TREE OF LIFE

The success of living organisms based on DNA, RNA, and protein has been spectacular. Through its billions of years of proliferation, life has populated the oceans, covered the land, penetrated deep into Earth's crust, and molded the surface of

Figure 1-7 How membrane protrusion is driven by a simple Brownian ratchet. A single actin filament is shown abutting the plasma membrane, which is fluctuating back and forth because of random thermal motions. When the membrane happens to move away from the end of the filament, it creates sufficient space for an additional subunit, which quickly adds on. The slightly longer filament acts as a ratchet and prevents the membrane from moving back to its original position. In a migrating animal cell, this Brownian ratchet process drives protrusion of the membrane and contributes to forward movement of the cell, as described in Chapter 16 (see pp. 956-957).

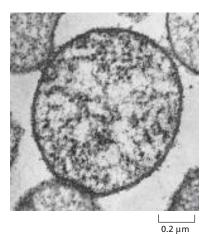

Figure 1-8 The small bacterium Mycoplasma genitalium. It is viewed here in cross section in an electron microscope, which uses a beam of electrons instead of light to create an image with a resolution that is many times higher than that of an image viewed in a conventional light microscope. Of the 525 genes this bacterium contains, 43 code for transfer RNAs, ribosomal RNAs, and other nonprotein-coding RNAs. Of the 482 protein-coding genes, 154 are involved in replication, transcription, translation, and related processes involving DNA, RNA, and protein; 98 are involved in the membrane and surface structures of the cell; 46 are involved in the transport of nutrients and other molecules across the plasma membrane; and 71 are involved in energy conversion and the synthesis and degradation of small molecules (Courtesy of Roger Cole, in Medical Microbiology, 4th ed. [S. Baron, ed.] Galveston: University of Texas Medical Branch, 1996.)

MBOC7_ptr_ch01_001-048.indd 10 02/12/21 12:53 PM

our planet. Our oxygen-rich atmosphere, the deposits of coal and oil, the layers of iron ores, the cliffs of chalk and limestone and marble—all these are products, directly or indirectly, of past biological activity on Earth.

Living things are not confined to the familiar temperate realm of land, water, and sunlight inhabited by plants and animals. They are found in the darkest depths of the ocean, in hot volcanic mud, in pools beneath the frozen surface of the Antarctic, and buried kilometers deep in Earth's crust. The creatures that live in these extreme environments are generally unfamiliar, not only because they are inaccessible, but also because they are mostly microscopic and cannot be maintained in a laboratory. Even in more familiar habitats, most organisms are too small for us to see without special equipment: they tend to go unnoticed, unless they cause a disease or rot the timbers of our houses. Yet such *microorganisms* (microbes) are by far the most numerous living organisms on our planet. Only recently, through new methods of molecular analysis including rapid *DNA sequencing*, have we begun to get a picture of life on Earth that is not grossly distorted by our biased perspective as large animals living on dry land.

In this section, we consider—in very broad terms—the diversity of organisms on our planet and the relationships among them. Because the genetic information for every organism is written in the universal language of DNA sequences, and because the DNA sequence of any organism's genome can be readily determined, it is now possible to characterize, catalog, and compare any set of living organisms with reference to these sequences. From such comparisons we can specify the place of each organism in the family tree of living species—the "tree of life."

The Tree of Life Has Three Major Domains: Eukaryotes, Bacteria, and Archaea

The classification of living things has traditionally depended on comparisons of their outward appearances: we can see that a fish has eyes, jaws, backbone, brain, and so on, just as humans do, and that a worm does not—just as we can see that a rosebush is more similar to an apple tree than to grass. As Darwin showed, we can readily interpret such close family resemblances in terms of an evolution from common ancestors, and we can find the remains of many of these ancestors preserved in the fossil record. In this way, it became possible to draw a family tree of living organisms, showing the various lines of descent, as well as branch points in evolutionary history, where the ancestors of one group of species became different from those of another.

When the disparities between organisms become very great, however, these methods begin to fail. How do we decide whether a fungus is more closely related to a plant or to an animal? When it comes to microscopic organisms such as bacteria, the task becomes harder still: one tiny rod or sphere can look much like another. Moreover, much of our knowledge of the microbial world was traditionally restricted to those species that can be isolated and cultured in the laboratory. But direct DNA sequencing of populations of microbes in their natural habitats—such as soil, ocean water, or even the human mouth—has taught us that the vast majority of microbes cannot be easily cultured in the laboratory. Often, they thrive in the wild as components of complex ecosystems and—when separated from their natural surroundings—cannot survive. Until modern DNA sequencing was developed, these organisms were largely unknown to us, especially those that inhabit extreme environments such as the deep Earth's crust or seawater miles below the ocean surface.

Genome analysis has now provided us with a simple, direct, and powerful way to determine evolutionary relationships. The complete DNA sequence of an organism defines its nature with almost perfect precision and in exhaustive detail. Moreover, this specification is in a digital form—a string of letters—that can be entered into a computer and compared with the corresponding information for any other organism. Because DNA is subject to random changes that accumulate over long periods of time (as we will see shortly), the number of differences

MBOC7_ptr_ch01_001-048.indd 11 02/12/21 12:53 PM

between the DNA sequences of two organisms can provide a direct, objective, and quantitative indication of the evolutionary distance between them.

For constructing a comprehensive tree of life, it is necessary to begin with a segment of DNA that is easily recognized in the genomes of all organisms. We discussed earlier how all cells use the same fundamental mechanism to translate a nucleotide sequence into a protein sequence, and we saw that the ribosome is the "decoding machine" that carries this out. Ribosomes are fundamentally similar in all organisms, and an especially well-conserved component of them is the RNA molecules that make up their core. Although the exact sequence of these *ribosomal RNAs (rRNAs)* differs across organisms, they are similar enough to use them as a ruler to judge how closely two species are related: the more similar the ribosomal RNA sequences, the more recently the two species diverged from a common ancestor and the more related they must be. Once a rough approximation of the tree of life has been obtained in this way, many additional DNA sequences in genomes—those that might not be identifiable in all organisms—can accurately determine relationships among more closely related species.

This approach has revealed that the living world consists of three major divisions, or *domains*: eukaryotes, bacteria, and archaea, as illustrated in Figure 1–9; in the following paragraphs, we briefly introduce each in turn.

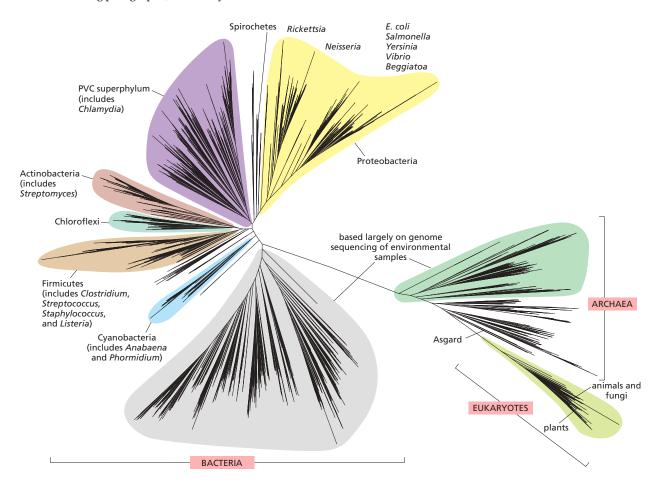

Figure 1–9 A global tree of life, based on genome comparisons, shows the three major divisions (domains) of the living world. The lengths of the branches are proportional to differences among genomes using common genes that can be recognized and compared across many different species. Some of the organisms discussed in this and later chapters are indicated. Of the three domains of life (bacteria, archaea, and eukaryotes), bacteria encompass by far the greatest diversity, commensurate with their ability to colonize nearly every ecological niche on the planet. So many new bacterial species are currently being identified through DNA sequencing of environmental samples that simply naming them has become a challenge. Although eukaryotes (and especially animals) are the main focus of this book, they comprise only a small slice of the global diversity. An expanded eukaryotic tree is shown in Figure 1–35, and an expanded tree of mammals is given in Figure 4–67. (Adapted from C.J. Castelle and J.F. Banfield, Cell 172:1181–1197, 2018.)

MBOC7_ptr_ch01_001-048.indd 12 02/12/21 12:53 PM

Eukaryotes Make Up the Domain of Life That Is Most Familiar to Us

The great variety of living creatures that we see around us are eukaryotes. The name is from the Greek, meaning "truly nucleated" (from the words *eu*, "well" or "truly," and *karyon*, "kernel" or "nucleus"), reflecting the fact that the cells of these organisms have their DNA enclosed in a membrane-bound organelle called the *nucleus*. Visible by simple light microscopy, this feature was used in the early twentieth century to classify living organisms as either **eukaryotes** (those with a nucleus) or **prokaryotes** (those without a nucleus). We now know that prokaryotes comprise two of the three major domains of life, the bacteria and archaea. Eukaryotic cells are typically much larger than those of bacteria and archaea; in addition to a nucleus, they typically contain a variety of membrane-bound organelles that are also lacking in the prokaryotes. The genomes of eukaryotes also tend to run much larger—containing more than 20,000 genes for humans and corals, for example, compared with 4000–6000 genes for the typical bacteria or archaea.

In addition to plants and animals, the eukaryotes include fungi (such as mushrooms or the yeasts used in beer- and bread-making), as well as an astonishing variety of single-celled, microscopic forms of life. Most of this book is focused on the cell biology of eukaryotic organisms (especially animals); in the final sections of this chapter, we shall return to eukaryotes and focus on the variety within this group.

On the Basis of Genome Analysis, Bacteria Are the Most Diverse Group of Organisms on the Planet

When modern trees of life were constructed using genome information, one of the big surprises was how much more evolutionarily diverse the bacterial world is compared with the eukaryotes; we now know that this great diversity reflects the much earlier appearance of bacteria in the evolutionary history of the planet. Bacteria are usually very small (and invisible to the unaided eye), and they generally live as independent individuals or in loosely organized communities, rather than as multicellular organisms. They are typically spherical or rod-shaped and measure a few micrometers (μ m) in linear dimension (**Figure 1–10**). They often have a tough protective coat, called a cell wall, beneath which a plasma membrane encloses a single cytoplasmic compartment—the *cytoplasm*—containing DNA, RNA, proteins, and the many small molecules needed for life (**Figure 1–11**). Although difficult to discern in the light microscope, the interior of a bacterium is nevertheless highly organized, a topic we discuss in Chapter 16.

Commensurate with the diversity of their genomes, bacteria live in an enormous variety of ecological niches, and they are astonishingly varied in their

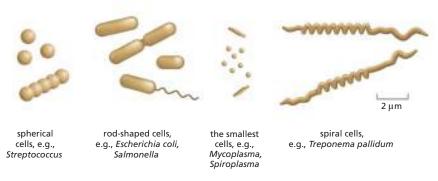

Figure 1–10 Shapes and sizes of some bacteria. Although most are small, as shown, measuring a few micrometers in linear dimension, there are also some giant species. An extreme example is the cigar-shaped bacterium $Epulopiscium\ fishelsoni$, which lives in the gut of a surgeonfish and can be up to 600 μ m long (not shown).

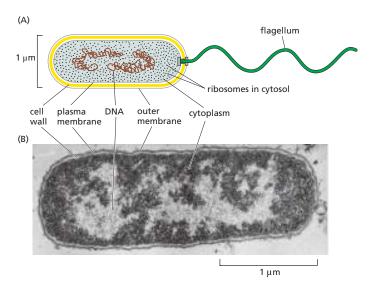

Figure 1-11 Bacterial structure. (A) A drawing of the bacterium Vibrio cholerae, showing its simple internal organization. This species can infect the human small intestine to cause cholera: the severe diarrhea that accompanies this disease kills more than 100,000 people a year worldwide. Like many other bacteria, Vibrio has a helical appendage at one end-a flagellum-that rotates as a propeller to drive the cell forward. (B) An electron micrograph of a longitudinal section through the widely studied bacterium Escherichia coli (E. coli). E. coli is part of our normal intestinal microbiota, the complete collection of microbes in our gut. It has many flagella distributed over its surface, but they are not visible in this section. Both of the bacteria shown here are Gram negative, having both an outer and an inner (plasma) membrane. However, many bacterial species lack the outer membrane: these are classified as Gram positive. (B, courtesy of E. Kellenberger.)

biochemical capabilities. There exist species that can utilize virtually any type of organic molecule as food, ranging from sugars and amino acids to hydrocarbons, including the simplest hydrocarbon, methane gas (CH₄). Other species (Figure 1–12) harvest light energy in a variety of ways; some, like plants, carry out photosynthesis and generate oxygen as a by-product. Still others can feed on a plain diet of inorganic nutrients, getting their carbon from CO₂, and relying on a host of other chemicals that occur in the environment to fuel their energy needs—including H_2 , Fe^{2+} , H_2S , and elemental sulfur (Figure 1–13).

A wide range of bacteria directly affect human health. The bubonic plague of the Middle Ages (estimated to have killed half the population of Europe) and the current tuberculosis pandemic (more than a million deaths a year) are each due to a specific species of bacteria. And thousands of different bacterial species reside in our gut and on our skin, where they are often beneficial to us. We shall discuss bacteria throughout the book, as it is the study of these relatively simple cells that led to much of our understanding of basic biological processes—including DNA replication, transcription, and translation. We focus again on bacteria in Chapter 24 when we examine the cell biology of infectious disease. Finally, genetic

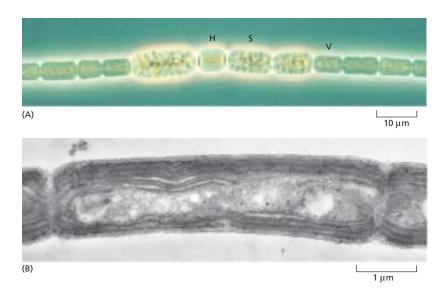

Figure 1-12 Photosynthetic bacteria. (A) A light micrograph of the bacterium Anabaena cylindrica. Its cells form long chains, in which most of the cells (labeled V) perform photosynthesis (and thereby capture CO2 and incorporate C into organic compounds); others (labeled H) become specialized for fixing N from N2; and still others (labeled S) develop into spores, which can resist unfavorable conditions. (B) An electron micrograph of a related photosynthetic bacterium, Phormidium laminosum, which shows the intracellular membranes where photosynthesis occurs. As shown in these micrographs, some prokaryotes have intracellular membranes and form colonies that resemble simple multicellular organisms. (A. courtesy of David Adams; B, courtesy of D.P. Hill and C.J. Howe.)

MBOC7_ptr_ch01_001-048.indd 14 02/12/21 12:53 PM

engineering techniques allow bacteria to be put to use as small "factories" to produce human pharmaceuticals, biofuels, and other high-value chemical products, as we discuss in Chapter 8.

Archaea: The Most Mysterious Domain of Life

Of the three domains of life, archaea remains the most poorly understood. Most of its members have been identified only by DNA sequencing of samples from the environment, and relatively few have been cultured and studied up close in the laboratory. Like bacteria, the archaea we know most about are small and lack the internal, membrane-bound organelles that distinguish the eukaryotes. But they differ from bacteria in many ways, including the chemistry of their cell walls, the kinds of lipids that make up their membrane, and the range of biochemical reactions that they can carry out. Another surprising conclusion came from genome comparisons: although archaea resemble bacteria in their outward appearances, their genomes are much more closely related to eukaryotes than to bacteria (see Figure 1–9). It has even been proposed that the tree of life should be considered to have only two principal domains, with the archaea and eukaryotes making up one domain and bacteria constituting the other. The close relationship of archaea and eukaryotes has also changed our views on how the earliest eukaryotic cell evolved, a topic addressed later in this chapter.

At first it was thought that archaea occupied only extreme environments such as volcanoes, salt lakes, acid hot springs, and the stomachs of cattle, but they are now recognized to be present also in more congenial surroundings such as soils, seawater, and our skin. Commensurate with the wide variety of ecological niches in which they have been found, different species of archaea have highly diverse chemistries. They are believed to be the predominant life-form in soil and seawater, and they play major roles in recycling nitrogen and carbon, two of the most important elements for all cells.

Organisms Occupy Most of Our Planet

To understand life on Earth, we need to understand more than its diversity; we also need to know where life is found on our planet and how various living species are distributed. Organisms inhabit nearly all of the planet, and we continue to discover new habitats. Amazingly, some bacteria and archaea even live miles down in Earth's deep crust and in the deepest and most hostile parts of the oceans.

How are the main groups of organisms distributed among different environments? DNA sequencing and other advanced technologies have been used recently to address this question. The total biomass on Earth is estimated to contain ~ 550 gigatons (10^{15} grams) of carbon, of which 450 gigatons of carbon (Gt C) is plants, 70 Gt C is bacteria, 7 Gt C is archaea, and 2 Gt C is animals (Figure 1–14). The plants are mainly terrestrial; the bacteria and archaea are mainly in the soil and Earth's crust. Total terrestrial biomass is 100 times greater than that in the oceans, although most of the animal mass is found in the oceans. The human biomass is 10 times greater than that of all measurable wild animals together, and—while human biomass continues to increase—that of wild animals is falling, largely as a result of human activities.

Although humans and other animals make up a small fraction of Earth's biomass, their existence depends completely on other forms of life. In the next section, we shall see some of the ways that these different life-forms work together to capture and recycle energy from Earth's inanimate features.

Cells Can Be Powered by a Wide Variety of Free-Energy Sources

Organisms obtain the free energy needed for life in different ways. Some—such as animals, fungi, and the many different bacteria that live in the human gut—get it by feeding on other living things or the organic chemicals they produce; such organisms are called *organotrophic* (from the Greek word *trophe*, meaning

Figure 1–13 The bacterium *Beggiatoa*. It lives in sulfurous environments (for example, see Figure 1–15) and gets its energy by oxidizing H₂S; it can fix carbon even in the dark. Note the yellow deposits of sulfur inside the cells. (Courtesy of Ralph S. Wolfe.)

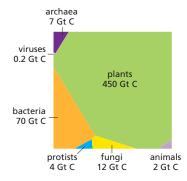

Figure 1–14 The distribution of living biomass on Earth. The total biomass on Earth expressed as gigatons of carbon (Gt C) is estimated to be ∼550 Gt C. In the graph shown, the area of each taxon represented is proportional to the taxon's global biomass, so plants account for about 80% (450/550) of the total biomass, whereas animals account for 0.4% (2/550). These recent estimates are based on various advanced techniques, including DNA sequencing and remote sensing. (Adapted from Y.M. Bar-On et al., *Proc. Natl. Acad. Sci. USA* 115:6506–6511, 2018. With permission from the authors.)

MBOC7_ptr_ch01_001-048.indd 15 02/12/21 12:53 PM

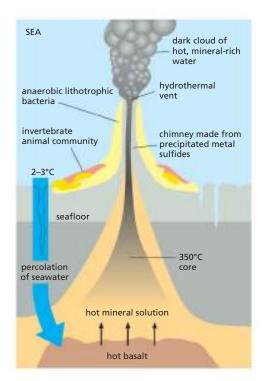

"food"). Others derive their free energy directly from the nonliving world. These primary energy converters fall into two classes: those that harvest the energy of sunlight, and those that capture their energy from energy-rich systems of inorganic chemicals in the environment (chemical systems that are far from chemical equilibrium). Organisms of the former class are called *phototrophic* (feeding on sunlight); those of the latter are called *lithotrophic* (feeding on rock). The organotrophic organisms like ourselves could not exist without these primary energy converters, which are the most plentiful form of life.

The phototrophic organisms include many types of bacteria, as well as algae and plants, on which we—and virtually all the living things that we ordinarily see around us—depend. Phototrophic organisms have changed the whole chemistry of our environment: as a prime example, the oxygen in Earth's atmosphere is a by-product of their biosynthetic activities.

Lithotrophic organisms are not such an obvious feature of our world, because they are microscopic and mostly live in habitats that humans do not frequent—deep in the ocean, buried in Earth's crust, or in various other seemingly inhospitable environments. But they are a major part of the living world, and they are especially important in any consideration of the history of life on Earth.

Some lithotrophs get energy from *aerobic* reactions, which use molecular oxygen from the environment; because atmospheric O_2 is ultimately the product of living phototrophic organisms, these aerobic lithotrophs are, in a sense, feeding on the products of past life. There are, however, many other lithotrophs that live *anaerobically*, in places where little or no molecular oxygen is present; these are circumstances similar to those that existed in the early days of life on Earth, before oxygen had accumulated.

The most dramatic of the anaerobic sites are the hot *hydrothermal vents* on the floor of the Pacific and Atlantic Oceans. They are located where the ocean floor is spreading as new portions of Earth's crust form by a gradual upwelling of material from Earth's interior (Figure 1–15). Downward-percolating seawater is heated and driven back upward as a submarine geyser, carrying with it a current of chemicals from the hot rocks below. A typical cocktail might include H_2S , H_2 , CO, Mn^{2+} , Fe^{2+} , Ni^{2+} , CH_4 , NH_4^+ , and phosphorus-containing compounds.

hydrothermal vent in the ocean floor. As indicated, seawater percolates down toward the hot, molten, volcanic rock upwelling (basalt) from Earth's interior and is heated and driven back upward, carrying a mixture of minerals leached from the hot rock. A temperature gradient

Figure 1-15 The geology of a hot

is set up, from more than 350°C near the core of the vent, down to 2–3°C in the surrounding ocean. Minerals precipitate from the water as it cools, forming a chimney. Different classes of organisms, thriving at different temperatures, live in different neighborhoods of the chimney. A typical chimney might be a few meters tall, spewing out hot, mineral-rich water. The locations of lithotrophic bacteria and the invertebrate marine animals that depend on them are also shown (see Figure 1–16).

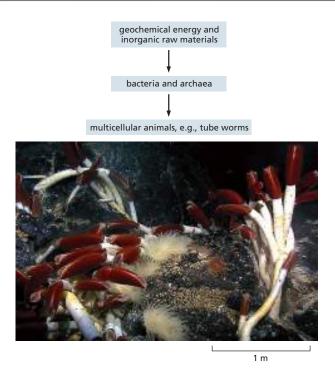

Figure 1–16 Organisms living at a depth of 2500 meters near a vent in the ocean floor. Close to the vent, at temperatures up to about 120°C, various lithotrophic species of bacteria and archaea live. directly fueled by geochemical energy. A little further away, where the temperature is lower, various invertebrate animals live by feeding on these microorganisms. Most remarkable are the giant (2-meter-long) tube worms, Riftia pachyptila, which are shown in the photograph. Rather than feed on the lithotrophic microbes, these worms live in symbiosis with them: specialized organs in the worms harbor huge numbers of symbiotic sulfur-oxidizing bacteria, which harness geochemical energy and supply nourishment to their hosts, which have no mouth, gut, or anus. The tube worms are thought to have evolved from more conventional animals and to have become secondarily adapted to life at hydrothermal vents. (Science History Images/Alamy Stock Photo.)

A dense population of microorganisms lives in the neighborhood of the vent, thriving on this austere diet and harvesting free energy from reactions between the available chemicals. Various invertebrate marine animals—clams, mussels, and giant marine worms—in turn, live off the microbes at the vent, forming an entire ecosystem analogous to the world of plants and animals that we belong to, but one powered by geochemical energy instead of light (Figure 1–16).

Some Cells Fix Nitrogen and Carbon Dioxide for Other Cells

To make a living cell requires matter, as well as free energy. DNA, RNA, and protein are composed of just six elements: hydrogen, carbon, nitrogen, oxygen, sulfur, and phosphorus. These are all plentiful in the nonliving environment, in Earth's rocks, water, and atmosphere. But they are not present in chemical forms that allow easy incorporation into biological molecules. Atmospheric N2 and CO2, in particular, are extremely unreactive. A large amount of free energy is required to drive the reactions that use these inorganic molecules to make the organic compounds needed for further biosynthesis; that is, to fix nitrogen and carbon dioxide, so as to make N and C available to living organisms. Many types of cells lack the biochemical machinery to achieve this fixation; they instead rely on other classes of cells to do the job for them. We animals depend on plants, directly or indirectly, for our supplies of carbon- and nitrogen-containing organic compounds. Plants in turn, although they can fix carbon dioxide from the atmosphere, lack the ability to fix atmospheric nitrogen; they depend in part on nitrogen-fixing bacteria to supply their need for nitrogen-containing organic compounds. Plants of the pea family, for example, harbor symbiotic nitrogen-fixing bacteria in nodules in their roots.

Because living cells can differ widely in some of the most basic aspects of their biochemistry, cells with complementary needs and capabilities have frequently developed close associations. Some of these *symbiotic* associations, as we will see later, have evolved to the point where the partners have lost their separate identities altogether: they have joined forces to form a single composite cell—an *endosymbiotic* association, as opposed to an *ectosymbiotic* one between separate organisms.

MBOC7_ptr_ch01_001-048.indd 17 02/12/21 12:53 PM

Genomes Diversify Over Evolutionary Time, Producing New Types of Organisms

Having discussed our current views on the diversity of life-forms, how they are distributed across Earth, and how they depend on one another, we now turn to the question of how this great diversity was generated. All life depends on the storage of genetic information in the form of each organism's DNA genome, so our focus is on how genomes change over evolutionary time.

In storing and copying genetic information, random accidents and errors occur, altering the nucleotide sequence; that is, creating mutations. Therefore, when a cell divides, the genomes of its two daughters are often not quite identical to each other or to that of the parent cell. On rare occasions, the error may represent a change for the better; more probably, it will cause no significant difference in the cell's prospects. But in some cases, the error will cause serious damage; for example, by disrupting the coding sequence for a key protein or RNA molecule. Changes due to mistakes of the first type will tend to be perpetuated, because the altered cell has an increased likelihood of surviving and reproducing itself. Changes due to mistakes of the second type—neutral changes—may be perpetuated or not: in the competition for limited resources, it is a matter of chance whether the altered cell or its cousins will succeed. But changes that cause serious damage lead nowhere: the cell that suffers them dies, leaving no progeny. Through endless repetition of this cycle of error and trial—of mutation and natural selection—organisms evolve: their genetic specifications change, sometimes giving organisms new ways to exploit the environment more effectively, to survive in competition with others, and to reproduce successfully.

Some parts of the genome will change more readily than others in the course of evolution. A segment of DNA that does not code for protein or RNA and has no significant regulatory role is free to change at a rate limited only by the frequency of random errors. In contrast, a gene that codes for a highly optimized, essential protein or RNA molecule cannot alter so easily: when mistakes occur, the faulty cells are almost always disabled and eliminated. Genes of this latter sort are therefore *highly conserved*. Through 3.5 billion years or more of evolutionary history, many DNA sequences have changed beyond all recognition, but the most highly conserved genes remain perfectly recognizable in all living species.

These latter genes are the ones we must examine if we wish to trace family relationships between the most distantly related organisms in the tree of life. We discussed an example of one such gene—that for ribosomal RNA—when we introduced the classification of the living world into the three domains of eukaryotes, bacteria, and archaea. Because the production of proteins is fundamental to all living cells, this component of the ribosome has been highly conserved since early in the history of life on Earth (Figure 1–17).

The ribosomal RNA genes are exceptional in being so well conserved, whereas most parts of genomes have diversified much more dramatically over evolutionary time. A complete DNA sequence for an organism—its genome sequence—reveals all the genes that an organism possesses, as well as those it lacks. When we

human

Methanococcus

E. coli

Figure 1–17 Genetic information conserved since the days of the last universal common ancestor of all living things. A part of the gene that codes for the smaller of the two main ribosomal RNA (rRNA) molecules in the ribosome is shown. (The complete molecule is about 1500–1900 nucleotides long, depending on the species.) Corresponding segments of nucleotide sequences from an archaeon (*Methanococcus jannaschii*), a bacterium (*Escherichia coli*), and a eukaryote (*Homo sapiens*) are aligned. The *red vertical lines* indicate sites where the nucleotides are identical between the species; the human sequence is repeated at the bottom of the alignment so that all three two-way comparisons can be seen. The *black dot* halfway along the *E. coli* sequence denotes a site where a nucleotide has been either deleted from the bacterial lineage in the course of evolution or inserted in the other two lineages. Note that the sequences from these three organisms, representative of the three domains of the living world, still retain unmistakable similarities.

MBOC7_ptr_ch01_001-048.indd 18 02/12/21 12:53 PM

compare the three domains of the living world, we can begin to see which genes are common to all of them—and must therefore have been present in the last universal common ancestral cell that was the founder of all present-day living things. We can also identify those genes that are peculiar to a single branch in the tree of life. To explain such findings, we need to consider how new genes arise and, more generally, how genomes evolve.

New Genes Are Generated from Preexisting Genes

The raw material of evolution is the DNA sequence that already exists: there is no natural mechanism for making long stretches of new, random, DNA sequence. In this sense, no gene is ever entirely new. Innovation can, however, occur in several ways (Figure 1–18):

- 1. *Intragenic mutation*: an existing gene can be randomly modified by changes in its DNA sequence, through various types of errors that occur in the process of DNA replication and DNA repair.
- 2. *Gene duplication*: an existing gene can be accidentally duplicated, creating a pair of initially identical genes within a single cell; these two genes may then diverge in the course of evolution.
- 3. *DNA segment shuffling*: two or more existing genes can break and rejoin to make a hybrid gene consisting of DNA segments that originally belonged to separate genes.
- 4. Horizontal (intercellular) DNA transfer: a piece of DNA can be transferred from the genome of one cell to that of another—including between species. This process contrasts with the usual vertical transfer of genetic information from parent to progeny.

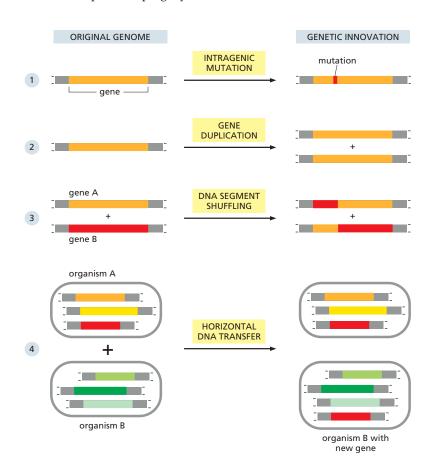

Figure 1–18 Four modes of genetic innovation and their effects on the DNA sequence of an organism. A special form of horizontal transfer occurs when cells of two different species enter into a permanent symbiotic association; genes from one of the cells may subsequently be transferred to the genome of the other, as we will see later when we discuss the likely evolutionary origins of mitochondria and chloroplasts.

MBOC7_ptr_ch01_001-048.indd 19 02/12/21 12:53 PM

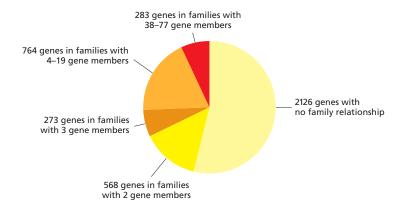

Figure 1–19 Families of evolutionarily related genes in the genome of *Bacillus subtilis*. The largest gene family in this bacterium consists of 77 genes coding for varieties of a class of membrane transport proteins called ABC transporters, which are found in all three domains of the living world. (Adapted from F. Kunst et al., *Nature* 390:249–256, 1997.)

Each of these types of change leaves a characteristic trace in the DNA sequence of the organism, and there is clear evidence that all four processes have occurred frequently during evolution. In Chapters 4 and 5, we discuss the mechanisms underlying these changes, but for the present we focus on the consequences.

Gene Duplications Give Rise to Families of Related Genes Within a Single Genome

A cell duplicates its entire genome each time it divides into two daughter cells. However, accidents occasionally result in the inappropriate duplication of just part of the genome, with retention of both the original and duplicate segments in a single cell. Once a gene has been duplicated in this way (see mode 2 in Figure 1–18), the two gene copies can acquire mutations and become specialized to perform different functions within the same cell and its descendants. Repeated rounds of this process of gene duplication and divergence, over many millions of years, have enabled one gene to give rise to a family of related genes within a single genome. Analysis of the DNA sequence of prokaryotic genomes reveals many examples of such **gene families**: in the bacterium *Bacillus subtilis*, for example, 47% of the genes have one or more obvious relatives (**Figure 1–19**).

The above evolutionary process must be distinguished from the genetic divergence that occurs when one species of organism splits into two separate lines of descent at a branch point in the family tree—when the human line separated from that of chimpanzees, for example. In the latter case, the genes gradually become different in the course of evolution, but they are likely to continue to have corresponding functions in the two sister species. Genes that are related by descent in this way—that is, genes in two separate species that derive from the same ancestral gene in the last common ancestor of those two species—are called **orthologs**. Related genes that have resulted from a gene duplication event within a single genome—and are likely to have diverged in their function—are called **paralogs**. Genes that are related by descent in either way are called **homologs**, a general term used to cover both types of relationship (**Figure 1–20**).

The Function of a Gene Can Often Be Deduced from Its Nucleotide Sequence

Family relationships among genes are important not just for their evolutionary interest, but also because they simplify the task of deciphering gene functions. Once the nucleotide sequence of a newly discovered gene has been determined, a scientist can tap a few keys on a computer to search large databases of known gene sequences for gene relatives. In many cases, the function of one or more of these homologs will have been already determined experimentally—generally in one of the model organisms described later in this chapter. Because gene sequence determines gene function, one can frequently make a good guess at the new gene's function, as it is likely to be similar to that of the already

MBOC7_ptr_ch01_001-048.indd 20 02/12/21 12:53 PM

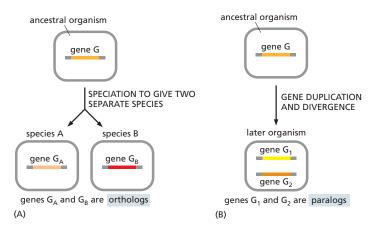

Figure 1–20 Two types of gene homology based on different evolutionary pathways. (A) Orthologs. (B) Paralogs. Genes related by either mechanism are called homologs.

known homologs. In this way, it is possible to decipher a great deal about the biology of an organism simply by analyzing the DNA sequence of its genome.

More Than 200 Gene Families Are Common to All Three Domains of Life

Given the complete genome sequences of representative organisms from all three domains of life—eukaryotes, bacteria, and archaea—we can search systematically for homologies that span this enormous evolutionary divide. In this way, we can begin to take stock of the common inheritance of all living things. There are considerable difficulties in this enterprise. For example, individual species have often lost some of the ancestral genes, and other genes have almost certainly been acquired by horizontal transfer from another species and therefore are not truly ancestral. In fact, genome comparisons strongly suggest that both lineage-specific gene loss and horizontal gene transfer, in some cases between evolutionarily distant species, have been major factors in evolution, at least among bacteria and archaea. As an additional difficulty, in the course of 2 or 3 billion years, some genes that were initially shared will have changed beyond recognition through mutation.

Because of all these vagaries of the evolutionary process, it is difficult, if not impossible, to determine the ancestral gene set that diversified into the present-day variety of life. A crude approximation can be obtained by tallying the gene families that have representatives in multiple—but not necessarily all—species from the three major domains of life. One such analysis revealed 264 ancient conserved families, each of which could be assigned a function on the basis of the best-characterized family member. As shown in Table 1-1, the largest number of shared gene families were involved in translation and in amino acid metabolism and transport. However, it must be emphasized that this set of highly conserved gene families represents only a very rough sketch of the common inheritance of all modern life.

Summary

For most of human history, the living world around us was classified by what we could see. Genome sequencing has radically changed our view of life on the planet, and we now realize that living things fall into three broad domains: bacteria, archaea, and eukaryotes. The organisms in the first two domains are largely invisible to our naked eye, and many of them cannot yet be grown in a laboratory—being known only by their DNA sequences. But they make up the vast majority of life's evolutionary diversity, including species that can obtain all their energy and nutrients from inorganic chemical sources—such as the reactive mixtures of minerals released at hydrothermal vents on the ocean floor—the sort of diet that may

MBOC7_ptr_ch01_001-048.indd 21 02/12/21 12:53 PM

TABLE 1-1 The Number of Gene Families, Classified by Function, Common to All Three Domains of the Living World			
Information processing		Metabolism	
Translation	63	Energy production and conversion	19
Transcription	7	Carbohydrate transport and metabolism	16
DNA replication, recombination, and repair	13	Amino acid transport and metabolism	43
Cellular processes and signaling		Nucleotide transport and metabolism	15
Cell-cycle control, mitosis, and meiosis	2	Coenzyme transport and metabolism	22
Defense mechanisms	3	Lipid transport and metabolism	
Signal-transduction mechanisms	1	Inorganic ion transport and metabolism	
Cell wall/membrane biogenesis	2	Secondary metabolite biosynthesis, 5 transport, and catabolism	
Intracellular trafficking and secretion	4	Poorly characterized	
Post-translational modification, protein turnover, chaperones	8	General biochemical function predicted; specific biological role unknown	24

For the purpose of this analysis, gene families are defined as "universal" if they are represented in the genomes of at least two diverse archaea (Archaeoglobus fulgidus and Aeropyrum pernix), two evolutionarily distant bacteria (Escherichia coli and Bacillus subtilis), and one eukaryote (yeast, Saccharomyces cerevisiae). (Data from R.L. Tatusov et al., Science 278:631–637, 1997; R.L. Tatusov et al., BMC Bioinformatics 4:41, 2003; and the COGs database at the US National Library of Medicine.)

have nourished the first living cells more than 3.5 billion years ago. The eukaryotes (whose cells are larger and contain a variety of membrane-bound organelles) evolved later in evolutionary history and are consequently less diverse as a group than either the bacteria or archaea. Eukaryotes, which include all plants and animals, are the organisms most familiar to us, and they are the main focus of this textbook.

Many of the genes within a single organism or species show strong family resemblances in their DNA sequences, implying that they originated from the same ancestral gene through gene duplication and divergence. Family resemblances (homologies) are also clear when gene sequences are compared between different species, and more than 200 gene families have been so highly conserved that they can be recognized as common to most species from all three domains of the living world, suggesting they were present in the ancestral cell from which all life evolved. Given the DNA sequence of a newly discovered gene in any organism, it is therefore often possible to deduce the gene's function from the known function of a homologous gene in a better-studied organism.

EUKARYOTES AND THE ORIGIN OF THE EUKARYOTIC CELL

Eukaryotic cells, in general, are bigger and more elaborate than bacterial and archaeal cells, and their genomes are bigger and more elaborate, too. The greater cell size is accompanied by radical differences in cell structure and function: in particular, eukaryotes contain a diverse set of intracellular **organelles**—discrete membrane-enclosed subcompartments and large membraneless macromolecular assemblies—each with a distinct composition and function. Some eukaryotic cells live independent lives as single-cell organisms. Others live in multicellular assemblies—indeed, all of the more complex multicellular organisms on Earth, including plants, animals, and fungi, are formed from eukaryotic cells.

We begin by discussing how eukaryotic cells are organized and how they might have evolved from more ancient prokaryotes. We then briefly consider how eukaryotic genomes differ from those of prokaryotes, as well as how the cells in

MBOC7_ptr_ch01_001-048.indd 22 02/12/21 12:53 PM

multicellular organisms become differently specialized as an embryo develops, so as to contribute to the welfare of the organism as a whole.

Eukaryotic Cells Contain a Variety of Organelles

By definition, eukaryotic cells keep almost all their DNA in a membrane-enclosed internal compartment—the *nucleus*, which is usually the most conspicuous organelle (Figure 1–21). The long DNA polymers in the nucleus are packaged with proteins to form *chromosomes*, which only become visible in a light microscope when they condense in preparation for cell division. The *nuclear envelope*, a double layer of membrane, surrounds the nucleus and separates the nuclear DNA from the *cytoplasm*, which, in a eukaryotic cell, includes everything between the plasma membrane and the nucleus. As shown in the figure, the nuclear envelope is perforated by *nuclear pores*, which are channels formed by protein complexes that mediate the two-way traffic of large molecules between the nucleus and the cytoplasm.

Eukaryotic cells have many other features that set them apart from bacterial and archaeal cells. They are typically 10–30 times bigger in linear dimension and 1000–10,000 times larger in volume than a typical prokaryotic cell. They have an elaborate *cytoskeleton* in the cytoplasm, consisting of several types of protein filaments (see Figure 1–21) that, together with the many proteins that attach to them, form a network of girders, ropes, and motors that gives the cell mechanical strength and performs various other functions: when the cell divides, for example, the cytoskeleton reorganizes and pulls the replicated chromosomes apart and distributes them equally to the two daughter cells. In the case of animal cells and some free-living, single-cell eukaryotes, the cytoskeleton controls cell shape

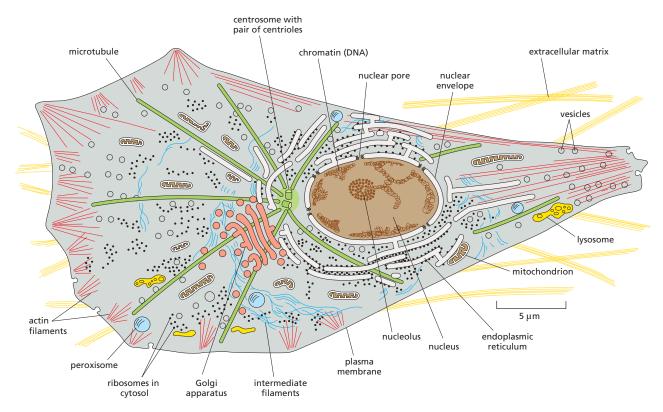

Figure 1–21 The major features of eukaryotic cells. The drawing depicts the major contents of a typical animal cell seen in cross section, but almost all the same components are found in plant cells and fungi, as well as in single-cell eukaryotes. The cytoskeleton (discussed in Chapter 16) consists of three types of protein filaments: actin filaments (red), microtubules (green), and intermediate filaments (blue). Plant cells (not shown) contain chloroplasts in addition to the components shown here; they also have a rigid external cell wall that contains cellulose surrounding their plasma membrane, which means they are largely immobile. The interior of cells is, in reality, much more crowded than depicted in this simplified diagram.

MBOC7_ptr_ch01_001-048.indd 23 02/12/21 12:53 PM

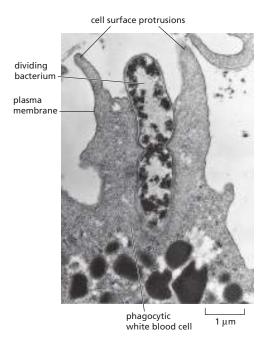

Figure 1–22 Phagocytosis. An electron micrograph of a mammalian phagocytic white blood cell (a neutrophil) ingesting a bacterium that is in the process of dividing. Only the part of the cell that is extending surface protrusions to engulf the bacterium is shown. (Courtesy of Dorothy Bainton.)

and drives and guides cell movements (Movie 1.1). Lacking the kind of tough cell wall characteristic of bacteria and archaea, these eukaryotic cells can change their shape rapidly, in some cases enabling them to move and engulf other cells and small objects by a process called *phagocytosis* (Figure 1–22).

There are many other membrane-enclosed organelles in eukaryotic cells. Unlike the nucleus, most of them are enclosed by single membranes. The most extensive organelle is the *endoplasmic reticulum* (*ER*), which is where most cell membrane components are made, along with materials destined for secretion to the outside of the cell. The *Golgi apparatus* receives these molecules from the ER and modifies and packages them for secretion or transport to another cell compartment. *Lysosomes* are small irregularly shaped organelles in which intracellular digestion occurs. *Peroxisomes* are small vesicles where hydrogen peroxide is used to inactivate toxic molecules.

A continual exchange of materials occurs between these single-membrane-enclosed organelles, mediated mainly by small *transport vesicles* that pinch off from the membrane of one organelle and fuse with that of another. To connect the eukaryotic cell with its surroundings, a similar vesicle-mediated exchange goes on continually at the cell surface. Here, portions of the plasma membrane pinch in to form intracellular vesicles that carry material captured from the external medium into the cell—a process called *endocytosis*; and in the reverse process, called *exocytosis*, vesicles from inside the cell fuse with the plasma membrane and release their contents to the exterior (Figure 1–23).

Besides the nucleus, there are two other eukaryotic cell organelles that are enclosed in double membranes—*mitochondria* and, in plant cells and algae, *chloroplasts*. Mitochondria take up oxygen and harness energy from the oxidation of food molecules, such as sugars and fats, to produce most of the ATP (adenosine triphosphate) that powers the cell's activities. *Chloroplasts* perform photosynthesis in plant cells and algae, using the energy of sunlight to synthesize carbohydrates from atmospheric CO₂ and water, delivering these energy-rich products to the host cell as food. In many eukaryotic cells, roughly half of the cytoplasm is occupied by membrane-enclosed organelles. The surrounding fluid is called the *cytosol*. It contains *ribosomes*, which translate RNAs into proteins, and it is also where most of the cell's other metabolic reactions take place.

In addition to the membrane-enclosed organelles just described, eukaryotic cells contain a variety of smaller organelles that lack membranes. Instead,

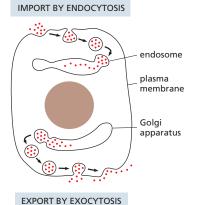

Figure 1–23 Endocytosis and exocytosis across the plasma membrane. Eukaryotic cells import extracellular materials by endocytosis and secrete intracellular materials by exocytosis. The endocytosed material is first delivered to singlemembrane-enclosed organelles called endosomes, discussed in Chapter 12.

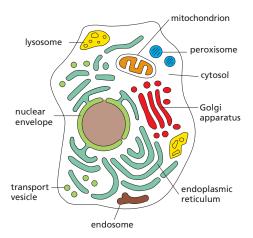

Figure 1–24 Membrane-enclosed organelles are distributed throughout the eukaryotic cell cytoplasm. The membrane-enclosed organelles, shown in different colors, are each specialized to perform a different function. The cytoplasm that fills the space outside of these organelles is called the cytosol.

multiple components that work together are held in close proximity in **bio-molecular condensates**, which will be described in Chapters 3, 6, and 12. An example is the nucleolus, where ribosome assembly takes place (see Figure 1–21). **Figure 1–24** summarizes the membrane-enclosed organelles in eukaryotic cells, each of which will be discussed in detail in later chapters.

Mitochondria Evolved from a Symbiotic Bacterium Captured by an Ancient Archaeon

A fundamental question in both evolution and cell biology is how did the first eukaryotic cell arise? The evidence suggests that it happened when an archaeal and a bacterial cell merged about 2 billion years ago, in a world that had contained only prokaryotes for more than 1.5 billion years.

All eukaryotic cells contain (or at one time did contain) mitochondria (Figure 1-25). Mitochondria are similar in size to small bacteria, and both reproduce by dividing. The mitochondria contain their own DNA, with genes that resemble bacterial genes; they also contain their own ribosomes and translation factors that resemble those in bacteria. These and other similarities between mitochondria and present-day bacteria provide strong evidence that mitochondria evolved from an aerobic bacterium (one that harvested energy by combining electrons derived from foodstuffs with oxygen gas) that was captured

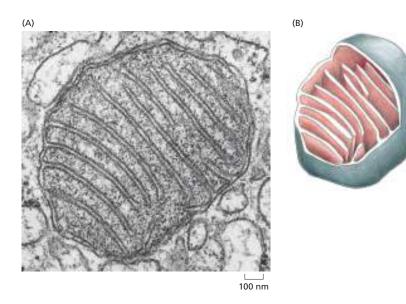

Figure 1–25 A mitochondrion. (A) An electron micrograph of the organelle seen in cross section. (B) A drawing of a mitochondrion with part of it cut away to show the three-dimensional structure (Movie 1.2). Note the smooth outer membrane and the convoluted inner membrane, which houses the proteins that generate ATP from the oxidation of food molecules. (A, courtesy of Daniel S. Friend and by permission of E.L. Bearer.)

MBOC7_ptr_ch01_001-048.indd 25 02/12/21 12:53 PM

Figure 1–26 A scanning electron micrograph of an Asgard archaeon in culture. This anaerobic cell proliferates very slowly, doubling only about every 20 days (compared to every half hour or so for the bacterium *E. coli*). It can be seen to extend elaborate membranous protrusions from its surface—including "blebs" and unique branched and unbranched structures. These protrusions are intimately associated with two other species—one bacterial, one archaeal—that were isolated with the Asgard strain as ectosymbionts, as indicated. The scientists had maintained the deep marine sediment under anaerobic conditions in a bioreactor for more than 2000 days, mimicking conditions of the seabed, and they attempted to culture samples from this bioreactor under a range of different conditions. Only after many years and repeated subculturing were they able to isolate this archaeon with its ectosymbionts. (From H. Imachi et al., *Nature* 577:519–525, 2020.)

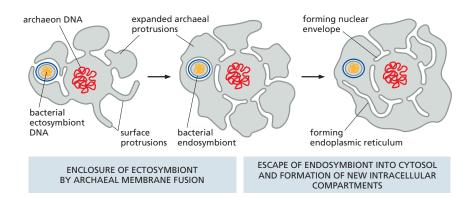

by an anaerobic cell. These two cells (and their descendants) were then able to evolve an endosymbiotic relationship, providing mutual metabolic support within a common cytoplasm.

There are also good reasons to believe that the ancestral capturing cell was an archaeon. As we have seen, the genomes of present-day archaea encode many proteins that are characteristic of present-day eukaryotic cells. Those archaea with the most eukaryotic-like genes belong to the Asgard lineage, first identified by sequencing DNA fragments obtained from the seabed. But no living example had been seen or cultivated—until very recently, when, after a heroic 12-year-long isolation procedure, the first Asgard archaeon was propagated in culture. This remarkable, living, anaerobic archaeon looked like no other prokaryote—having long branching protrusions—and it seemed to live in an ectosymbiotic relationship with another bacterium and another archaeon, both of which were isolated with it (Figure 1–26). The discovery of the strange Asgard archaeon provides a glimpse of how an ancient archaeon might eventually have captured an aerobic bacterium to initiate the eukaryotic lineage, with a hypothetical pathway being illustrated in Figure 1–27 and discussed in detail in Chapter 12.

Chloroplasts Evolved from a Symbiotic Photosynthetic Bacterium Engulfed by an Ancient Eukaryotic Cell

Chloroplasts (Figure 1–28) perform photosynthesis in plant cells and algae, using the energy of sunlight to synthesize their own "food" (in the form of carbohydrates) from atmospheric CO_2 and water. Like mitochondria, they are enclosed in double membranes, have their own "circular" genomes, and reproduce by dividing. They almost certainly evolved from a symbiotic photosynthetic bacterium that was captured by an ancient eukaryotic cell that already possessed mitochondria. This bacterium may have been captured by phagocytosis, a frequent process in eukaryotes (see Figure 1–22).

Whereas some single-cell eukaryotes are hunters that live by capturing other cells and eating them (see Figure 1–34), a eukaryotic cell equipped with chloroplasts has no need to chase after other cells as prey; it is nourished by the captive chloroplasts it has inherited from its ancient eukaryotic ancestors. Correspondingly, plant cells, although they possess the cytoskeletal equipment for movement, have lost the ability to change shape rapidly and to engulf other cells

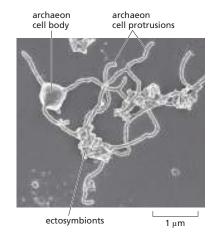

Figure 1-27 A possible model for some early steps in eukaryotic cell evolution. In this model, the surface protrusions of an ancient Asgard archaeon expanded and surrounded an ectosymbiotic aerobic bacterium to create a symbiotic relationship between the two types of cells. Eventually, the protrusions fused with one another. trapping the bacterium as an endosymbiont in the archaeon cytoplasm, where it was initially enclosed by an internal membrane derived from the archaeon's plasma membrane (the bacterium itself retaining its own membranes). At some point, the endosymbiont escaped from the enclosing archaeon-derived membrane and entered the cytosol, where it eventually evolved into a mitochondrion-with both its DNA and membranes derived from the engulfed bacterium. As shown, it is postulated that the internal archaeon membranes generated by this mechanism of protrusion expansion and fusion progressively formed both the nucleus and single-membraneenclosed organelles, such as the endoplasmic reticulum. The evidence for this general type of model of eukaryoticcell evolution is discussed further in Chapter 12. (Adapted from H. Imachi et al., Nature 577:519-525, 2020, and from D.A. Baum and B. Baum, BMC Biol. 12:76-92, 2014.)

by phagocytosis. Instead, they wrap themselves in a tough, protective cell wall. If some eukaryotic cells can be viewed as hunters, then one might view plant cells as having given up hunting for farming.

Fungi represent yet another eukaryotic way of life. Fungal cells, like animal cells, possess mitochondria but not chloroplasts; they have a tough outer wall that limits their ability to move rapidly or to take up other cells. Fungi, it seems, have turned from hunters into scavengers. Other cells secrete nutrient molecules or release them after death, and fungi feed on these leavings—often performing whatever digestion is necessary extracellularly, by secreting digestive enzymes to the exterior.

Eukaryotes Have Hybrid Genomes

As just discussed, the genetic information of eukaryotic cells has a hybrid origin—from an ancestral anaerobic archaeon and from the bacteria it adopted as endosymbionts (Figure 1–29). Most of this genetic information (DNA) is stored in the nucleus, although a small amount remains inside the organelles that evolved

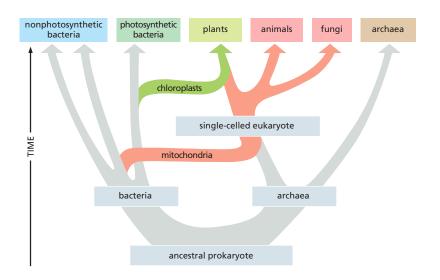

Figure 1-29 A model for the evolution of eukaryotic cells in the tree of life. All living cells are thought to have evolved from an ancestral prokaryotic cell (the last universal common ancestor) between 3.5 and 3.8 billion years ago). Many millions of years later, it seems an anaerobic archaeon acquired an aerobic bacterial symbiont, which evolved into mitochondria (see Figure 1-27). Later still, a mitochondria-containing eukaryotic cell acquired a photosynthetic bacterium, which evolved into chloroplasts. Mitochondria are essentially the same in plants, animals, and fungi, indicating that they were acquired before these three lineages diverged about 1.5 billion years ago.

MBOC7_ptr_ch01_001-048.indd 27 02/12/21 12:53 PM

from the captured bacteria—the mitochondria and, in plant and algal cells, the chloroplasts. When the mitochondrial DNA and the chloroplast DNA are separated from the nuclear DNA and individually sequenced, both the mitochondrial and chloroplast genomes are found to be cut-down versions of the corresponding bacterial genomes: in a human cell, for example, the mitochondrial genome consists of only 16,569 nucleotide pairs, and it codes for only 13 proteins plus a set of 24 RNAs involved in protein synthesis.

Many of the genes that are missing from the mitochondria and chloroplasts have not been lost; instead, they have moved from the endosymbiont genomes into the DNA of the host-cell nucleus. Thus the nuclear DNA of animals contains many genes coding for proteins that serve essential functions inside the mitochondria; in plants and algae, the nuclear DNA contains many genes specifying proteins required in chloroplasts. In both cases, the DNA sequences of these nuclear genes still show clear evidence of their bacterial origins.

Eukaryotic Genomes Are Big

Natural selection has evidently favored mitochondria with small genomes. By contrast, the nuclear genomes of most eukaryotes seem to have been free to enlarge. Perhaps the eukaryotic way of life has made large size an advantage: predatory cells, for example, typically need to be bigger than their prey, and cell size generally increases in proportion to genome size. Whatever the reason, the genomes of most eukaryotes have become hundreds of times larger than those of bacteria and archaea (Figure 1–30).

The freedom to be extravagant with DNA has had profound implications. Eukaryotes not only have more genes than prokaryotes; they also have vastly more DNA that does not code for protein or RNA. The human genome contains about 700 times as many nucleotide pairs as the genome of a typical bacterium such as $E.\ coli$, but it contains only about 4.5 times as many protein-coding genes because a much greater proportion of the human genome does not code for protein (\sim 98.5% compared to 11% in $E.\ coli$). The estimated genome sizes and gene numbers for a few selected eukaryotes are compared with the bacterium $E.\ coli$ in Table 1–2; we will discuss shortly how each of these organisms serves as a model organism.

Eukaryotic Genomes Are Rich in Regulatory DNA

As discussed in Chapter 4, much of our nonprotein-coding DNA is almost certainly dispensable "junk," retained during evolution like a mass of old papers because, when there is little pressure to keep an archive small, it is easier to retain

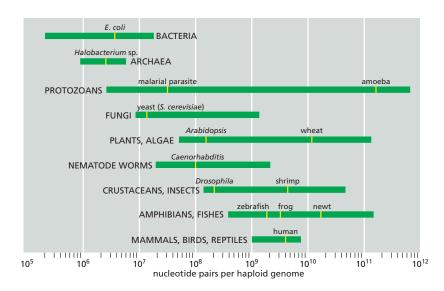

Figure 1-30 Genome sizes compared. Genome size is measured in nucleotide (base) pairs of DNA per haploid genome, that is, per single copy of the genome. (The body cells of sexually reproducing, multicellular organisms such as ourselves are generally diploid: they contain two copies of the genome, one inherited from the mother, the other from the father.) Note that closely related organisms can vary widely in the quantity of DNA in their genomes (as indicated by the length of the green bars), even though they contain similar numbers of protein-coding genes. (Data from T.R. Gregory, 2021, Animal Genome Size Database: www.genomesize

TABLE 1-2 Some Model Organisms and Their Genomes			
Organism	Approximate genome size* (nucleotide pairs)	Approximate number of protein-coding genes**	
Escherichia coli (bacterium)	4.6×10^{6}	4300	
Saccharomyces cerevisiae (yeast)	12.5×10^{6}	6600	
Caenorhabditis elegans (roundworm)	100 × 10 ⁶	20,000	
Arabidopsis thaliana (plant)	135 × 10 ⁶	27,000	
Drosophila melanogaster (fruit fly)	180 × 10 ⁶	14,000	
Danio rerio (zebrafish)	1400 × 10 ⁶	26,000	
Mus musculus (mouse)	2800 × 10 ⁶	20,000	
Homo sapiens (human)	3100 × 10 ⁶	20,000	

^{*}Genome size includes an estimate for the amount of highly repeated, noncoding DNA sequence, which does not appear in genome databases.

everything than to sort out the valuable information and discard the rest. Certain exceptional eukaryotic species, such as the puffer fish, bear witness to the profligacy of their relatives; they have somehow managed to rid themselves of large quantities of nonprotein-coding DNA, and, yet, they appear similar in structure, behavior, and fitness to related species that have vastly more such DNA.

Even in compact eukaryotic genomes such as that of the puffer fish, there is more nonprotein-coding DNA than protein-coding DNA. As in all eukaryotic organisms, at least some of the noncoding DNA certainly has important functions. In particular, it regulates the expression of genes. With this *regulatory DNA*, eukaryotes have evolved distinctive, highly sophisticated ways of controlling when and where a gene is brought into play. Elaborate mechanisms for gene regulation are especially crucial for the formation and function of complex multicellular organisms, which have many different cell types, each with different functions, as we now discuss.

Eukaryotic Genomes Define the Program of Multicellular Development

The cells in an individual animal or plant are extraordinarily varied. Blood cells, skin cells, bone cells, nerve cells—they seem as dissimilar as any cells could be (Figure 1–31). Yet all these cell types are the descendants of a single fertilized egg cell, and all (with very minor exceptions) contain identical copies of the genome of the species.

The differences result from the way in which the cells make selective use of their genetic instructions according to their developmental history and the cues they receive from their surroundings in a developing embryo. The DNA is not just a shopping list specifying the molecules that every cell must have, and the cell is not an assembly of all the items on the list. Rather, the cell behaves as a multipurpose machine, with sensors to receive environmental signals and with highly developed abilities to call different sets of genes into action according to signals it receives. The genome in each cell is big enough to accommodate the information that specifies an entire multicellular organism, but in any individual cell only part of that information is used.

Many genes in the eukaryotic genome code for proteins that regulate the activities of other genes, a topic discussed in detail in Chapter 7. Most of these regulatory genes encode *transcription regulators* that act by binding, directly or

Figure 1–31 Cell types can vary enormously in size and shape. A human nerve cell is compared here with a human neutrophil, a type of white blood cell. Both are drawn to scale.

MBOC7_ptr_ch01_001-048.indd 29 02/12/21 12:53 PM

^{**}There are also genes that code for functional RNA molecules that do not code for proteins.

Figure 1–32 Genetic control of the program of multicellular development. The role of a regulatory gene is demonstrated in the snapdragon Antirrhinum. In this example, a mutation in a single gene coding for a regulatory protein causes leafy shoots to develop in place of flowers: because the regulator protein has been changed, the cells adopt characters that would be appropriate to a different location in the normal plant. The mutant is on the left, the normal plant on the right. (Courtesy of Enrico Coen and Rosemary Carpenter.)

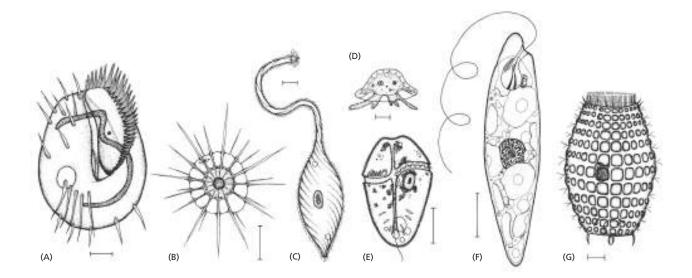

indirectly, to the many different DNA sequences that control which genes are to be expressed, and at what levels. Eukaryotic genomes also produce many noncoding RNA molecules; as the name implies, they are not translated into protein but control gene expression in a variety of ways. The expanded genome of eukaryotes therefore not only specifies the hardware of the cell but also stores the software that controls how that hardware is used (Figure 1–32).

Cells do not just passively receive signals; rather, they actively exchange signals with their neighbors. Thus, in a developing multicellular organism, an internal control system governs each cell that has different consequences depending on the messages exchanged. The outcome, astonishingly, is a precisely patterned array of cells of different types, each displaying a character appropriate to its position in the multicellular structure.

Many Eukaryotes Live as Solitary Cells

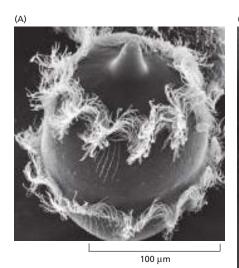

Many species of eukaryotic cells lead a solitary life. As we have seen, some of these single-cell organisms are hunters, some are photosynthesizers, still others are scavengers. Figure 1–33 conveys something of the astonishing variety of single-cell eukaryotes, whose anatomy can be remarkably elaborate, including

Figure 1–33 An assortment of single-cell eukaryotes. The drawings are done to different scales, but in each case the scale bar represents 10 μm . The organisms in (A), (C), and (G) are ciliates; (B) is a heliozoan; (D) is an amoeba; (E) is a dinoflagellate; and (F) is a euglenoid. MODEL ORGANISMS 31

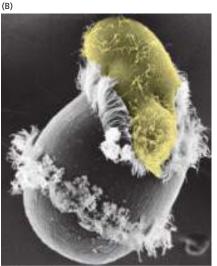

Figure 1-34 A single-cell eukaryote that eats other cells. (A) Didinium is a carnivorous protist, belonging to the group of ciliates. (A protist is defined as a free-living, single-cell, mobile eukaryote.) Didinium has a globular body, about 150 μm in diameter, encircled by two fringes of cilia-sinuous, whiplike appendages that beat continually; its front end is flattened except for a single protrusion, rather like a snout. (B) A Didinium engulfing its prey. It normally swims around in the water at high speed by means of the synchronous beating of its cilia. When it encounters a suitable prey, usually another type of protist, it releases numerous small paralyzing darts from its snout region. Then, it attaches to and devours its prey (artificially colored yellow) by phagocytosis, inverting like a hollow ball to engulf its victim, which can be almost as large as itself. (Courtesy of D. Barlow.)

such structures as sensory bristles, photoreceptors, sinuously beating cilia, leglike appendages, mouth parts, stinging darts, and muscle-like contractile bundles. Although they are single cells, they can be as intricate, as versatile, and as complex in their behavior as many multicellular organisms (Figure 1–34, Movie 1.4, and Movie 1.5).

Humans tend to focus on plants and animals, while neglecting single-cell eukaryotes because (along with bacteria and archaea) they are microscopic. But thanks to DNA comparisons, we now know that the genomes of single-cell eukaryotes are far more evolutionarily diverse than those of multicellular animals and plants, meaning that animals and plants arose relatively late in the complex and fascinating eukaryotic pedigree. With genome data, we can position the many different single-celled eukaryotes in the tree of life and identify our closest relatives (Figure 1–35). Scientists are using this information to probe the origins of multicellularity, with a focus on what these strange creatures can tell us about our own evolutionary past.

Summary

Eukaryotic cells, by definition, keep most of their DNA in a separate membrane-enclosed compartment—the nucleus. They have, in addition, an elaborate set of other organelles, each carrying out different functions, such as the oxidation of food-derived molecules and production of ATP in mitochondria. Eukaryotic cells also contain a cytoskeleton for structural support and movements. There is compelling evidence that mitochondria and, in plants and algae, chloroplasts evolved from captured symbiotic bacteria, which explains why these organelles contain their own DNA and ribosomes.

Eukaryotic cells typically have 3–8 times as many protein-coding genes as bacteria and archaea and often a thousand times more noncoding DNA. Although much of this DNA is probably unimportant, some of it allows for great complexity in the regulation of gene expression, as required for the construction of complex multicellular organisms containing many different cell types.

MODEL ORGANISMS

Because all cells appear to have descended from a common ancestor, whose fundamental properties have been conserved through evolution, the knowledge gained from the study of one organism contributes to our understanding of all others, including ourselves. It turns out that certain organisms are much more accessible than others for study in the laboratory. Some reproduce rapidly and

MBOC7_ptr_ch01_001-048.indd 31 02/12/21 12:53 PM

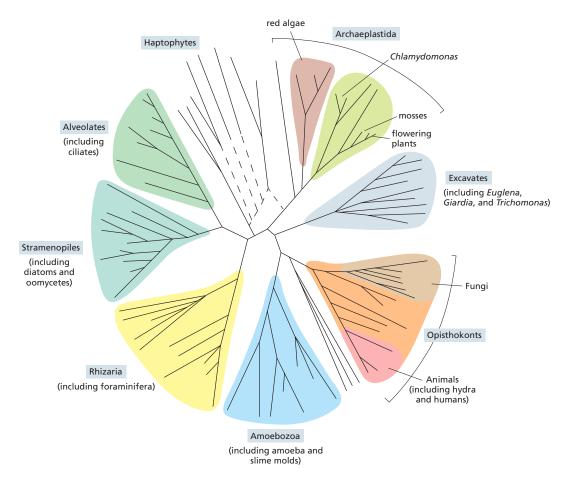

Figure 1–35 A eukaryotic tree of life based on genome comparisons. The lengths of the lines are proportional to the extents of genome diversity, with broken lines indicating uncertain relationships. Note that animals and plants are separated by many single-cell species (including the Excavates), suggesting that multicellularity arose independently several times during eukaryotic evolution. (Adapted from F. Burki, Cold Spring Harb. Perspect. Biol. 6:a016147, 2014.)

are easily manipulated using powerful genetic techniques. Others are transparent and readily develop in the laboratory from a fertilized egg to a multicellular organism, so that one can readily trace how their cells behave to produce internal tissues and organs.

Over time, different groups of biologists have focused on studying a few chosen species, which allows their knowledge and research tools to be pooled to gain a deeper understanding than could be achieved if their efforts were spread over many different organisms. Although the list of these representative, model organisms is continually expanding, a few stand out in terms of the breadth and depth of information that has been accumulated about them over the years—knowledge that has been essential for our understanding of how all cells work. In this section, we examine some of these organisms and review the benefits that each offers to the study of cell biology and, in many cases, to the promotion of human health. We begin with a discussion of some especially powerful strategies that scientists have developed to understand the cell, and we shall see how these approaches dictated the choice of model organisms.

Mutations Reveal the Functions of Genes

Without additional information, no amount of gazing at genome sequences will reveal the functions of genes. We may recognize that gene B is like gene A, but how do we discover the function of gene A in the first place? And even if we know

MBOC7_ptr_ch01_001-048.indd 32 02/12/21 12:53 PM

MODEL ORGANISMS 33

the function of gene A, how do we test whether the function of gene B is truly the same as the sequence similarity suggests? How do we connect the world of abstract genetic information that was introduced in the previous sections with the world of living cells and organisms?

The analysis of gene functions depends on two highly complementary approaches: biochemistry and genetics. Biochemistry directly examines the functions of purified molecules, such as the protein and RNA produced from a specific gene: first we obtain that molecule from an organism and then study its chemical activities in detail. In contrast, genetics starts with the study of mutants: we either find or make an organism in which the specific gene is altered, and we then examine the effects on the mutant organism's structure and performance (Figure 1–36). When combined with biochemistry, careful studies of an organism (and its isolated cells) mutated for a particular protein or RNA molecule can reveal the biological role of that molecule.

Biochemistry and genetics, used in combination with cell biology, provide a powerful way to connect genes and molecules directly to cell and organism structure and function. In recent years, DNA sequence information and the powerful tools of molecular biology have greatly accelerated progress in this endeavor. From sequence comparisons, we can often identify particular subregions within a gene that have been conserved nearly unchanged over the course of evolution. These subregions are often the most important parts of the gene in terms of function. We can test their individual contributions to the gene's function by creating in the laboratory mutations of specific sites within the subregion or by constructing artificial hybrid genes that combine part of one gene with parts of another. Organisms can be engineered to make either the RNA or protein specified by the gene in large quantities to facilitate biochemical analysis. Specialists in molecular structure can determine the three-dimensional conformation of the gene product, revealing the exact position of every atom in it. Biochemists can determine how each of the parts of the genetically specified molecule contributes to its chemical behavior and function in a test tube. Cell biologists determine the many other molecules that interact with the molecule of interest and where all these molecules are located within a cell. And they also analyze the behavior of cells that are engineered to express a mutant version of the gene.

There is, however, no one simple universal recipe for discovering a gene's function. We may discover, for example, that the product of a given gene is an enzyme that catalyzes a certain chemical reaction, and yet have no idea how or why that reaction is important to the organism. The functional characterization of each new gene product or family of gene products, unlike the description of the gene sequences, presents a fresh challenge to the biologist's ingenuity. Moreover, we will never fully understand the function of a gene until we learn its role in the life of the organism, which means studying whole organisms, not just isolated molecules or cells.

Molecular Biology Began with a Spotlight on One Bacterium and Its Viruses

Because living organisms are so complex, the more we learn about any particular species, the more attractive it becomes as an object for further study. Each discovery in such a chosen organism raises new questions and provides new tools with which to tackle general biological questions. For this reason, large communities of biologists have become dedicated to studying different aspects of the same **model organism**.

In the early days of molecular biology, the chosen model was the bacterium *Escherichia coli* (*E. coli*—see Figure 1–11B). This small, rod-shaped cell normally lives in the gut of humans and other vertebrates, but it can be grown easily in a simple nutrient broth in a culture bottle or dish, where under favorable conditions, it can reproduce every 20 minutes or so. It adapts to variable chemical conditions and can evolve by mutation and selection at a remarkable speed.

5μm

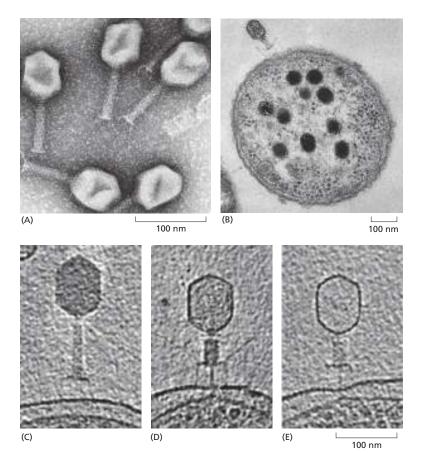

Figure 1-36 An alteration in organism shape resulting from a gene mutation. Scanning electron micrographs (discussed in Chapter 9) of a normal yeast (of the species Schizosaccharomyces pombe) compared with a mutant yeast, where a change in a single gene has converted the cell from a cigar shape (left) to a T shape (right). The mutant gene therefore has a function controlling cell shape. But how, in molecular terms, does the gene product perform that function? That is a harder question, and it needs biochemical analysis to answer it. (Courtesy of Kenneth Sawin and Paul Nurse.)

MBOC7_ptr_ch01_001-048.indd 33 02/12/21 12:53 PM

Also of special early interest were a few of the viruses that infect this bacterium—inasmuch as their much smaller genomes made them even easier to analyze in detail.

Viruses are small packets of genetic material that have evolved as parasites that depend on the reproductive and biosynthetic machinery of the host cells they infect. Viruses are not strictly alive, because they depend on the machinery of their host cells for their reproduction. Although we now know that viruses are the most abundant—in terms of sheer numbers—of all the biological entities on this planet, they are too small to be seen in the light microscope. For this reason, they were completely missed until the end of the nineteenth century, when a few viruses were identified as infectious agents that pass through filters that trap bacteria, but are retained by the even-finer filters that allow large molecules to pass. Only with the invention of the electron microscope could viruses finally be visualized as tiny particles with defined shapes and sizes. We now know that viruses consist of many families, with different families having distinct structures and modes of replication (discussed in Chapters 6 and 23).

Those viruses that infect bacteria are called *bacteriophages*, and two that infect *E. coli* have played critical roles as model organisms that advanced our understanding of molecular cell biology. Detailed genetic analyses of these two viruses, bacteriophage lambda and bacteriophage T4, came first, followed by biochemistry that used the analysis of mutant genes to identify and characterize specific proteins of interest. Geneticists, for example, generated and then characterized more than a hundred different mutant genes in bacteriophage T4, a large virus with a double-strand DNA genome (**Figure 1–37**). Sets of T4 genes that encode components of the head and the tail of the bacteriophage were identified, allowing biochemical studies to reveal important principles of biological assembly processes. Similarly, a set of T4 genes that geneticists showed were essential for T4

(A) An electron micrograph of particles of the T4 bacteriophage, a virus that infects E. coli bacteria. The hexagonal head of the virus contains the viral DNA; the tail contains the apparatus for injecting the DNA into a host bacterium. (B) A cross section of an E. coli bacterium with a T4 bacteriophage attached to its surface. The large dark objects inside the bacterium are the assembling heads of new T4 particles. When the particles are mature, the bacterium will burst open and release them. (C-E) The process of DNA injection into the bacterium, as visualized in unstained, frozen samples by cryo-electron microscopy (discussed in Chapter 9). (C) Attachment begins. (D) Attached state during DNA injection. (E) Virus head has emptied its entire DNA into the bacterium. (A, courtesy of James Paulson; B, courtesy of Jonathan King and Erika Hartwig from G. Karp, Cell and Molecular Biology, 2nd ed. New York: John Wiley & Sons,

MODEL ORGANISMS 35

DNA replication allowed those proteins to be purified, so that biochemists could decipher the central mechanisms of DNA replication in a test tube. In the same way, it was extensive studies of bacteriophage lambda that led to our early understanding of transcription regulators and gene regulatory networks (see Panel 7–1 on pp. 404–405 and Figure 7–43).

We now know that these two bacteriophages have many close relatives distributed throughout the biosphere. Relatives of bacteriophage T4, for example, are abundant in the ocean, where they infect the ubiquitous marine cyanobacteria. As a whole, ocean viruses are present in enormous numbers, estimated at 10³⁰. If lined up end to end, they would extend beyond our nearest galaxies; they kill approximately 20% of the total ocean microbial biomass per day. Because these viruses have such a huge role in nutrient recycling, they profoundly affect Earth's ecology.

Although not themselves living cells, viruses often serve as vectors for gene transfer between cells. A virus will replicate in one cell, emerge from it with a protective wrapping, and then enter and infect another cell, which may be of the same or different species. Often, the infected host cell is killed by the massive proliferation of virus particles inside it, but sometimes the viral DNA, instead of directly generating new virus particles, may persist in its host for many cell generations as a relatively innocuous passenger—either as a separate intracellular fragment of DNA, known as a *plasmid*, or as a DNA sequence inserted into the cell's own genome. In their travels, viruses can accidentally pick up fragments of DNA from the genome of one host cell and ferry them into another cell. Such transfers of genetic material are very common in prokaryotes.

Many bacterial and archaeal species have a remarkable capacity to take up even nonviral DNA molecules from their surroundings and thereby capture the genetic information these molecules carry. By this route or by virus-mediated gene transfer, bacteria and archaea in the wild can acquire genes from neighboring cells relatively easily. Genes that confer resistance to an antibiotic or an ability to produce a toxin, for example, can be transferred from species to species and provide the recipient bacterium with a selective advantage, greatly enhancing its rate of spread. In this way, new and sometimes dangerous strains of antibiotic-resistant bacteria have been observed to evolve in the bacterial ecosystems that inhabit hospitals or various niches in the human body. On a longer time scale, the results can be even more profound; it has been estimated that at least 18% of all the genes in the present-day genome of *E. coli* have been acquired by horizontal transfer from another species within the past 100 million years.

The Focus on *E. coli* as a Model Organism Has Accelerated Many Subsequent Discoveries

The standard laboratory strain *E. coli* K-12 has a genome of approximately 4.6 million nucleotide pairs contained in a single circular molecule of DNA that codes for about 4300 different kinds of proteins (**Figure 1–38**). In molecular terms, we probably have a more complete understanding of *E. coli* than of any other living organism. Most of our understanding of the fundamental mechanisms of life—for example, how cells replicate their DNA or how they decode the instructions represented in the DNA to direct the synthesis of specific RNAs and proteins—initially came from studies of *E. coli* and its viruses. This is because the basic genetic mechanisms have turned out to be highly conserved throughout evolution and are essentially the same in our own cells as in *E. coli*.

It should be noted that, as with other bacteria, different strains of *E. coli*, though classified as members of a single species, differ genetically to a much greater degree than do different varieties of an organism such as a plant or animal. One *E. coli* strain may possess many hundreds of genes that are absent from another, and the two strains could have as little as 50% of their genes in common. These differences are largely the result of rampant horizontal gene transfer, characteristic of this and many other bacterial and archaeal species.

MBOC7_ptr_ch01_001-048.indd 35 02/12/21 12:53 PM

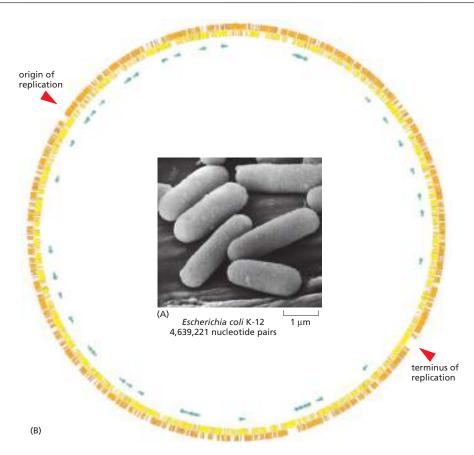

Figure 1–38 The genome of *E. coli*. (A) A cluster of *E. coli* cells viewed in a scanning electron microscope. (B) A diagram of the genome of *E. coli* strain K-12. The diagram is circular because the DNA of *E. coli*, like that of most other bacteria, forms a single, closed loop. Protein-coding genes are shown as *yellow* or *orange bars*, depending on the DNA strand from which they are transcribed; RNA molecules produced from nonprotein-coding genes are indicated by *green arrows*, with the arrowheads indicating their direction of transcription. Some genes are transcribed from one strand of the DNA double helix (in a clockwise direction in this diagram), others from the other strand (counterclockwise). The origin and terminus of DNA replication are marked with *red arrowheads*. (A, Dr. Tony Brain & David Parker/Science Source; B, adapted from F.R. Blattner et al., *Science* 277:1453–1462, 1997.)

A Yeast Serves as a Minimal Model Eukaryote

The molecular and genetic complexity of eukaryotes is daunting, and biologists need to concentrate their limited resources on a small number of selected model organisms to unravel this complexity.

To analyze the internal workings of the eukaryotic cell without the additional problems of multicellular development, it makes sense to use a single-cell species that is as simple as possible. The popular choice for this role of minimal model eukaryote has been the yeast *Saccharomyces cerevisiae* (Figure 1–39)—the same species that is used by brewers of beer and bakers of bread.

S. cerevisiae is a small, single-cell member of the kingdom of fungi and, in terms of its genome sequence, much more closely related to animals than to plants (see Figure 1–35). It is robust and easy to grow in a simple nutrient medium. Like other fungi, it has a tough cell wall, is relatively immobile, and possesses mitochondria but not chloroplasts. When nutrients are plentiful, it grows and divides about every hundred minutes. It can reproduce either vegetatively (that is, by ordinary cell division, or mitosis), or sexually: two yeast cells that are *haploid* (possessing a single copy of each chromosome, n=1) can fuse to create a cell that is *diploid* (containing two copies of each chromosome, n=1), and the diploid cell can undergo *meiosis* (a reduction division) to produce cells that are once again

MODEL ORGANISMS 37

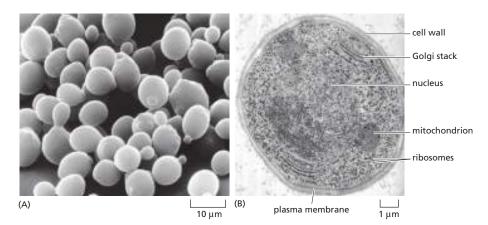

Figure 1–39 The yeast Saccharomyces cerevisiae. (A) A scanning electron micrograph of a cluster of yeast cells. This species is also known as budding yeast, because it proliferates by forming a protrusion, or bud, that enlarges and then separates from the mother cell. Many cells with buds are visible in this micrograph. (B) An electron micrograph of a cross section of a yeast cell, showing its plasma membrane and thick cell wall, as well as some of its intracellular organelles. (A, courtesy of Ira Herskowitz and Eric Schabtach; B, courtesy of Andrew Staehelin.)

haploid (Figure 1–40). In contrast to most animals, this yeast can therefore proliferate either sexually or asexually, a choice that an experimenter can make simply by changing the growth conditions.

In addition to these features, the yeast has a further property that makes it a convenient organism for genetic studies: its genome, by eukaryotic standards, is exceptionally small (see Table 1-2), yet it suffices for all the basic tasks that every eukaryotic cell must perform. Mutants are available for every gene, and thus the consequence of missing each gene—one by one—can be observed under any environmental condition using the high-throughput procedures described in Chapter 8. Over the past 50 years, extensive studies of yeast cells carried out by many laboratories have provided keys to crucial "eukaryotic-only" processes. These include the cell-division cycle (the critical chain of events by which the nucleus and all the other components of a cell are duplicated and parceled out to create two daughter cells from one) and meiosis (the process through which an organism's reproductive cells are formed). In addition, important insights into eukaryotic chromosome structure, the organization of the nucleus, the mechanisms of gene expression, the formation of organelles, and the ways that proteins are secreted from cells have come out of the work on yeasts. Many of these fundamental processes are so similar between yeasts and humans that a human homolog of a yeast protein will often faithfully carry out its functions when artificially expressed in yeast cells.

The Expression Levels of All the Genes of an Organism Can Be Determined

The complete genome sequence of *S. cerevisiae* consists of approximately 12,500,000 nucleotide pairs, including the small contribution (about 78,500 nucleotide pairs) of the mitochondrial DNA. This total is only about 2.7 times as much DNA as there is in *E. coli*, and it codes for only about 1.5 times as many distinct proteins (see Table 1–2). The way of life of *S. cerevisiae* is similar in many ways to that of a bacterium, and it seems that this yeast has likewise been subject to selection pressures (for rapid proliferation, for example) that have kept its genome compact.

Knowledge of the complete genome sequence of any organism—be it a yeast or a human—opens up new perspectives on the workings of the cell: many things that once seemed impossibly complex now seem to be within our grasp. Using techniques described in Chapter 8, it is possible, for example, to monitor simultaneously, the amount of mRNA produced from every gene in the yeast genome under any environmental condition. It is also possible to determine in real time

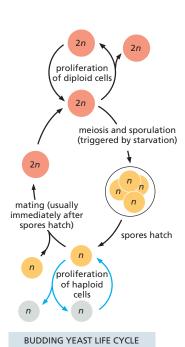

Figure 1-40 The reproductive cycles of the yeast S. cerevisiae. Depending on environmental conditions and on details of the genotype, cells of this species can exist in either a diploid (2n) state, with a double chromosome set, or a haploid (n) state, with a single chromosome set. The diploid form can either proliferate by ordinary celldivision cycles (mitosis) or undergo meiosis to produce haploid cells. The haploid form can either proliferate by ordinary cell-division cycles or undergo sexual fusion with another haploid cell to become diploid. Meiosis is triggered by starvation, and it gives rise to spores - haploid cells in a dormant state, resistant to harsh environmental conditions.

MBOC7_ptr_ch01_001-048.indd 37 02/12/21 12:53 PM

how the pattern of gene activity changes when conditions change. This type of analysis can be repeated with mRNA prepared from mutant cells lacking any gene we care to test, and, in this way, the influence of that gene on the expression of all other genes can be observed. Although pioneered in yeast, this approach now provides a way to reveal the entire system of controls that govern gene expression in any organism, as long as its genome sequence is known and it can be manipulated genetically.

Arabidopsis Has Been Chosen as a Model Plant

The large multicellular organisms that we see around us—the plants and animals—seem fantastically varied, but, as we have seen, they are much closer to one another in their evolutionary origins, and more similar in their basic cell biology, than the great host of microscopic single-celled organisms we have been discussing. Thus, while bacteria and archaea are separated by perhaps 3.5 billion years of evolution, vertebrates and insects are separated by about 700 million years, fish and mammals by about 450 million years, and the different species of flowering plants by only about 150 million years (see Figure 1–35).

Because of the close evolutionary relationship between all flowering plants (see Figure 1–35), we can, once again, gain insight into the cell and molecular biology of this whole class of organisms by focusing on just one or a few species for detailed analysis. Out of the nearly 400,000 known species of flowering plants, molecular biologists have chosen to concentrate their efforts on a small weed in the cabbage family, the common wall cress *Arabidopsis thaliana* (Figure 1–41), which can be grown indoors in large numbers and produces thousands of offspring per plant after 8–10 weeks. *Arabidopsis* has a total genome size of approximately 135 million nucleotide pairs, about 10 times the size of the yeast genome (see Table 1–2).

Work on *Arabidopsis* has provided a deep understanding of numerous key features of plants, including the mechanisms that cause flower development and its coordination with the seasons, the ability to grow toward sunlight, cell-to-cell signaling by hormones, and the special type of innate immune system that plants use to ward off pathogens. Comparison of the developmental programs between plants and animals has also highlighted some common principles, thereby allowing a glimpse into the basic logic through which large, highly differentiated, multicellular organisms evolved from single-cell ancestors.

The World of Animal Cells Is Mainly Represented by a Worm, a Fly, a Fish, a Mouse, and a Human

Although plants make up 80% of the biomass on Earth and animals make up less than 0.4% (see Figure 1–14), animals account for the majority of all named species of living organisms, and they are by far the most intensely studied. Five species have emerged as the foremost model organisms for molecular, cell, and developmental biological studies. In order of increasing body size, they are the nematode worm *Caenorhabditis elegans*, the fly *Drosophila melanogaster*, the zebrafish *Danio rerio*, the mouse *Mus musculus*, and the human, *Homo sapiens*. Genome sequences from many different individuals within each species have been determined.

Caenorhabditis elegans (Figure 1-42) is a small, harmless relative of the eelworm that attacks crops. With a life cycle of only a few days, an ability to survive in a freezer indefinitely in a state of suspended animation, a simple body

plan, and an unusual life cycle that is well suited for genetic studies, it is an attractive model animal. C. elegans develops with clockwork precision from a fertilized egg cell into an adult worm with exactly 959 body cells (plus a variable number of egg and sperm cells)—an unusual degree of regularity for animal development. We now have a minutely detailed description of the sequence of events by which this development occurs, as the cells divide, move, and change their character according to strict and predictable rules (see Figure 21-42). The genome of about 100 million nucleotide pairs codes for about 20,000 proteins, and many mutants and other tools are available for testing gene functions. Although the worm has a body plan very different from our own, the conservation of biological mechanisms has been sufficient for the worm to be a model for many of the developmental and cell-biological processes that occur in the human body. Thus, for example, studies of the worm have been critical for understanding the molecular mechanisms that mediate and regulate the many cell deaths that help control animal-cell numbers, both in normal development and during human cancer growth. This crucial process, called programmed cell death or apoptosis, is the subject of Chapter 18. In addition, studies in *C. elegans* first revealed many fascinating features of RNA interference (discussed in Chapters 7 and 8). They have also provided key insights into the ways neurons make their proper connections (discussed in Chapter 21) and informed many additional areas of cell biology.

Studies in the Fruit Fly *Drosophila* Provide a Key to Vertebrate Development

The fruit fly *Drosophila melanogaster* (Figure 1–43) has been used as a model for animal genetic studies for longer than any other organism; in fact, the foundations of classical genetics were built to a large extent on studies of this insect. Nearly 100 years ago, for example, the fly provided definitive proof that genes—the abstract units of hereditary information at the time—are carried on chromosomes, whose behavior had been closely followed with the light microscope during eukaryotic cell division but whose function was at first unknown. The proof depended on one of the many features that make *Drosophila* especially convenient for molecular genetic studies—the giant chromosomes, which have a characteristic banded appearance that is visible in some of its cells (Figure 1–44). Specific changes in the hereditary information, manifest in families of mutant flies, were found to correlate exactly with the loss or alteration of specific bands in the giant chromosomes.

In more recent times, *Drosophila*, more than any other organism, has shown us how to trace the chain of cause and effect from the genetic instructions encoded in the chromosomal DNA to the structure of the adult multicellular body. *Drosophila* mutants with body parts strangely misplaced (Figure 1–43) or mispatterned provided the key to the identification and characterization of the genes required to make a properly structured body, with gut, limbs, eyes, and all the other parts in their correct places. Once these *Drosophila* genes were identified, scientists could identify homologous genes in vertebrates, and then test their functions

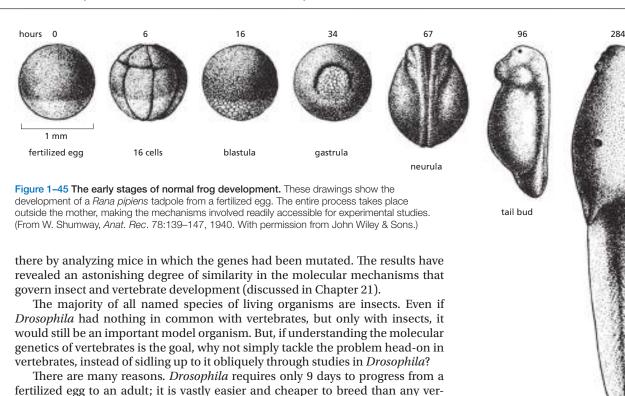

Because many rounds of DNA replication have occurred without an intervening cell division, each of the chromosomes in these unusual cells contains more than 1000 identical double-strand DNA molecules, all aligned in register. This makes them easy to see in the light microscope, where they display a characteristic and reproducible pattern of bands. Specific bands can be identified as the locations of specific genes: a mutant fly with a region of the banding pattern missing or altered shows a phenotype reflecting loss of the genes in that region (not shown). Genes that are being transcribed at a high rate correspond to bands with a "puffed" appearance (black arrow). The bands stained dark brown in the micrograph are sites where a particular regulatory protein is bound to the DNA; the regulatory protein is identified by the binding of a specific antibody. (From R. Paro, Trends Genet. 6:416-421. 1990.

MBOC7_ptr_ch01_001-048.indd 39

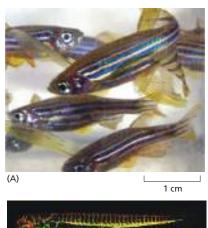

tebrate, and its genome is much smaller—about 180 million nucleotide pairs, compared with about 3.1 billion for a human (see Table 1–2). Its genome codes for about 14,000 proteins, and mutants are now available for essentially any gene. In addition to its foundational contributions to animal development, research on *Drosophila* continues to uncover many other insights into biology, ranging from deeply conserved mechanisms that neutralize pathogens to ways that external stimuli from the environment are processed in the brain.

The Frog and the Zebrafish Provide Highly Accessible Vertebrate Models

Frogs have long been used to study the early steps of embryonic development in vertebrates. Because their eggs are big, easy to manipulate, and fertilized outside of the animal, the subsequent development of the early embryo can be easily followed (Figure 1-45). *Xenopus laevis*, the African clawed frog, continues to be an important model organism (Movie 1.6 and see Movie 21.1). Although the species is poorly suited for genetic analysis, cytoplasm isolated from unfertilized *Xenopus* eggs has the remarkable ability to recapitulate the formation of cellular structures and organelles in a test tube. These *egg extracts* allow powerful biochemical approaches to study such fundamental processes as the cell division cycle, described in Chapter 17.

The zebrafish *Danio rerio*, in contrast, is well suited for genetic analysis. Its genome is compact—only half as big as that of a mouse or a human (see Table 1–2)—and it has a generation time of only about 3 months, which is much

Figure 1–46 Zebrafish as a model for studies of vertebrate development. (A) These small, hardy tropical fish are found in many home aquaria and are convenient for laboratory genetic studies. They are ideal for developmental studies as their embryos develop outside of the mother and are transparent, so one can observe cells and internal structures in the living organism throughout its development from an egg to an adult. (B) In this fluorescence image of a 2-day-old embryo, a red fluorescent protein marks the developing blood vessels, and a green fluorescent protein marks the developing lymphatic vessels; regions where the two markers coincide appear *yellow*. MODEL ORGANISMS 41

shorter than that of *Xenopus laevis*. Many mutants are available, and genetic manipulation is relatively simple. The zebrafish has the added virtue that it is transparent for the first 2 weeks of its life, so behavior of specific tissues and individual cells can easily be followed in the living organism as it develops (**Figure 1-46**; see Movie 21.2). All this has made it an increasingly important model vertebrate, one that has been especially crucial for understanding the development of the heart and the circulatory system, as discussed in Chapter 22.

The Mouse Is the Predominant Mammalian Model Organism

In terms of genome size and function, cell biology, and molecular mechanisms, mammals are a highly uniform group of organisms. Even anatomically, the differences among mammals are chiefly a matter of size and proportions; it is hard to think of a human body part that does not have a counterpart in elephants and mice, and vice versa. Evolution plays freely with quantitative features, but it does not readily change the logic of the basic structure.

Mammals have typically about 1.5 times as many protein-coding genes as *Drosophila*, a genome that is about 16 times larger, and an adult body made up of millions or billions of times as many cells. For an exact measure of how closely mammalian species resemble one another genetically, we can compare the nucleotide sequences of corresponding (orthologous) genes or the amino acid sequences of the proteins that these genes encode. The results for individual genes and proteins vary widely. But typically, if we line up the amino acid sequence of a human protein with that of the orthologous protein from, say, an elephant, more than 80% of the amino acids are identical. A similar comparison between human and bird shows an amino acid identity of about 70%—because the bird and mammalian lineages have had longer to diverge than those of the elephant and the human, they have accumulated more differences (Figure 1-47).

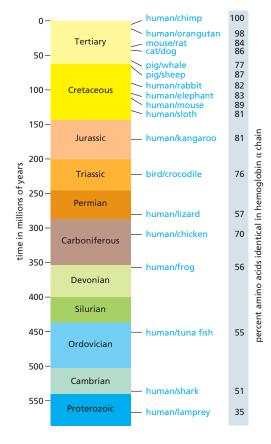

Figure 1–47 Times of divergence of different vertebrates. The scale on the left shows the estimated date and geological era of the last common ancestor of each specified pair of animals. Each time estimate is based on comparisons of the amino acid sequences of orthologous proteins; the longer the animals of a pair have had to evolve independently, the smaller the percentage of amino acids that remain identical. The time scale has been calibrated to match the fossil evidence showing that the last common ancestor of mammals and birds lived about 320 million years ago.

The figures on the right show the amino acid sequence divergence for one particular protein—the α chain of hemoglobin. Note that although there is a clear general trend of increasing divergence with increasing time for this protein, there are irregularities that are thought to reflect the action of natural selection causing especially rapid changes in hemoglobin sequence when the organisms experienced special physiological demands. Some proteins that are subject to stricter functional constraints evolve much more slowly than hemoglobin, whereas others evolve as much as five times faster. (Adapted from S. Kumar and S.B. Hedges, Nature 392:917-920, 1998.)

MBOC7_ptr_ch01_001-048.indd 41 02/12/21 12:54 PM

Figure 1–48 Similar mutations produce the same effect in human and mouse. The human baby and the mouse shown here have remarkably similar abnormal white patches on their foreheads as a result of a mutation in the same gene (called *Kit*), which is required for the normal development, migration, and survival of some skin pigment cells. (Courtesy of R.A. Fleischman, from R.A. Fleischman et al., *Proc. Natl. Acad. Sci. USA* 88:10885–10889, 1991.)

The mouse, being small, hardy, and a rapid breeder, has become the foremost model organism for experimental studies of mammalian molecular cell biology. Many naturally occurring mutations are known, often mimicking the effects of corresponding mutations in humans to a remarkable extent (Figure 1–48). Moreover, methods have been developed to test the function of any chosen mouse gene or of any noncoding portion of the mouse genome by artificially creating mutations in the relevant part of the gene or genome, as we explain in Chapter 8.

Just one made-to-order mutant mouse can provide a wealth of information for the cell biologist. It reveals the effects of the chosen mutation in various contexts, simultaneously testing the action of the gene in the many different types of cells in the body that could in principle be affected. Studies of the mouse are so fundamental to understanding mammalian biology that we will encounter them in nearly every chapter of this book.

The COVID-19 Pandemic Has Focused Scientists on the SARS-CoV-2 Coronavirus

Having discussed several of the most prominent and well-studied model organisms—which are based on the cell as their fundamental unit—we now turn to an intensively studied virus. Viruses, which in essence feed on cells, are prevalent in all three domains of life: bacteria, archaea, and eukaryotes. We introduced them earlier in this chapter when we discussed several *E. coli* viruses that served as critical experimental systems for the initial development of molecular biology. Here, we focus on one prominent virus, SARS-CoV-2, that infects our own cells and has, due to the widespread attention it has received from scientists, become a model system for understanding eukaryotic viruses. But before discussing this virus in detail, we consider how viruses—genomes packaged in protective shells—first came to be, and how they have evolved over time.

As described in Chapter 6, cells are believed to have first evolved in an "RNA world," before there were proteins or DNA molecules. Scientists suspect that even at that time, parasitic genetic elements were present, in the form of small RNA molecules that took advantage of more advanced replicating entities to proliferate. These are believed to have been the ancestors of today's smallest viruses, which contain single-strand RNA genomes composed of as few as 3000 nucleotides. Thus, virus-like entities have probably been a ubiquitous feature of life on Earth for more than 3 billion years.

At a minimum, a virus requires a genome that encodes two core functions: first, a nucleic acid replication process that produces multiple copies of its genome once inside its host cell, and second, a genome-packaging process that surrounds these new genomes with a protective protein coat, while allowing the viruses to exit the host cell and subsequently enter others. But the viruses present today have evolved through billions of infectious cycles, during which there has been a constant war between host organisms and the viruses—with host cells evolving

MBOC7_ptr_ch01_001-048.indd 42 02/12/21 12:54 PM

MODEL ORGANISMS 43

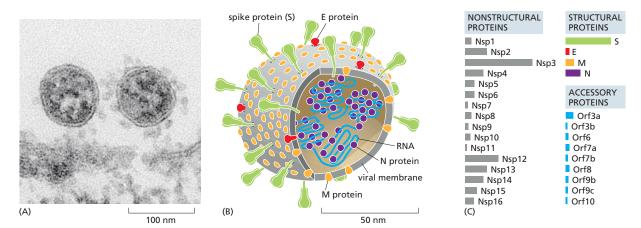

Figure 1–49 The coronavirus. (A) Electron micrograph of SARS-CoV-2 virus particles attached to the surface of a cultured monkey cell. (B) A cut-away drawing of the virus that highlights its protruding spike protein molecules plus a few other major proteins. The spike protein is the major target for vaccines that are designed to block infections, because it attaches the virus to the outside of host cells and then catalyzes transfer of the viral genome into the cell interior. As indicated, the RNA genome is packaged unevenly inside the enveloped virus particle. (C) The 29 proteins produced by SARS-CoV-2, grouped into three different categories. The locations of the structural proteins S, M, E, and N in the virus are indicated in panel B. Each of the proteins listed in the "accessory" category has a role in protecting the virus from host antiviral responses. The functions of the nonstructural proteins include binding to ribosomes to block host protein synthesis (Nsp1), forming a double-membrane "replication organelle" from host-cell membranes (Nsp 3, 4, and 6), and forming the RNA-dependent RNA polymerase (Nsp 7, 8, and 12). The way in which the virus reproduces itself, once inside a host cell, is shown in Figure 5–62. (A, from M. Laue et al. Sci. Rep. 11:3515, 2021. With permission from Cold Spring Harbor Press.)

multiple antivirus defenses and viruses evolving various ways to overcome these defenses. As a result, through cycles of random mutation followed by natural selection over long evolutionary times, most virus genomes have grown much larger than needed for their two core functions, with many of the additional genes encoding proteins that help the viruses to circumvent their host-cells' defenses.

Coronavirus genomes are large, single-strand RNA molecules, about 30,000 nucleotides long. This RNA is packaged in a protein coat that is covered with a lipid bilayer envelope, from which protein spikes protrude (Figure 1–49A and B). Many coronavirus strains circulate in animal species, including pigs, birds, and bats. Some strains also circulate among humans; these so-called "endemic" strains cause only mild symptoms and are responsible for about one in four common colds. But on rare occasions, a bat coronavirus mutates in a way that allows it to infect humans, where it can cause very severe, even fatal, disease. It is thought that the COVID-19 pandemic of 2020 originated in this way.

The virus that causes COVID-19, SARS-CoV-2, produces 29 proteins (Figure 1–49C). Some are structural proteins that package the virus's RNA genome into the virus particle. The nonstructural proteins are critical for replicating the viral genome inside of the host cell, as well as for ensuring that the viral genes are appropriately translated into proteins, including the viral RNA polymerase complex. And, as one would expect, other proteins help the virus to avoid the host's immune defenses, which are described in Chapter 24.

The SARS-CoV-2 virus is closely related to the coronaviruses that cause colds, as well as to the SARS-CoV virus that emerged from bats in 2002 and killed nearly 1 in 10 of the humans it infected. We still do not understand what makes SARS-CoV and SARS-CoV-2 infections so much more dangerous to humans than the infections caused by their close relatives that cause only a mild cold. But, given the thousands of research laboratories currently focused on understanding the cell biology of SARS-CoV-2 with the aim of ameliorating the COVID-19 pandemic, we should know the answers to these questions in the near future. These studies are certain to make us much better prepared to deal with the next virus that emerges to threaten us.

MBOC7_ptr_ch01_001-048.indd 43 02/12/21 12:54 PM

Humans Are Unique in Reporting on Their Own Peculiarities

As humans, we have a special interest in the human genome. We want to know how our genes and their products work. But, even if you were a mouse, preoccupied with how mouse genes and their products work, humans would be attractive as model genetic organisms because of one special property: through medical examinations and self-reporting, we catalog our own genetic (and other) disorders. The human population is enormous, consisting today of some 8 billion individuals, and this self-documenting property means that a huge database exists of human mutations and their effects. And the human genome sequence of more than 3 billion nucleotide pairs has been determined for hundreds of thousands of people, making it easier than ever before to identify at a molecular level the precise genetic change responsible for any given human mutant phenotype.

But what precisely do we mean when we speak of the human genome? Whose genome? On average, any two people taken at random will differ at roughly 4 million different sites in their DNA sequence (see Table 4–3, p. 247). Thus, the human genome is very complex, embracing the entire pool of variant genes found in the human population. As described in Chapter 4, knowledge of this variation is helping us to understand human biology; for example, why some people are prone to one disease, others to another, and why some respond well to a drug, but others badly. It is also providing clues to our history, including population movements, interbreeding among our ancestors, the infections they suffered, and the diets they ate. All these things have left traces in the variant forms of genes that survive today in the human communities that populate our planet, and by exploiting this fact, scientists have been discovering fascinating aspects of our past.

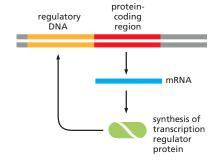

By drawing together the insights from humans, mice, fish, flies, worms, yeasts, plants, and bacteria—using DNA sequence similarities to map out the correspondences between one model organism and another—we are greatly enriching our understanding of them all.

To Understand Cells and Organisms Will Require Mathematics, Computers, and Quantitative Information

Empowered by knowledge of complete genome sequences, we can list the genes, proteins, and RNA molecules in a cell, and we have powerful methods to analyze the complex web of interactions between them. But how are we to use all this information to understand how cells work? Even for a single cell type belonging to a single species of organism, the current deluge of data seems overwhelming. The informal reasoning that biologists usually rely on seems increasingly inadequate in the face of such complexity.

The difficulty is more than just a matter of information overload. Biological systems are, for example, full of feedback loops, and the behavior of even the simplest of systems with feedback is remarkably difficult to predict by intuition alone (Figure 1–50); small changes in parameters can cause radical changes in outcome. To go from a circuit diagram to a prediction of the behavior of the

Figure 1–50 A very simple gene regulatory circuit. A single gene regulates its own expression because its protein product is a transcription regulator that binds to the regulatory DNA of its own gene. Simple schematic diagrams such as this are found throughout this book. They are often used to summarize what we know, but they leave many questions unanswered. When the protein binds, does it inhibit or stimulate transcription from the gene? How steeply does the transcription rate depend on the protein concentration? How long, on average, does a molecule of the protein remain bound to the DNA? How long does it take to make each molecule of mRNA or protein, and how quickly does each type of molecule get degraded? As explained in Chapter 8, mathematical modeling shows that we need quantitative answers to all these and other questions—obtained by direct observations and experiments—before we can predict the behavior of even this simple circuit. For different parameter values, the system may settle to a unique steady state; or it may behave as a switch, capable of existing in one or another of a set of alternative states; or it may oscillate; or it may even show large random fluctuations.

MBOC7_ptr_ch01_001-048.indd 44 02/12/21 12:54 PM

MODEL ORGANISMS 45

system, we need detailed quantitative information, and to draw deductions from that information we need mathematics and computers.

Such tools for quantitative reasoning are essential, but they are not all-powerful. You might think that, knowing how each protein in a cell influences each other protein, and how the expression of each gene is regulated by the products of other genes, we should soon be able to calculate how the cell as a whole will behave, just as an astronomer can calculate the orbits of the planets or a chemical engineer can calculate the flows through a chemical plant. But any attempt to perform this feat for anything close to an entire living cell rapidly reveals the limits of our present knowledge. The information we have, plentiful as it is, is full of gaps and uncertainties, and it is largely qualitative rather than quantitative. Most often, cell biologists studying a cell's control systems sum up their knowledge in simple schematic diagrams—this book is full of them—rather than in numbers, graphs, and differential equations.

To progress from qualitative descriptions and intuitive reasoning to quantitative descriptions and mathematical deduction is one of the biggest challenges for contemporary cell biology. So far, the challenge has been met for only a few very simple fragments of the machinery of living cells—subsystems involving a handful of different proteins, or two or three genes that regulate one another, where theory and experiment go closely hand in hand. We discuss some of these examples later in the book and devote much of Chapter 8 to some new approaches designed to answer the increasingly complex questions that arise in biology.

Knowledge and understanding bring the power to intervene—with humans, to prevent and treat disease; with plants, to create better crops; with bacteria, archaea, and fungi, to control them for our own benefit. All these biological enterprises are linked, because the genetic information of all living organisms is written in the same language. The recent ability of molecular biologists to read and decipher this language has already begun to transform our relationship to the living world. The account of cell biology in the subsequent chapters will, we hope, equip the reader to understand, and possibly to contribute to, the great biosciences adventure that we can anticipate through the rest of this century.

Summary

Powerful new technologies, including rapid and cheap genome sequencing, are enabling rapid advances in our knowledge of human biology, with implications for understanding and treating human disease. But living systems are incredibly complex, and simpler model organisms have played a critical part in revealing universal genetic and molecular cell biological mechanisms. Thus, for example, early research on the bacterium E. coli and its viruses provided the foundations needed to decipher the fundamental genetic mechanisms in all cells. And research on the unicellular yeast Saccharomyces cerevisiae, which continues to serve as a simple model organism for eukaryotic cell biology, has revealed the molecular basis for many critical processes that have been strikingly conserved during more than a billion years of eukaryotic evolution. Biologists have also chosen a small number of multicellular organisms for intensive study: a worm, a fly, a fish, the mouse, and humans serve as model organisms for animals, and a small member of the cabbage family serves as a model for plant biology. Even today, research that focuses on these and other model organisms remains crucial for understanding ourselves, as well as for driving scientific and medical advances.

MBOC7_ptr_ch01_001-048.indd 45 02/12/21 12:54 PM

PROBLEMS

Which statements are true? Explain why or why not.

- 1–1 DNA and RNA use the same four-letter alphabet.
- 1–2 Each member of the human hemoglobin gene family, which consists of seven genes arranged in two clusters on different chromosomes, is an ortholog to all of the other members.
- 1–3 Most of the DNA sequences in a bacterial genome code for proteins, whereas most of the DNA sequences in the human genome do not.
- **1–4** Without additional information, no amount of gazing at genome sequences will reveal the functions of genes.

Discuss the following problems.

- 1–5 "Life" is easy to recognize but difficult to define. Dictionaries commonly define life as "The state or quality that distinguishes living beings or organisms from dead ones and from inorganic matter, characterized chiefly by metabolism, growth, the ability to reproduce, and the ability to respond to stimuli." Score a car, a cactus, and yourself with respect to these characteristics.
- 1-6 Since it was deciphered more than five decades ago, some have claimed that the genetic code must be a frozen accident, while others have argued that it was shaped by natural selection. A striking feature of the genetic code is its inherent resistance to the effects of mutation. For example, a change in the third position of a codon often specifies the same amino acid or one with similar chemical properties. The natural code resists mutation more effectively (is less susceptible to error) than most other possible versions, as illustrated in Figure Q1-1. Only one in a million computer-generated "random" codes is more error-resistant than the natural genetic code. Does the extraordinary mutation resistance of the genetic code argue in favor of its origin as a frozen accident or as a result of natural selection? Explain your reasoning.

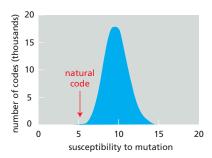

Figure Q1–1 Susceptibility to mutation of the natural code shown relative to that of millions of computer-generated alternative genetic codes (Problem 1–6). Susceptibility measures the average change in amino acid properties caused by random mutations in a genetic code. A small value indicates that mutations tend to cause minor changes. (Data courtesy of Steve Freeland.)

- 1–7 You have begun to characterize a sample obtained from the depths of the oceans on Europa, one of Jupiter's moons. Much to your surprise, the sample contains a lifeform that grows well in a rich broth. Your preliminary analysis shows that it is cellular and contains DNA, RNA, and protein. When you show your results to a colleague, she suggests that your sample was contaminated with an organism from Earth. What approaches might you try to distinguish between contamination and a novel cellular life-form that is based on DNA, RNA, and protein?
- **1–8** It is not so difficult to imagine what it means to feed on the organic molecules that living things produce. That is, after all, what we do. But what does it mean to "feed" on sunlight, as phototrophs do? Or, even stranger, to "feed" on rocks, as lithotrophs do? Where is the "food," for example, in the mixture of chemicals (H_2S , H_2 , CO, Mn^+ , Fe^{2+} , Ni^{2+} , CH_4 , and NH_4^+) that spews from a hydrothermal vent?
- **1–9** How many possible different trees (branching patterns) can be drawn to display the evolution of bacteria, archaea, and eukaryotes, assuming that they all arose from a common ancestor?
- **1–10** The genes for ribosomal RNA are highly conserved (relatively few sequence changes) in all organisms on Earth; thus, they have evolved very slowly over time. Were ribosomal RNA genes "born" perfect?
- 1–11 Rates of evolution appear to vary in different lineages. For example, the rate of evolution in the rat lineage is significantly higher than in the human lineage. These rate differences are apparent whether one looks at changes in nucleotide sequences that encode proteins and are subject to selective pressure or at changes in noncoding nucleotide sequences, which are not under obvious selection pressure. Can you offer one or more possible explanations for the slower rate of evolutionary change in the human lineage versus the rat lineage?
- 1–12 Genes participating in informational processes such as replication, transcription, and translation undergo horizontal gene transfer between species much less often than do genes involved in metabolism. The basis for this inequality is unclear at present, but one suggestion is that it relates to the underlying complexity of the two types of processes. Informational processes tend to involve large aggregates of different gene products, whereas metabolic reactions are usually catalyzed by enzymes composed of a single protein. Why would the complexity of the underlying process—informational or metabolic—have any effect on the rate of horizontal gene transfer?
- 1–13 Animal cells have neither cell walls nor chloroplasts, whereas plant cells have both. Fungal cells are somewhere in between; they have cell walls but lack chloroplasts. Are fungal cells more likely to be animal cells that

MBOC7_ptr_ch01_001-048.indd 46 02/12/21 12:54 PM

REFERENCES 47

gained the ability to make cell walls or to be plant cells that lost their chloroplasts? This question represented a difficult issue for early investigators who sought to assign evolutionary relationships solely on the basis of cell characteristics and morphology. How do you suppose that this question was eventually decided?

- **1–14** *Giardia lamblia* is a fascinating eukaryotic parasite; it contains a nucleus but no mitochondria and no discernible endoplasmic reticulum or Golgi apparatus—one of the very rare examples of such a cellular organization among eukaryotes. This cell organization might have arisen because *Giardia* is an ancient lineage that separated from the rest of the eukaryotes before mitochondria were acquired and internal membranes were developed. Or it might be a stripped-down version of a more standard eukaryote that has lost these structures because they are not necessary for its parasitic lifestyle. How might you use nucleotide sequence comparisons to distinguish between these alternatives?
- 1–15 When plant hemoglobin genes were first discovered in legumes, it was so surprising to find a gene typical of animal blood that it was hypothesized that the plant gene arose by horizontal transfer from an animal. Many more hemoglobin genes have now been sequenced, and a phylogenetic tree based on some of these sequences is shown in Figure Q1–2.
- **A.** Does this tree support or refute the hypothesis that the plant hemoglobins arose by horizontal gene transfer?
- B. Supposing that the plant hemoglobin genes were originally derived from a parasitic nematode, for example, what would you expect the phylogenetic tree to look like?

VERTERRATES Rabbit Whale Cobra Chicken Cat Salamander Human Cow Frog Goldfish Barley **PLANTS** Lotus Earthworm Alfalfa Insect Chlamydomonas **INVERTEBRATES** Nematode **PROTOZOA** Paramecium

Figure Q1–2 Phylogenetic tree for hemoglobin genes from a variety of species (Problem 1–15). The legumes are highlighted in *green*. The lengths of lines that connect the present-day species represent the evolutionary distances that separate them.

Cell Chemistry and Bioenergetics

CHAPTER

2

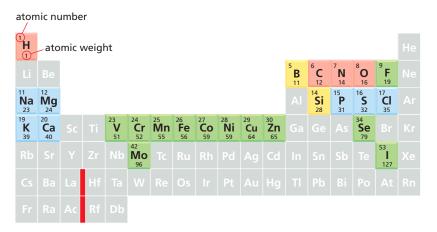

It is at first sight difficult to accept the idea that living creatures are merely chemical systems. Their incredible diversity of form, their seemingly purposeful behavior, and their ability to grow and reproduce all seem to set them apart from the world of solids, liquids, and gases that chemistry normally describes. Indeed, until the late nineteenth century, animals were generally believed to contain a Vital Force—an "animus"—that was responsible for their distinctive properties.

We now know that there is nothing in living organisms that disobeys chemical or physical laws. However, the chemistry of life is indeed special. First, life depends on chemical reactions that take place in aqueous solution, and it is based overwhelmingly on carbon compounds, the study of which is known as *organic chemistry*. Second, although cells contain a variety of small carbon-containing molecules, most of the carbon atoms present are incorporated into enormous polymeric molecules—chains of chemical subunits linked end-to-end. It is the unique properties of these *macromolecules* that enable cells and organisms to grow and reproduce—and to do all the other things that are characteristic of life. Third, and most important, cell chemistry is enormously complex: even the simplest cell is vastly more complicated in its chemistry than any other chemical system known. In fact, we now recognize that the many interlinked networks of chemical reactions in cells can give rise to so-called *emergent properties*, which will require the development of new experimental and computational methods to understand.

Much of the information in this chapter is summarized—and in some cases further elaborated—in the nine two-page Panels with which the chapter ends (Panels 2–1 to 2–9). Although the Panels will be cited at appropriate places in the text, they should also be useful for refreshing background knowledge when reading later chapters.

THE CHEMICAL COMPONENTS OF A CELL

Living organisms are made of only a small selection of the 92 naturally occurring elements, four of which—carbon (C), hydrogen (H), nitrogen (N), and oxygen (O)—make up 96.5% of an organism's weight (Figure 2-1). The *atoms* of these

IN THIS CHAPTER

The Chemical Components of a Cell

Catalysis and the Use of Energy by Cells

How Cells Obtain Energy from Food

Figure 2–1 The main elements in cells, highlighted in the periodic table. When ordered by their atomic number and arranged in this manner, elements fall into vertical columns that show similar properties.

The four elements highlighted in red constitute 99% of the total number of atoms present in the human body (and 96.5% of its weight). An additional seven elements, highlighted in blue, together represent about 0.9% of the total atoms in our bodies. The elements shown in green are required in trace amounts by humans. It remains unclear whether those elements shown in yellow are essential in humans.

The chemistry of life is therefore predominantly the chemistry of lighter elements. The atomic weights shown here are those of the most common isotope of each element. The vertical *red* line marks a break in the periodic table where a group of large atoms with similar chemical properties is omitted.

MBOC7_ptr_ch02_049-114.indd 49 08/12/21 11:24 AM

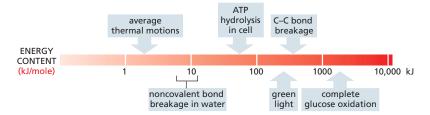

Figure 2–2 Some energies important for cells. A crucial property of any bond—covalent or noncovalent—is its strength. Bond strength is measured by the amount of energy that must be supplied to break it, expressed in units of either kilojoules per mole (kJ/mole) or kilocalories per mole (kcal/mole). Thus if 100 kJ of energy must be supplied to break 6 × 10²³ bonds of a specific type (that is, 1 mole of these bonds), then the strength of that bond is 100 kJ/mole. Note that, in this diagram, energies are compared on a logarithmic scale. (Typical strengths and lengths of the main classes of chemical bonds are given in Table 2–1, later in text.)

One joule (J) is the amount of energy required to move an object a distance of 1 meter (m) against a force of 1 newton (N). This measure of energy is derived from the SI units (Système International d'Unités) universally employed by physical scientists. A second unit of energy, often used by cell biologists, is the kilocalorie (kcal):1 calorie (cal) is the amount of energy needed to raise the temperature of 1 gram (g) of water by 1°C. One kilojoule (kJ) is equal to 0.239 kcal.

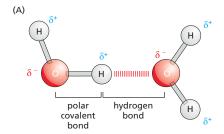

elements are linked together by **covalent bonds** to form *molecules* (see **Panel 2-1**, pp. 94-95). Because covalent bonds are typically 100 times stronger than the thermal energies within a cell, they resist being pulled apart by thermal motions, and they are normally broken only during biologically catalyzed chemical reactions that are of use to the cell. *Noncovalent bonds* are much weaker (**Figure 2-2**), but sets of them allow molecules to recognize each other and reversibly associate, which is critical for the vast majority of biological functions.

Water Is Held Together by Hydrogen Bonds

Because 70% of the weight of a cell is water, the reactions that make life possible occur in an aqueous environment. Life on Earth is thought to have begun in shallow bodies of water that had concentrated essential molecules, and the conditions in that primeval environment have left a permanent stamp on the chemistry of all living things.

The chemical properties of water are reviewed in Panel 2-2 (pp. 96-97). In a water molecule (H₂O), the two H atoms are linked to the O atom by covalent bonds that are highly polar, inasmuch as the O atom attracts electrons more strongly than does the H atom. Consequently, there is a preponderance of positive charge on the two H atoms and of negative charge on the O atom. When a positively charged region of one water molecule (that is, one of its H atoms) approaches a negatively charged region (that is, the O atom) of a second water molecule, the electrical attraction between them can result in a hydrogen bond (Figure 2-3A). These bonds are much weaker than covalent bonds and are easily broken by the random thermal motions that reflect the heat energy of the molecules. Thus, each bond lasts only a very short time. But the combined effect of many weak bonds can be profound. For example, each water molecule can form hydrogen bonds through its two H atoms to two other water molecules, producing a network in which hydrogen bonds are being continually broken and formed. It is only because of these hydrogen bonds that link water molecules together that water is a liquid at room temperature—with a high boiling point and high surface tension—rather than a gas.

Hydrogen bonds are not limited to water, and they are central to much of biology. This bond represents a special form of polar interaction in which an electropositive hydrogen atom is shared by two electronegative atoms. The hydrogen in this bond can be viewed as a proton that has partially dissociated from a donor atom, allowing it to be shared by a second, acceptor atom. Unlike a typical electrostatic interaction, this bond is highly directional—being strongest when a straight line can be drawn between all three of the involved atoms (Figure 2–3B).

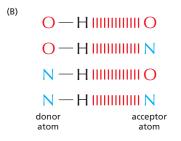

Figure 2-3 The noncovalent hydrogen bond. (A) A hydrogen bond forms between two water molecules. The slight positive charge associated with the hydrogen atom is electrically attracted to the slight negative charge of the oxygen atom. This causes water to exist as a large hydrogen-bonded network (see Panel 2-2, pp. 96-97). (B) In cells, hydrogen bonds commonly form between molecules that contain an oxygen or nitrogen. The atom bearing the hydrogen is considered the H-bond donor, and the atom that interacts with the hydrogen is the H-bond acceptor. This type of dipole-dipole interaction is of critical importance in biology. For this reason, and because it is highly directional, the hydrogen bond receives special attention among the set of noncovalent attractions that we discuss next.

Molecules, such as alcohols, that contain polar bonds and that can form hydrogen bonds with water dissolve readily in water. Molecules carrying charges (ions) likewise interact favorably with water. Such molecules are termed **hydrophilic**, meaning that they are water-loving. Many of the molecules in the aqueous environment of a cell necessarily fall into this category, including sugars, DNA, RNA, and most proteins. **Hydrophobic** (water-fearing) molecules, by contrast, are uncharged and form few or no hydrogen bonds, and so do not dissolve in water. Hydrocarbons are an important example. In these molecules, all of the H atoms are covalently linked to C atoms by a largely nonpolar bond; thus, they cannot form effective hydrogen bonds to other molecules (see Panel 2–1, pp. 94–95). This makes the hydrocarbon as a whole hydrophobic—a property that is exploited in cells, whose membranes are constructed from molecules that have long hydrocarbon tails, as we shall see in Chapter 10.

Four Types of Noncovalent Attractions Help Bring Molecules Together in Cells

Much of biology depends on the specific binding between different molecules caused by three types of **noncovalent bonds**—hydrogen bonds, electrostatic attractions (ionic bonds), and van der Waals attractions—combined with a fourth factor that can push molecules together: the hydrophobic force.

Electrostatic attractions are strongest when the atoms involved are fully charged, or ionized. But a weaker electrostatic attraction occurs between molecules that contain polar covalent bonds. Like hydrogen bonds, electrostatic attractions are extremely important in biology. For example, any large molecule with many polar groups will have a pattern of partial positive and negative charges on its surface. When such a molecule encounters a second molecule with a complementary set of charges, the two will be drawn to each other by electrostatic attraction.

In addition to hydrogen bonds and electrostatic attractions, a third type of noncovalent bond, called a **van der Waals attraction**, comes into play when any two atoms approach each other closely. These weak, nonspecific interactions are due to fluctuations in the distribution of electrons in every atom, which can generate a transient attraction when the atoms are in very close proximity. These attractions occur in all types of molecules, even those that are nonpolar.

The relative lengths and strengths of these three types of noncovalent bonds are compared to the length and strength of covalent bonds in **Table 2-1**, both in the presence and in the absence of water. Note that, because water forms competing interactions with the involved molecules, the strength of both electrostatic attractions and hydrogen bonds is greatly weakened inside of the cell.

The fourth effect that often brings molecules together in water is not, strictly speaking, a bond at all. However, a very important **hydrophobic force** is caused by a pushing of nonpolar surfaces out of the hydrogen-bonded water network, where they would otherwise physically interfere with the highly favorable

TABLE 2-1 Covalent and Noncovalent Chemical Bonds					
			Strength (kJ/mole**)		
Bond type		Length (nm)	In vacuum	In water	
Covalent		0.10	377 (90)	377 (90)	
Noncovalent	lonic*	0.25	335 (80)	12.6 (3)	
	Hydrogen	0.17	16.7 (4)	4.2 (1)	
	van der Waals attraction (per atom)	0.35	0.4 (0.1)	0.4 (0.1)	

^{*}An ionic bond is an electrostatic attraction between two fully charged atoms.

MBOC7_ptr_ch02_049-114.indd 51 08/12/21 11:24 AM

^{**}Values in parentheses are kcal/mole. 1 kJ = 0.239 kcal and 1 kcal = 4.18 kJ.

interactions between water molecules. Bringing any two nonpolar surfaces together reduces their contact with water, and in this sense, the force is nonspecific. Nevertheless, we shall see in Chapter 3 that hydrophobic forces are central to the proper folding of protein molecules.

The properties of the four types of noncovalent attractions are presented in **Panel 2-3** (pp. 98–99). Although each individual noncovalent attraction would be much too weak to be effective in the face of thermal motions, the energies of these noncovalent attractions can sum to create a strong force between two separate molecules. Thus, it is an entire set of noncovalent attractions that enables the complementary surfaces of two macromolecules to hold the two macromolecules together (**Figure 2-4**).

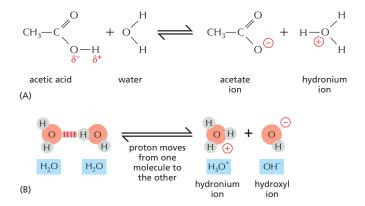

Some Polar Molecules Form Acids and Bases in Water

One of the simplest kinds of chemical reaction, and one that has a considerable significance for cells, takes place when a molecule containing a highly polar covalent bond between a hydrogen and another atom dissolves in water. The hydrogen atom in such a molecule has given up its electron almost entirely to the companion atom, and so exists as an almost naked positively charged hydrogen nucleus; in other words, a **proton** (\mathbf{H}^+). When this polar molecule becomes surrounded by water molecules, the proton will be attracted to the partial negative charge on the O atom of an adjacent water molecule. The proton can easily dissociate from its original partner and associate instead with the oxygen atom of the water molecule, generating a **hydronium ion** ($\mathbf{H_3O^+}$) (Figure 2–5A). The reverse reaction also takes place very readily, so in an aqueous solution protons are constantly flitting to and fro between one molecule and another.

Substances that release protons when they dissolve in water, thus forming H_3O^+ , are termed **acids**. The higher the concentration of H_3O^+ , the more acidic the solution. H_3O^+ is present even in pure water, at a concentration of 10^{-7} M, as a result of the movement of protons from one water molecule to another (**Figure 2–5B**). By convention, the H_3O^+ concentration is usually referred to as the H^+ concentration, even though most protons in an aqueous solution are present as H_3O^+ . As explained in Panel 2–2, to avoid the use of unwieldy numbers the concentration of H_3O^+ is expressed using a logarithmic scale called the **pH scale**. Pure water has a pH of 7.0 and is said to be neutral; that is, neither acidic (pH < 7) nor basic (pH > 7).

Acids are characterized as being strong or weak, depending on how readily they give up their protons to water. Strong acids, such as hydrochloric acid (HCl), easily lose their protons. Acetic acid, on the other hand, is a weak acid because it holds on to its proton more tightly when dissolved in water. Many of the acids important in the cell—such as molecules containing a carboxyl (COOH) group—are weak acids.

Because the proton of a hydronium ion can be passed readily to many types of molecules in cells, altering their character, the concentration of $\rm H_3O^+$ inside a cell (the acidity) must be closely regulated. Acids—especially weak acids—will give

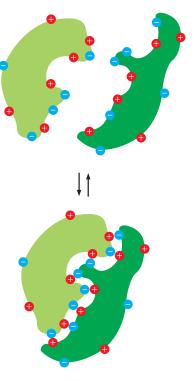

Figure 2-4 Schematic indicating how two macromolecules with complementary surfaces can bind tightly to one another through noncovalent interactions. Noncovalent chemical bonds have less than 1/20 the strength of a covalent bond. They are able to produce tight binding only when many of them are formed simultaneously. Although only electrostatic attractions are illustrated here, in reality all four noncovalent forces often contribute to holding two macromolecules together (Movie 2.1).

Figure 2–5 How protons readily move in aqueous solutions. (A) The reaction that takes place when a molecule of acetic acid dissolves in water. At pH 7, nearly all of the acetic acid is present as acetate ion. (B) Water molecules continually exchange protons with each other to form hydronium and hydroxyl ions. These ions in turn rapidly recombine to form water molecules.

MBOC7_ptr_ch02_049-114.indd 52 08/12/21 11:24 AM

up their protons more readily if the concentration of ${\rm H_3O^+}$ in solution is low and will tend to receive them back if the concentration in solution is high.

The opposite of an acid is a **base**. Any molecule capable of accepting a proton from a water molecule is called a base. Sodium hydroxide (NaOH) is basic (the term *alkaline* is also used) because it dissociates readily in aqueous solution to form Na⁺ ions and OH⁻ ions. Because of this property, NaOH is called a strong base. More important in living cells, however, are the weak bases—those that have a weak tendency to reversibly accept a proton from water. Many biologically important molecules contain an amino (NH₂) group. This group is a weak base that can generate OH⁻ by taking a proton from water: $-NH_2 + H_2O \rightarrow -NH_3^+ + OH^-$ (see Panel 2-2, pp. 96–97).

Because an OH $^-$ ion combines with an H_3O^+ ion to form two water molecules, any increase in the OH $^-$ concentration forces a decrease in the concentration of H_3O^+ , and vice versa. Thus the product of the two values, $[OH^-] \times [H_3O^+]$, is always 10^{-14} (moles/liter) 2 . A pure solution of water contains an equal concentration (10^{-7} M) of both ions, rendering it neutral. The interior of a cell is also kept close to neutrality by the presence of **buffers**: weak acids and bases that can release or take up protons near pH 7, keeping the environment of the cell relatively constant under a variety of conditions.

A Cell Is Formed from Carbon Compounds

Having briefly reviewed the ways that atoms combine into molecules and how these molecules behave in an aqueous environment, we now examine the main classes of small molecules found in cells. We shall see that a few categories of molecules, formed from a handful of different elements, give rise to all the extraordinary richness of form and behavior shown by living things.

If we disregard water and inorganic ions such as potassium, nearly all the molecules in a cell are based on carbon. Carbon is outstanding among all the elements in its ability to form large molecules; silicon is a poor second. Because carbon is small and has four electrons and four vacancies in its outermost shell, a carbon atom can form four covalent bonds with other atoms. Most important, one carbon atom can join to other carbon atoms through highly stable covalent C–C bonds to form chains and rings and hence generate large and complex molecules with no obvious upper limit to their size. The carbon compounds made by cells are called *organic molecules*. In contrast, all other molecules, including water, are said to be *inorganic*.

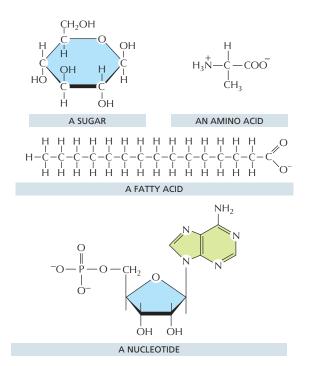

Certain combinations of atoms, such as the methyl (-CH₃), hydroxyl (-OH), carboxyl (-COOH), carbonyl (-C=O), phosphate (-PO₃²⁻), sulfhydryl (-SH), and amino (-NH₂) groups, occur repeatedly in the molecules made by cells. Each such **chemical group** has distinct chemical and physical properties that influence the behavior of the molecule in which the group occurs. The most common chemical groups and some of their properties are summarized in Panel 2–1 (pp. 94–95).

Cells Contain Four Major Families of Small Organic Molecules

The small organic molecules of the cell are carbon-based compounds that have masses in the range of 100–1000 daltons and contain up to 30 or so carbon atoms. They are usually found free in solution and have many different fates. Some are used as *monomer* subunits to construct the giant polymeric *macromolecules* that make up most of the mass of the cell—proteins, nucleic acids, and large polysaccharides. Others act as energy sources and are broken down and transformed into other small molecules in a maze of intracellular metabolic pathways. Many small molecules have more than one role in the cell; for example, acting both as a potential subunit for a macromolecule and as an energy source. Small organic molecules account for only about one-tenth of the total mass of organic matter in a cell, but they are very diverse. Nearly 4000 different kinds of small organic molecules have been detected in the well-studied bacterium, *Escherichia coli*.

All organic molecules are synthesized from and are broken down into the same set of simple compounds. As a consequence, the compounds in a cell are

MBOC7_ptr_ch02_049-114.indd 53 08/12/21 11:24 AM

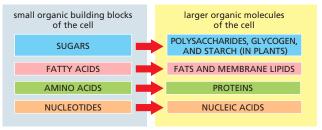

Figure 2–6 The four main families of small organic molecules in cells. These small molecules form the monomeric building blocks, or subunits, for most of the macromolecules and other assemblies of the cell. Some, such as the sugars and the fatty acids, are also energy sources. Their structures are outlined here and shown in more detail in the Panels at the end of this chapter and in Chapter 3.

chemically related and most can be classified into a few distinct families. Broadly speaking, cells contain four major families of small organic molecules: the *sugars*, the *fatty acids*, the *nucleotides*, and the *amino acids* (Figure 2–6). Although many compounds present in cells do not fit into these categories, these four families of small organic molecules, together with the macromolecules made by linking them into long chains, account for a large fraction of the cell mass.

Amino acids and the proteins that they form will be the subject of Chapter 3. A summary of the structures and properties of the remaining three families—sugars, fatty acids, and nucleotides—is presented in Panels 2-4, 2-5, and 2-6, respectively (see pp. 100-105).

The Chemistry of Cells Is Dominated by Macromolecules with Remarkable Properties

By weight, **macromolecules** are the most abundant carbon-containing molecules in a living cell (**Figure 2–7**). They are the principal components from which a cell is constructed, and they also determine the most distinctive properties of living organisms. The macromolecules in cells are polymers that are constructed

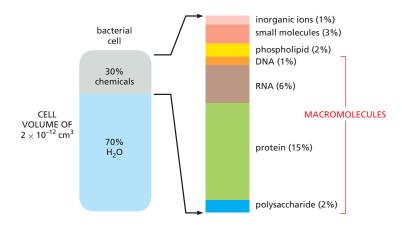

Figure 2–7 The distribution of molecules in cells. The approximate composition of a bacterial cell is shown by weight. The composition of an animal cell is similar, even though its volume is roughly 1000 times greater. Note that macromolecules dominate. The major inorganic ions include Na⁺, K⁺, Mg²⁺, Ca²⁺, and Cl⁻.

MBOC7_ptr_ch02_049-114.indd 54 08/12/21 11:24 AM

by covalently linking small organic molecules (called *monomers*) into long chains (Figure 2–8). They have remarkable properties that could not have been predicted from their simple constituents.

Proteins are abundant and spectacularly versatile, performing thousands of distinct functions in cells. Many proteins serve as *enzymes*, the catalysts that facilitate the many covalent bond-making and bond-breaking reactions that the cell needs. Enzymes catalyze all of the reactions in which cells extract energy from food molecules, for example. Other proteins are used to build structural components, such as tubulin, a protein that self-assembles to make the cell's long microtubules, or histones, proteins that compact the DNA in chromosomes. Many proteins serve as signaling devices, producing networks that control cell functions. Yet other proteins act as molecular motors to produce force and movement, as for myosin in muscle. We shall describe the remarkable chemistry that underlies these diverse roles throughout this book.

Although the chemical reactions that add subunits to each polymer are different in detail for proteins, nucleic acids, and polysaccharides, they share important features. Each polymer grows by the addition of a monomer onto the end of a growing chain in a *condensation reaction*, in which one molecule of water is lost with each subunit added (Figure 2–9). The stepwise polymerization of monomers into a long chain is a simple way to manufacture a large, complex molecule, because the subunits are added by the same reaction performed over and over again by the same set of enzymes. Apart from some of the polysaccharides, most macromolecules are made from a limited set of monomers that are slightly different from one another; for example, the 20 different amino acids from which proteins are made. It is critical to life that the polymer chain is not assembled at random from these subunits; instead, the subunits are added in a precise order, or *sequence*. The elaborate mechanisms that allow enzymes to accomplish this task are described in detail in Chapters 5 and 6.

Noncovalent Bonds Specify Both the Precise Shape of a Macromolecule and Its Binding to Other Molecules

Most of the covalent bonds in a macromolecule allow rotation of the atoms they join, giving the polymer chain great flexibility. In principle, this allows a macromolecule to adopt an almost unlimited number of shapes, or *conformations*, as random thermal energy causes the polymer chain to writhe and rotate. However, the shapes of most biological macromolecules are highly constrained because of the many weak *noncovalent bonds* that form between different parts of the same molecule. If these noncovalent bonds are formed in sufficient numbers, the polymer chain can strongly prefer one particular conformation, determined by the linear sequence of monomers in its chain. Most protein molecules and many of the small RNA molecules found in cells fold tightly into a highly preferred conformation in this way (Figure 2–10).

The four types of noncovalent interactions important in biological molecules were presented earlier (see also Panel 2–3, pp. 98–99). In addition to folding biological macromolecules into unique shapes, they can also add up to create a strong attraction between two different molecules (see Figure 2–4). This form of

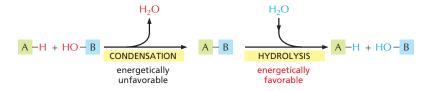

Figure 2–9 Condensation and hydrolysis as opposite reactions. The macromolecules of the cell are polymers that are formed from subunits (or monomers) by a condensation reaction, and they are broken down by hydrolysis. The condensation reactions are all energetically unfavorable; thus, polymer formation requires an energy input, as will be described in the text.

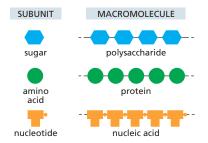

Figure 2–8 Three families of macromolecules. Each is a polymer formed from small molecules (called monomers) linked together by covalent bonds. There are two types of nucleic acid: RNA and DNA.

MBOC7_ptr_ch02_049-114.indd 55 08/12/21 11:24 AM

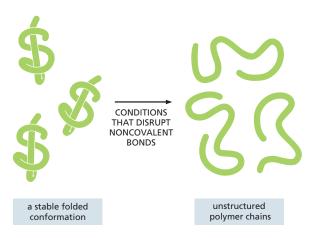

Figure 2–10 Proteins and RNA molecules are folded into a particularly stable three-dimensional shape, or conformation. If the noncovalent bonds maintaining the stable conformation are disrupted, the molecule becomes a flexible chain that loses its biological activity.

molecular interaction provides for great specificity, inasmuch as the close multipoint contacts required for strong binding make it possible for a macromolecule to select out—through binding—just one of the many thousands of types of molecules present inside a cell. Moreover, because the strength of the binding depends on the number of noncovalent bonds that are formed, interactions of almost any affinity are possible—allowing rapid dissociation where appropriate.

As we discuss next, binding of this type underlies all biological catalysis, making it possible for proteins to function as enzymes. In addition, noncovalent interactions allow macromolecules to be used to build larger structures, thereby forming intricate machines with multiple moving parts that perform such complex tasks as DNA replication and protein synthesis (Figure 2–11).

Summary

Living organisms are autonomous, self-propagating chemical systems. They are formed from a distinctive and restricted set of small carbon-based molecules that are essentially the same for every living species. Each of these small molecules is composed of a set of atoms linked to each other in a precise configuration through covalent bonds. The main categories are sugars, fatty acids, amino acids, and nucleotides.

Most of the dry mass of a cell consists of macromolecules that have been produced as linear polymers of amino acids (proteins) or nucleotides (DNA and RNA), covalently linked to each other in an exact order. Most of the protein molecules and many of the RNAs fold into a particular conformation that is determined

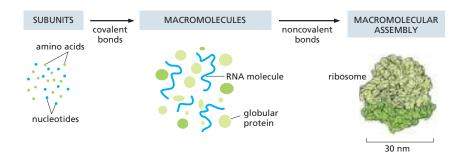

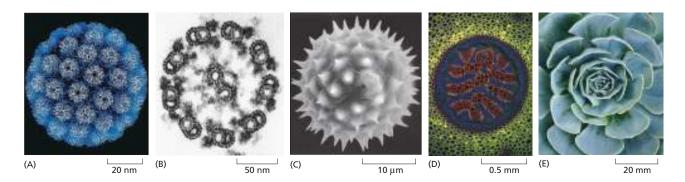

Figure 2–11 Small molecules are covalently linked to form macromolecules, which in turn can assemble through noncovalent interactions to form large complexes. Small molecules, proteins, and a ribosome are drawn approximately to scale. Ribosomes are a central part of the machinery that the cell uses to make proteins: each ribosome is formed as a complex of about 90 macromolecules (protein and RNA molecules).

MBOC7_ptr_ch02_049-114.indd 56 08/12/21 11:24 AM

by their sequence of subunits. This folding process creates unique surfaces, and it depends on a large set of weak attractions produced by noncovalent forces between atoms. These forces are of four types: electrostatic attractions, hydrogen bonds, van der Waals attractions, and an attraction between nonpolar groups caused by their hydrophobic expulsion from water. The same set of weak forces governs the specific binding of a macromolecule to both small molecules and other macromolecules, producing the myriad associations between biological molecules that generate the structure and the chemistry of a cell.

CATALYSIS AND THE USE OF ENERGY BY CELLS

One property of living things above all makes them seem almost miraculously different from nonliving matter: they create and maintain order in a universe that is tending always to greater disorder (Figure 2-12). To create this order, the cells in a living organism must perform a never-ending stream of chemical reactions. In some of these reactions, small organic molecules—amino acids, sugars, nucleotides, and lipids—are being taken apart or modified to supply the many other small molecules that the cell requires. In other reactions, small molecules are being used to construct an enormously diverse range of proteins, nucleic acids, and other macromolecules that endow living systems with all of their most distinctive properties. Each cell can be viewed as a tiny chemical factory, performing many millions of reactions every second.

Cell Metabolism Is Organized by Enzymes

The chemical reactions that a cell carries out would normally proceed at an appreciable rate only at much higher temperatures than those existing inside cells. For this reason, each reaction requires a specific boost in chemical reactivity. This requirement is crucial, because it allows the cell to control its chemistry. The control is exerted through specialized biological *catalysts*. These are almost always proteins called *enzymes*, although RNA catalysts also exist, called *ribozymes*. Each enzyme accelerates, or *catalyzes*, just one of the many possible kinds of reactions that a particular molecule might undergo. Enzyme-catalyzed reactions are connected in series, so that the product of one reaction becomes the starting material, or *substrate*, for the next (Figure 2–13). Long linear reaction pathways are in turn linked to one another, forming a maze of interconnected reactions that enable the cell to survive, grow, and reproduce.

Figure 2-12 Biological structures are highly ordered. Well-defined, ornate, and beautiful spatial patterns can be found at every level of organization in living organisms. In order of increasing size: (A) protein molecules in the coat of a virus (a parasite that, although not technically alive, contains the same types of molecules as those found in living cells); (B) the regular array of microtubules seen in a cross section of a sperm tail; (C) surface contours of a pollen grain (a single cell); (D) cross section of a fern stem, showing the patterned arrangement of cells; and (E) a spiral arrangement of leaves in a succulent plant. (A. courtesy of Robert Grant, Stéphane Crainic, and James M. Hogle; B, courtesy of Lewis Tilney; C, courtesy of Colin MacFarlane and Chris Jeffree; D, courtesy of Jim Haseloff; E, courtesy of Aron van de Selenib.)

Figure 2–13 How a set of enzyme-catalyzed reactions generates a metabolic pathway. Each enzyme catalyzes a particular chemical reaction, leaving the enzyme unchanged. In this example, a set of enzymes acting in series converts molecule A to molecule F, forming a metabolic pathway. (For a diagram of many of the reactions in a human cell, abbreviated as shown, see Figure 2–62.)

MBOC7_ptr_ch02_049-114.indd 57 08/12/21 11:24 AM

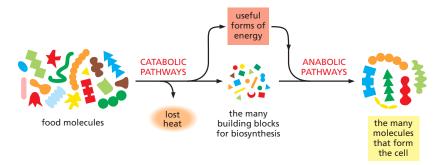

Figure 2–14 Schematic representation of the relationship between catabolic and anabolic pathways in metabolism. Catabolism produces both the building blocks and the energy required for biosynthesis. As indicated, a major portion of the energy stored in the chemical bonds of food molecules is dissipated as heat. As also suggested in this diagram, the mass of food required by any organism that derives all of its energy from catabolism is much greater than the mass of the molecules that it can produce by anabolism.

Two opposing streams of chemical reactions occur in cells: (1) the *catabolic* pathways break down foodstuffs into smaller molecules, thereby generating both a useful form of energy for the cell and some of the small molecules that the cell needs as building blocks; (2) the *anabolic*, or *biosynthetic*, pathways use the small molecules plus the energy harnessed by catabolism to drive the synthesis of the many other molecules that form the cell. Together these two sets of reactions constitute the **metabolism** of the cell (**Figure 2-14**).

The many details of cell metabolism form the traditional subject of *biochemistry*. Most of these details need not concern us here. But the general principles by which cells obtain energy from their environment and use it to create order are central to cell biology. We begin with a discussion of why a constant input of energy is needed to sustain all living things.

Biological Order Is Made Possible by the Release of Heat Energy from Cells

The universal tendency of things to become disordered is a fundamental law of physics—the *second law of thermodynamics*—which states that in the universe or in any isolated system (a collection of matter that is completely isolated from the rest of the universe), the degree of disorder always increases. This law has such profound implications for life that we will restate it in several ways.

For example, we can present the second law in terms of probability by stating that systems will change spontaneously toward those arrangements that have the greatest probability. If we consider a box of 100 coins all lying heads-up, a series of accidents that disturbs the box will tend to move the arrangement toward a mixture of 50 heads and 50 tails. The reason is simple: there is a huge number of possible arrangements of the individual coins in the mixture that can achieve the 50–50 result, but only one possible arrangement that keeps all of the coins oriented heads-up. Because the 50–50 mixture is therefore the most probable, we say that it is more "disordered." For the same reason, it is a common experience that one's living space will become increasingly disordered without intentional effort: the movement toward disorder is a *spontaneous process*, requiring a periodic effort to reverse it (Figure 2–15).

The amount of disorder in a system can be quantified and expressed as the **entropy** of the system: the greater the disorder, the greater the entropy. Thus, another way to express the second law of thermodynamics is to say that systems will change spontaneously toward arrangements with greater entropy.

Living cells—by surviving, growing, and forming complex organisms—are generating order and thus might appear to defy the second law of thermodynamics. How is this possible? The answer is that a cell is not an isolated system: it takes in energy from its environment in the form of the chemical bonds in food

MBOC7_ptr_ch02_049-114.indd 58 08/12/21 11:24 AM

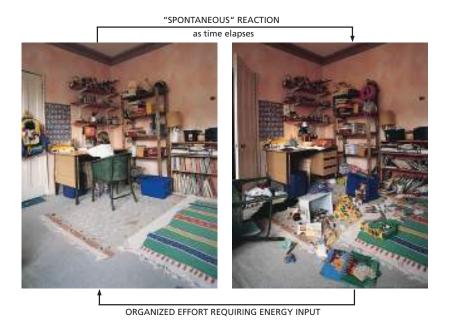

Figure 2–15 An everyday illustration of the spontaneous drive toward disorder. Reversing this tendency toward disorder requires an intentional effort and an input of energy: it is not spontaneous. In fact, from the second law of thermodynamics, we can be certain that the human intervention required will release enough heat to the environment to more than compensate for the reordering of the items in this room.

or as photons from the Sun (or even, as in some chemosynthetic bacteria, from inorganic molecules alone). It then uses this energy to generate order within itself. Critically, during the chemical reactions that generate order, the cell converts part of the energy it uses into heat. The heat is discharged into the cell's environment and disorders the surroundings. As a result, the total entropy—that of the cell plus its surroundings—increases, as demanded by the second law of thermodynamics.

To understand the principles governing these energy conversions, think of a cell surrounded by a sea of matter representing the rest of the universe. As the cell lives and grows, it creates internal order. But it constantly releases heat energy as it synthesizes molecules and assembles them into cell structures. Heat is energy in its most disordered form—the random jostling of molecules. When the cell releases heat to the sea, it increases the intensity of molecular motions there (thermal motion)—thereby increasing the randomness, or disorder, of the sea. The second law of thermodynamics is satisfied because the increase in the amount of order inside the cell is always more than compensated for by an even greater decrease in order (increase in entropy) in the surrounding sea of matter (Figure 2–16).

Where does the heat that the cell releases come from? Here we encounter another important law of thermodynamics. The first law of thermodynamics

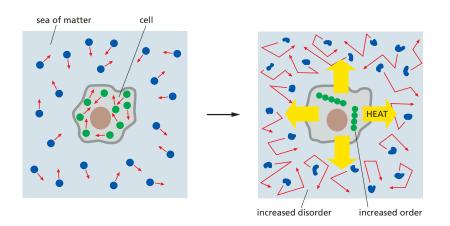

Figure 2-16 A simple thermodynamic analysis of a living cell. In the diagram on the left, the molecules of both the cell and the rest of the universe (the sea of matter) are depicted in a relatively disordered state. In the diagram on the right, the cell has taken in energy from food molecules and released heat through reactions that order the molecules the cell contains. The heat released increases the disorder in the environment around the cell (depicted by jagged arrows and distorted molecules, indicating increased molecular motions caused by heat). As a result, if enough heat is released, the second law of thermodynamics-which states that the amount of disorder in the universe must always increase—is satisfied as the cell grows and divides. For a detailed discussion, see Panel 2-7 (pp. 106-107).

MBOC7_ptr_ch02_049-114.indd 59 08/12/21 11:24 AM

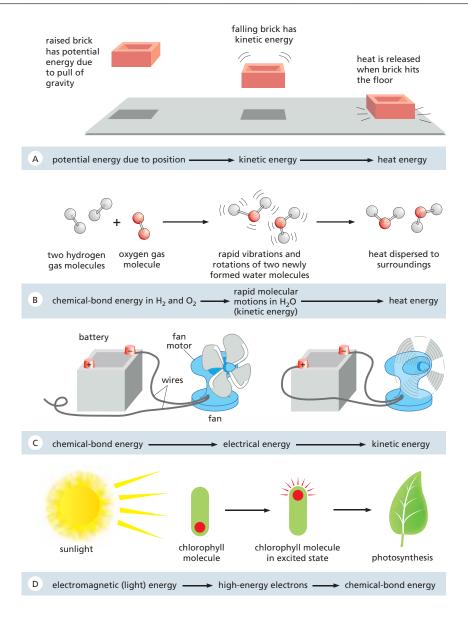

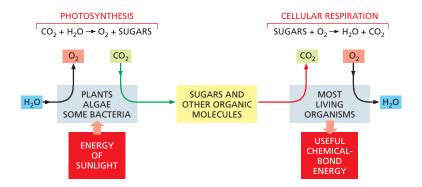

Figure 2-17 Some interconversions between different forms of energy. (A) We can use the height and weight of the brick to predict exactly how much heat will be released when it hits the floor. (B) The large amount of chemicalbond energy released when water (H₂O) is formed from H₂ and O₂ is initially converted to very rapid thermal motions in the two new H₂O molecules; however, collisions with other H₂O molecules almost instantaneously spread this kinetic energy evenly throughout the surroundings (heat transfer), making the new H₂O molecules indistinguishable from all the rest. (C) Through coupled processes to be described later, cells can convert chemical-bond energy into kinetic energy to drive, for example, molecular motor proteins; however, this occurs without the intermediate conversion of chemical energy to electrical energy that a manmade appliance such as this fan requires. (D) Some cells can also harvest the energy from sunlight to form chemical bonds via photosynthesis.

states that energy can be converted from one form to another, but that it cannot be created or destroyed. Figure 2-17 illustrates some interconversions between different forms of energy. The amount of energy in different forms will change as a result of the chemical reactions inside the cell, but the first law tells us that the total amount of energy must always be the same. For example, an animal cell takes in foodstuffs and converts some of the energy present in the chemical bonds between the atoms of these food molecules (chemical-bond energy) into the random thermal motion of molecules (heat energy)—it is this heat that keeps our bodies warm.

The cell cannot derive any benefit from the heat energy it releases unless the heat-generating reactions inside the cell are directly linked to the processes that generate molecular order. It is the tight *coupling* of heat production to an increase in order that distinguishes the metabolism of a cell from the wasteful burning of fuel in a fire. Later, we illustrate how this coupling occurs. For now, it is sufficient to recognize this critical fact: a direct linkage of the "controlled burning" of food molecules to the generation of biological order

MBOC7_ptr_ch02_049-114.indd 60 08/12/21 11:24 AM

is required for cells to create and maintain an island of order in a universe tending toward chaos.

Cells Obtain Energy by the Oxidation of Organic Molecules

All animal and plant cells are powered by energy stored in the chemical bonds of organic molecules, whether they are sugars that a plant has photosynthesized as food for itself or the mixture of large and small molecules that an animal has eaten. Organisms must extract this energy in usable form to live, grow, and reproduce. In both plants and animals, energy is extracted from food molecules by a process of gradual oxidation, or controlled burning.

Earth's atmosphere contains a great deal of oxygen, and in the presence of oxygen the most energetically stable form of carbon is CO_2 and that of hydrogen is H_2O . A cell is therefore able to obtain energy from sugars or other organic molecules by allowing their carbon and hydrogen atoms to combine with oxygen to produce CO_2 and H_2O , respectively—a process called **aerobic respiration**.

Photosynthesis (discussed in detail in Chapter 14) and respiration are complementary processes (Figure 2–18). This means that the transactions between plants and animals are not all one way. Plants, animals, and microorganisms have existed together on this planet for so long that many of them have become an essential part of the others' environments. The oxygen released by photosynthesis is consumed in the combustion of organic molecules during aerobic respiration. And some of the $\rm CO_2$ molecules that are fixed today into organic molecules by photosynthesis in a green leaf were yesterday released into the atmosphere by the respiration of an animal—or by the respiration of a fungus or bacterium decomposing dead organic matter. We therefore see that carbon utilization forms a huge cycle that involves the biosphere (all of the living organisms on Earth) as a whole (Figure 2–19). Similarly, atoms of nitrogen, phosphorus, and sulfur move between the living and nonliving worlds in cycles that involve plants, algae, animals, fungi, and bacteria.

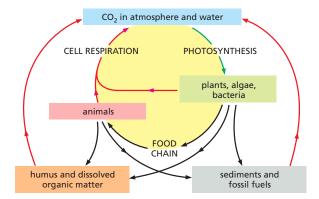

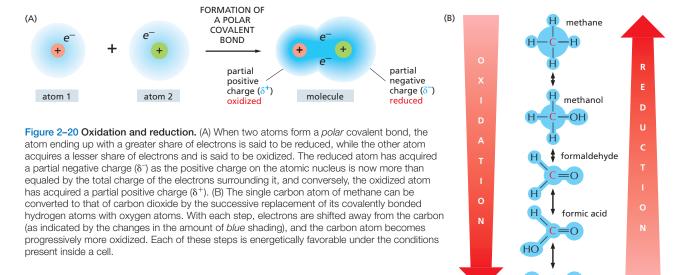

Figure 2-18 Photosynthesis and respiration as complementary processes in the living world. Photosynthesis converts the electromagnetic energy in sunlight into chemical-bond energy in sugars and other organic molecules. Plants, algae, and cyanobacteria obtain the carbon atoms that they need for this purpose from atmospheric CO2 and the hydrogen from water, producing sugars and releasing O2 gas as a by-product. The organic molecules produced by photosynthesis in turn serve as food for other organisms. Many of these organisms carry out aerobic respiration, a process that uses O2 to form CO2 from the same carbon atoms that had been taken up as CO2 and converted into sugars by photosynthesis. In the process, the organisms that respire obtain the chemical-bond energy that they need to survive.

The first cells on Earth are thought to have been capable of neither photosynthesis nor respiration (discussed in Chapter 14). However, photosynthesis must have preceded respiration on Earth, because there is strong evidence that billions of years of photosynthesis were required before O₂ had been released in sufficient quantity to create an atmosphere rich in this gas. (Earth's atmosphere currently contains 21% O₂.)

Figure 2–19 How carbon atoms cycle through the biosphere. Individual carbon atoms are incorporated into organic molecules of the living world by the photosynthetic activity of bacteria, algae, and plants. They pass to animals, microorganisms, and organic material in soil and oceans in cyclic paths. CO₂ is restored to the atmosphere when organic molecules are oxidized by cells during respiration or burned by humans as fossil fuels. In this diagram, the *green arrow* denotes an uptake of CO₂, whereas a *red arrow* indicates CO₂ release.

As indicated in Chapter 1, the total biomass on Earth is estimated to contain ~550 gigatons (10¹⁵ grams) of carbon (Gt C), of which 450 Gt C are plants, 70 are bacteria, 7 are archaea, and 2 are animals (see Figure 1–14).

MBOC7_ptr_ch02_049-114.indd 61 08/12/21 11:24 AM

carbon dioxide

Oxidation and Reduction Involve Electron Transfers

The cell does not oxidize organic molecules in one step, as occurs when organic material is burned in a fire. Through the use of enzyme catalysts, metabolism takes these molecules through a large number of reactions that only rarely involve the direct addition of oxygen. Before we consider some of these reactions and their purpose, we discuss what is meant by the process of oxidation.

Oxidation refers to more than the addition of oxygen atoms; the term applies more generally to any reaction in which electrons are transferred from one atom to another. Oxidation in this sense refers to the removal of electrons, and **reduction**—the converse of oxidation—means the addition of electrons. Thus, Fe^{2+} is oxidized if it loses an electron to become Fe^{3+} , and a chlorine atom is reduced if it gains an electron to become Cl^- . Because the number of electrons is conserved (no loss or gain) in a chemical reaction, oxidation and reduction always occur simultaneously; that is, if one molecule gains an electron in a reaction (reduction), a second molecule loses the electron (oxidation). When a sugar molecule is oxidized to CO_2 and H_2O , for example, the O_2 molecules involved in forming H_2O gain electrons and thus are said to have been reduced.

Why is a "gain" of electrons referred to as a "reduction"? The term arose before anything was known about the movement of electrons. Originally, reduction reactions involved a liberation of oxygen—for example, when metals are extracted from ores by heating—which caused the samples to become lighter; in other words, "reduced" in mass.

It is important to recognize that the terms "oxidation" and "reduction" apply even when there is only a partial shift of electrons between atoms linked by a covalent bond (Figure 2–20). When a carbon atom becomes covalently bonded to an atom with a strong affinity for electrons, such as oxygen, chlorine, or sulfur, for example, it gives up more than its equal share of electrons and forms a *polar* covalent bond. Because the positive charge of the carbon nucleus is now somewhat greater than the negative charge of its electrons, the atom acquires a partial positive charge and is said to be oxidized. Conversely, a carbon atom in a C-H linkage has slightly more than its share of electrons, and so it is said to be reduced.

When a molecule in a cell picks up an electron (e^-), it often picks up a proton (H^+) at the same time (protons being freely available in water). The net effect in this case is to add a hydrogen atom to the molecule.

$$A + e^- + H^+ \rightarrow AH$$

Even though a proton plus an electron is involved (instead of just an electron), such *hydrogenation* reactions are reductions, and the reverse *dehydrogenation*

MBOC7 ptr ch02 049-114.indd 62 08/12/21 11:24 AM

reactions are oxidations. It is especially easy to tell whether an organic molecule is being oxidized or reduced: reduction is occurring if its number of C–H bonds increases, whereas oxidation is occurring if its number of C–H bonds decreases (see Figure 2–20B).

Cells use enzymes to catalyze the oxidation of organic molecules in small steps, through a sequence of reactions that allows useful energy to be harvested. We now need to explain how enzymes work and some of the constraints under which they operate.

Enzymes Lower the Activation-Energy Barriers That Block Chemical Reactions

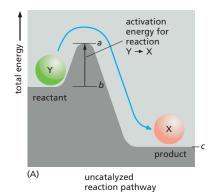

Consider the reaction

paper
$$+ O_2 \rightarrow$$
 smoke $+$ ashes $+$ heat $+ CO_2 + H_2O$

Once ignited, the paper burns readily, releasing to the atmosphere both energy as heat and water and carbon dioxide as gases. The reaction is irreversible, as the smoke and ashes never spontaneously retrieve these entities from the heated atmosphere and reconstitute themselves into paper. When the paper burns, its chemical energy is dissipated as heat—not lost from the universe, as energy can never be created or destroyed, but irretrievably dispersed in the chaotic random thermal motions of molecules. At the same time, the atoms and molecules of the paper become dispersed and disordered. In the language of thermodynamics, there has been a loss of *free energy*; that is, of energy that can be harnessed to do work or drive chemical reactions. This loss reflects a reduction of orderliness in the way the energy and molecules were stored in the paper.

We shall discuss free energy in more detail shortly, but the general principle is clear enough intuitively: chemical reactions proceed spontaneously only in the direction that leads to a loss of free energy. In other words, the spontaneous direction for any reaction is the direction that goes "downhill," where a "downhill" reaction is one that is *energetically favorable*.

Although the most energetically favorable form of carbon under ordinary conditions is CO_2 , and that of hydrogen is H_2O , a living organism does not disappear in a puff of smoke, and the paper book in your hands does not burst into flames. This is because the molecules both in the living organism and in the book are in a relatively stable state, and they cannot be changed to a state of lower energy without an input of energy; in other words, a molecule requires **activation energy—** a kick over an energy barrier—before it can undergo a chemical reaction that leaves it in a more stable state (**Figure 2–21**). In the case of a burning book, the activation energy can be provided by the heat of a lighted match. For the molecules in the watery solution inside a cell, the kick is delivered by an unusually energetic random collision with surrounding molecules.

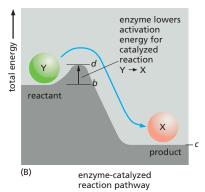

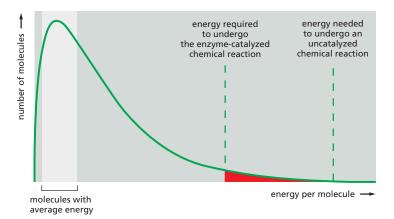

Figure 2-21 The important principle of activation energy. (A) Compound Y (a reactant) is in a relatively stable state, and energy is required to convert it to compound X (a product), even though X is at a lower overall energy level than Y. This conversion will not take place, therefore, unless compound Y can acquire enough activation energy (energy a minus energy b) from its surroundings to undergo the reaction that converts it into compound X. This energy may be provided by means of an unusually energetic collision with other molecules. For the reverse reaction, $X \rightarrow Y$, the activation energy will be much larger (energy a minus energy c); this reaction will therefore occur much more rarely. Activation energies are always positive; note, however, that the total energy change for the energetically favorable reaction $Y \rightarrow X$ is energy c minus energy b, a negative number. (B) Energy barriers for specific reactions can be lowered by catalysts, as indicated by the line marked d. Enzymes are particularly effective catalysts because they greatly reduce the activation energy for the reactions they perform.

MBOC7_ptr_ch02_049-114.indd 63 08/12/21 11:24 AM

The chemistry in a living cell is tightly controlled, because the kick over energy barriers is greatly aided by a specialized class of proteins—the **enzymes**. Each enzyme binds tightly to one or more molecules, called **substrates**, and holds them in a way that greatly reduces the activation energy of a particular chemical reaction that the bound substrates can undergo. A substance that can lower the activation energy of a reaction is termed a **catalyst**; catalysts increase the rate of chemical reactions because they allow a much larger proportion of the random collisions with surrounding molecules to kick the substrates over the energy barrier, as illustrated in **Figure 2–22**. Enzymes are among the most effective catalysts known: some are capable of speeding up reactions by factors of 10^{14} or more. Enzymes thereby allow reactions that would not otherwise occur to proceed rapidly at normal temperatures.

Enzymes Can Drive Substrate Molecules Along Specific Reaction Pathways

An enzyme cannot change the equilibrium point for a reaction. The reason is simple: when an enzyme (or any catalyst) lowers the activation energy for the reaction $Y \to X$, of necessity it also lowers the activation energy for the reverse reaction $X \to Y$ by exactly the same amount (see Figure 2–21). The forward and backward reactions will therefore be accelerated by the same factor by an enzyme, and the equilibrium point for the reaction will be unchanged (Figure 2–23).

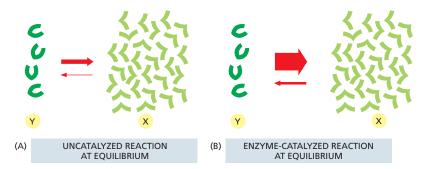

Figure 2–23 Enzymes cannot change the equilibrium point for reactions. Enzymes, like all catalysts, speed up the forward and backward rates of a reaction by the same factor. Therefore, for both the catalyzed and the uncatalyzed reactions shown here, the number of molecules undergoing the transition $X \to Y$ is equal to the number of molecules undergoing the transition $Y \to X$ when the ratio of X molecules to Y molecules is Y to 1. In other words, the two reactions will eventually reach exactly the same equilibrium point, although the catalyzed reaction will reach equilibrium much faster.

Figure 2-22 Lowering the activation energy greatly increases the probability of a reaction. At any given instant, a population of identical substrate molecules will have a range of energies, distributed as shown on the graph. The varying energies come from collisions with surrounding molecules, which make the substrate molecules jiggle, vibrate, and spin. For a molecule to undergo a chemical reaction. the energy of the molecule must exceed the activation-energy barrier for that reaction (dashed lines). For most biological reactions, this almost never happens without enzyme catalysis. Even with enzyme catalysis, the substrate molecules must experience a particularly energetic collision to react (red shaded area). Raising the temperature will also increase the number of molecules with sufficient energy to overcome the activation energy needed for a reaction; but in marked contrast to enzyme catalysis, this effect is nonselective, speeding up all reactions (Movie 2.2).

MBOC7_ptr_ch02_049-114.indd 64 08/12/21 11:24 AM

Figure 2–24 Directing substrate molecules through a specific reaction pathway by enzyme catalysis. A substrate molecule in a cell (green ball) is converted into a different molecule (red ball) by means of a series of enzyme-catalyzed reactions. As indicated (yellow box), several reactions are energetically favorable at each step, but only one is catalyzed by each enzyme. Sets of enzymes thereby determine the exact reaction pathway that is followed by each molecule inside the cell.

Thus no matter how much an enzyme speeds up a reaction, it cannot change its direction.

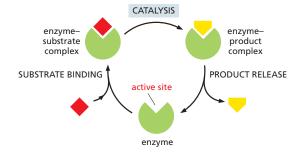

Despite the above limitation, enzymes steer all of the reactions in cells through specific reaction paths. This is because enzymes are both highly selective and very precise, usually catalyzing only one particular reaction. In other words, each enzyme selectively lowers the activation energy of only one of the several possible chemical reactions that its bound substrate molecules could undergo. In this way, sets of enzymes can direct each of the many different molecules in a cell along a particular reaction pathway (Figure 2–24).

The success of living organisms is attributable to a cell's ability to make enzymes of many types, each with precisely specified properties. Each enzyme has a unique shape containing an *active site*, a pocket or groove in the enzyme into which only particular substrates will fit (Figure 2–25). Like all other catalysts, enzyme molecules themselves remain unchanged after participating in a reaction and therefore can function over and over again. In Chapter 3, we discuss further how enzymes work.

How Enzymes Find Their Substrates: The Enormous Rapidity of Molecular Motions

An enzyme will often catalyze the reaction of thousands of substrate molecules every second. This means the enzyme must be able to bind a new substrate molecule in a fraction of a millisecond. But both enzymes and their substrates are present in relatively small numbers in a cell. How do they find each other so fast? Rapid binding is possible because the motions caused by heat energy are enormously fast at the molecular level. These molecular motions can be classified broadly into three kinds: (1) the movement of a molecule from one place to another (*translational motion*), (2) the rapid back-and-forth movement of covalently linked atoms with respect to one another (*vibrations*), and (3) *rotations*. All three of these motions help to bring the surfaces of interacting molecules together.

The rates of molecular motions can be measured by a variety of spectroscopic techniques. A large globular protein is constantly tumbling, rotating about its axis approximately a million times per second. Molecules are also in constant translational motion, which causes them to explore the space inside the cell very efficiently by wandering through it—a process called **diffusion**. In this way, every molecule in a cell collides with a huge number of other molecules each second. As the molecules in a liquid collide and bounce off one another, an individual molecule moves first one way and then another, its path constituting a *random*

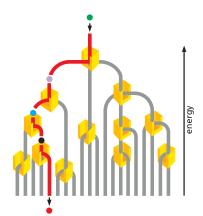

Figure 2–25 How enzymes work. Each enzyme has an active site to which one or more substrate molecules bind, forming an enzyme–substrate complex. A reaction occurs at the active site, producing an enzyme–product complex. The product is then released, allowing the enzyme to bind further substrate molecules.

MBOC7_ptr_ch02_049-114.indd 65 08/12/21 11:24 AM

walk (Figure 2-26). In such a walk, the average net distance that each molecule travels (as the "crow flies") from its starting point is proportional to the square root of the time involved; that is, if it takes a molecule 1 second on average to travel 1 μ m, it takes 4 seconds to travel 2 μ m, 100 seconds to travel 10 μ m, and so on.

The inside of a cell is very crowded (Figure 2-27). Nevertheless, experiments in which fluorescent dyes and other labeled molecules are injected into cells show that small organic molecules diffuse through the watery gel of the cytosol nearly as rapidly as they do through water. A small organic molecule, for example, takes only about one-fifth of a second on average to diffuse a distance of $10~\mu m$. Diffusion is therefore an efficient way for small molecules to move the limited distances in the cell (a typical animal cell is $15~\mu m$ in diameter).

Proteins also move rapidly in cells. But because enzymes move more slowly than substrates, we can think of them as sitting still. The rate of encounter of each enzyme molecule with its substrate will depend on the concentration of the substrate molecule. For example, some abundant substrates are present at a concentration of 0.5 mM. As pure water is 55.5 M, there is only about one such substrate molecule in the cell for every 10⁵ water molecules. Nevertheless, the active site on an enzyme molecule that binds this substrate will be bombarded by about 500,000 random collisions with the substrate molecule per second. (For a substrate concentration tenfold lower, the number of collisions drops to 50,000 per second, and so on.) A random collision between the active site of an enzyme and the matching surface of its substrate molecule often leads immediately to the formation of an enzyme–substrate complex. A reaction in which a covalent bond is broken or formed can then occur extremely rapidly. When one appreciates how quickly molecules move and react, the observed rates of enzymatic catalysis do not seem so amazing.

Two molecules that are held together by noncovalent bonds can also dissociate. The multiple weak noncovalent bonds that they form with each other will persist until random thermal motion causes the two molecules to separate. In general, the stronger the binding of the enzyme and substrate, the slower their rate of dissociation. In contrast, whenever two colliding molecules have poorly matching surfaces, they form few noncovalent bonds and the total energy of association will be negligible compared with that of thermal motion. In this case, the two molecules dissociate as rapidly as they come together, preventing incorrect and unwanted associations between mismatched molecules, such as between an enzyme and the wrong substrate.

The Free-Energy Change for a Reaction, ΔG , Determines Whether It Can Occur Spontaneously

Although enzymes speed up reactions, they cannot by themselves force energetically unfavorable reactions to occur. In terms of a water analogy, enzymes by themselves cannot make water run uphill. Cells, however, must do just that in order to grow and divide: they must build highly ordered and energy-rich molecules from small and simple ones. We shall see that this is done through enzymes that directly *couple* energetically favorable reactions, which release energy and produce heat, to energetically unfavorable reactions, which produce biological order.

What do cell biologists mean by the term "energetically favorable," and how can this be quantified? According to the second law of thermodynamics, the universe tends toward maximum disorder (largest *entropy* or greatest probability). Thus, a chemical reaction can proceed spontaneously only if it results in a net increase in the disorder of the universe (see Figure 2–16). This disorder of the universe can be expressed most conveniently in terms of the *free energy* of a system, a concept we touched on earlier.

Free energy, G, is an expression of the *energy available to do work*; for example, the work of driving chemical reactions. The value of G is of interest only when a system undergoes a *change*. The **free-energy change**, denoted ΔG (delta G), is critical because, as explained in **Panel 2-7** (pp. 106–107), it is a direct measure of the

Figure 2–26 A random walk. Molecules in solution move in a random fashion as a result of the continual buffeting they receive in collisions with other molecules. This movement allows small molecules to diffuse rapidly from one part of the cell to another, as described in the text (Movie 2.3).

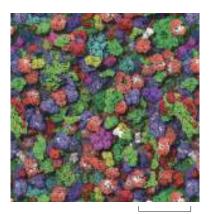

Figure 2–27 The crowded structure of the cell interior. Only the macromolecules, which are drawn to scale and displayed in different colors, are shown. Enzymes and other macromolecules diffuse relatively slowly inside the cell, in part because they interact with many other macromolecules; small molecules, by contrast, diffuse nearly as rapidly as they do in water (Movie 2.4). (From S.R. McGuffee and A.H. Elcock, PLoS Comput. Biol. 6(3):e1000694, 2010.)

MBOC7_ptr_ch02_049-114.indd 66

amount of disorder created in the universe when a reaction takes place. Energetically favorable reactions, by definition, are those that decrease free energy; in other words, they have a *negative* ΔG and disorder the universe (Figure 2–28).

An example of an energetically favorable reaction on a macroscopic scale is the "reaction" by which a compressed spring relaxes to an expanded state, releasing its stored elastic energy as heat to its surroundings; an example on a microscopic scale is salt dissolving in water. Conversely, energetically unfavorable reactions with a positive ΔG —such as the joining of two amino acids to form a peptide bond—by themselves create order in the universe. Therefore, these reactions can take place only if they are coupled to a second reaction with a *negative* ΔG so large that the ΔG of the overall process is negative (**Figure 2–29**).

The Concentration of Reactants Influences the Free-Energy Change and a Reaction's Direction

As we have just described, a reaction $Y \leftrightarrow X$ will go in the direction $Y \to X$ when the associated free-energy change, ΔG , is negative, just as a tensed spring left to itself will relax and lose its stored energy to its surroundings as heat. For a chemical reaction, however, ΔG depends not only on the energy stored in each individual molecule but also on the concentrations of the molecules in the reaction mixture. Remember that ΔG reflects the degree to which a reaction creates a more disordered—in other words, a more probable—state of the universe. Recalling our coin analogy, it is very likely that a coin will flip from a head to a tail orientation if a jiggling box contains 90 heads and 10 tails, but this is a less probable event if the box has 10 heads and 90 tails.

The same is true for a chemical reaction. For a reversible reaction $Y \leftrightarrow X$, a large excess of Y over X will tend to drive the reaction in the direction $Y \to X$. Therefore, as the ratio of Y to X increases, the ΔG becomes more negative for the transition $Y \to X$ (and more positive for the transition $X \to Y$).

The amount of concentration difference that is needed to compensate for a given decrease in chemical-bond energy (and accompanying heat release) is not intuitively obvious. In the late nineteenth century, the relationship was determined through a thermodynamic analysis that makes it possible to separate the concentration-dependent and the concentration-independent parts of the free-energy change, as we describe next.

The Standard Free-Energy Change, ΔG° , Makes It Possible to Compare the Energetics of Different Reactions

Because ΔG depends on the concentrations of the molecules in the reaction mixture at any given time, it is not a particularly useful value for comparing the relative energies of different types of reactions. To consider reactions on a comparable basis, we need to turn to the **standard free-energy change** of a reaction, ΔG° . The ΔG° is the change in free energy under a standard condition, defined as that where the concentrations of all the reactants are set to the same fixed value of 1 mole/liter. Defined in this way, ΔG° depends only on the intrinsic characters of the reacting molecules.

For the simple reaction Y \rightarrow X at 37°C, ΔG° is related to ΔG as follows:

$$\Delta G = \Delta G^{\circ} + RT \ln \frac{[X]}{[Y]}$$

where ΔG is in kilojoules per mole, [Y] and [X] denote the concentrations of Y and X in moles/liter, ln is the *natural logarithm*, and *RT* is the product of the gas constant, R, and the absolute temperature, T. At 37° C, RT = 2.58 kJ mole⁻¹. (A mole is 6×10^{23} molecules of a substance.)

A large body of thermodynamic data has been collected that has made it possible to determine the standard free-energy change, ΔG° , for the important metabolic reactions of a cell. Given these ΔG° values, combined with additional information about metabolite concentrations and reaction pathways, it is possible to quantitatively predict the course of most biological reactions.

ENERGETICALLY REACTION

The free energy of Y is greater than the free energy of X. Therefore $\Delta G < 0$, and the disorder of the universe increases during the reaction

this reaction can occur spontaneously

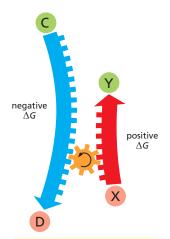

ENERGETICALLY UNFAVORABLE REACTION

universe would become more ordered.

this reaction can occur only if it is coupled to a second. energetically favorable reaction

Figure 2-28 The distinction between energetically favorable and energetically unfavorable reactions, and how they relate to ΔG .

the energetically unfavorable reaction $X \rightarrow Y$ is driven by the energetically favorable reaction $C \rightarrow D$, because the net free-energy change for the pair of coupled reactions is less

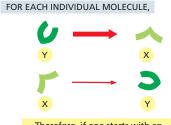

Figure 2-29 How reaction coupling is used to drive energetically unfavorable reactions.

MBOC7_ptr_ch02_049-114.indd 67 08/12/21 11:24 AM

FOR THE ENERGETICALLY FAVORABLE REACTION $Y \rightarrow X$,

if X and Y are at equal concentrations, [Y] = [X], the formation of X is energetically favored. In other words, the ΔG of Y ightarrow X is negative and the ΔG of X \rightarrow Y is positive. Nevertheless because of thermal bombardments,

there will always be some X converting to Y.

Therefore, if one starts with an equal mixture, the ratio of X to Y molecules will increase

Figure 2-30 Chemical equilibrium. When a reaction reaches equilibrium, the forward and backward fluxes of reacting molecules are equal and opposite. In these diagrams, the widths of the red arrows indicate the relative rates at which an individual molecule reacts.

conversion of Y to X will occur often.

Conversion of X to Y will occur less often than the transition $Y \rightarrow X$, because it requires a more energetic collision.

EVENTUALLY, there will be a large enough excess of X over Y to just compensate for the slow rate of $X \to Y$, such that the number of X molecules being converted to Y molecules each second is exactly equal to the number of Y molecules being converted to X molecules each second. At this point, the reaction will be at equilibrium.

AT EQUILIBRIUM, there is no net change in the ratio of Y to X, and the

The Equilibrium Constant and ΔG° Are Readily Derived from Each Other

Inspection of the above equation reveals that the ΔG equals the value of ΔG° when the concentrations of Y and X are equal. But as any favorable reaction proceeds, the concentrations of the products will increase as the concentration of the substrates decreases. This change in relative concentrations will cause [X]/[Y] to become increasingly large, making the initially favorable ΔG less and less negative (the logarithm of a number x is positive for x > 1, negative for x < 1, and zero for x = 1). Eventually, when $\Delta G = 0$, a chemical **equilibrium** will be attained; here there is no net change in free energy to drive the reaction in either direction, inasmuch as the concentration effect just balances the push given to the reaction by ΔG° . As a result, the ratio of product to substrate reaches a constant value at chemical equilibrium (Figure 2-30).

We can define the **equilibrium constant**, K, for the reaction $Y \rightarrow X$ as

$$K = \frac{[X]}{[Y]}$$

where [X] is the concentration of the product and [Y] is the concentration of the reactant at equilibrium. Remembering that $\Delta G = \Delta G^{\circ} + RT \ln [X]/[Y]$, and that $\Delta G = 0$ at equilibrium, we see that

$$\Delta G^{\circ} = -RT \ln \frac{[X]}{[Y]} = -RT \ln K$$

MBOC7_ptr_ch02_049-114.indd 68 08/12/21 11:24 AM At 37°C, where RT = 2.58, the equilibrium equation is therefore:

$$\Delta G^{\circ} = -2.58 \ln K$$

Converting this equation from the natural logarithm (ln) to the more commonly used base 10 logarithm (log), we get

$$\Delta G^{\circ} = -5.94 \log K$$

The above equation reveals how the equilibrium ratio of X to Y (expressed as the equilibrium constant, K) depends on the intrinsic character of the molecules (as expressed in the value of ΔG° in kilojoules per mole). The more energetically favorable a reaction, the more product will accumulate when the reaction proceeds to equilibrium. More precisely, for every 5.94 kJ/mole difference in free energy at 37°C, the equilibrium constant changes by a factor of 10 (Table 2–2). Note that this amount of free-energy difference is roughly equivalent to the free energy available from a single hydrogen bond.

More generally, for a reaction that has multiple reactants and products, such as $A+B \mathop{\rightarrow} C + D$,

$$K = \frac{[C][D]}{[A][B]}$$

The concentrations of the two reactants and the two products are multiplied because the rate of the forward reaction depends on the collision of A and B and the rate of the backward reaction depends on the collision of C and D. Thus, at 37°C,

$$\Delta G^{\circ} = -5.94 \log \frac{[C][D]}{[A][B]}$$

where ΔG° is in kilojoules per mole, and [A], [B], [C], and [D] denote the concentrations of the reactants and products in moles/liter.

The Free-Energy Changes of Coupled Reactions Are Additive

We have pointed out that unfavorable reactions can be coupled to favorable ones to drive the unfavorable ones forward (see Figure 2–29). In thermodynamic terms, this is possible because the overall free-energy change for a set of coupled reactions is the sum of the free-energy changes in each of its component steps. Consider, as a simple example, two sequential reactions

$$X \rightarrow Y$$
 and $Y \rightarrow Z$

whose ΔG° values are +5 and -13 kJ/mole, respectively. If these two reactions occur sequentially, the ΔG° for the coupled reaction will be -8 kJ/mole. This means that, with appropriate conditions, the unfavorable reaction $X \to Y$ can be driven by the favorable reaction $Y \to Z$, provided that this second reaction follows the first. For example, several of the reactions in the long pathway that converts sugars into CO_2 and H_2O have positive ΔG° values. But the pathway nevertheless proceeds because the total ΔG° for the series of sequential reactions has a large negative value.

Forming a sequential pathway is not adequate for many purposes. Often the desired pathway is simply $X \to Y$, without further conversion of Y to some other product. Fortunately, there are other more general ways of using enzymes to couple reactions together. In order to explain how this is possible, we need to introduce the activated carrier molecules that we discuss next.

Activated Carrier Molecules Are Essential for Biosynthesis

To make life possible, the energy released by the oxidation of food molecules must be stored temporarily before it can be channeled into the construction of the many other molecules needed by the cell. In most cases, the energy is stored as chemical-bond energy in a small set of activated "carrier molecules," which contain one or more energy-rich covalent bonds. These molecules diffuse rapidly throughout the cell and thereby carry their bond energy from sites of energy

TABLE 2–2 Relationship Between the Standard Free-Energy Change, ΔG° , and the Equilibrium Constant				
Equilibrium constant $\frac{[X]}{[Y]} = K$	Free energy of X minus free energy of Y [kJ/mole (kcal/ mole)]			
10 ⁵	<i>–</i> 29.7 (<i>–</i> 7.1)			
10 ⁴	-23.8 (-5.7)			
10 ³	-17.8 (-4.3)			
10 ²	-11.9 (-2.8)			
10 ¹	-5.9 (-1.4)			
1	0 (0)			
10 ⁻¹	5.9 (1.4)			
10 ⁻²	11.9 (2.8)			
10 ⁻³	17.8 (4.3)			
10 ⁻⁴	23.8 (5.7)			

Values of the equilibrium constant were calculated for the simple chemical reaction Y \leftrightarrow X using the equation given in the text. The ΔG° given here is in kilojoules per mole at 37°C, with kilocalories per mole in parentheses. One kilojoule (kJ) is equal to 0.239 kilocalories (kcal) (1 kcal = 4.18 kJ). As explained in the text, ΔG° represents the free-energy difference under standard conditions (where all components are present at a concentration of 1.0 mole/ liter).

29.7 (7.1)

10-5

From this table, we see that if there is a favorable standard free-energy change (ΔG°) of -17.8 kJ/mole (-4.3 kcal/mole) for the transition Y \rightarrow X, there will be 1000 times more molecules in state X than in state Y at equilibrium (K=1000).

MBOC7_ptr_ch02_049-114.indd 69 08/12/21 11:24 AM

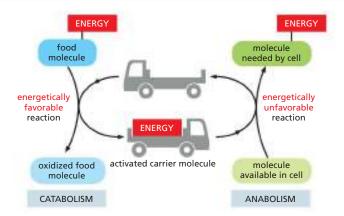

Figure 2–31 Energy transfer and the role of activated carriers in metabolism. By serving as energy shuttles, activated carrier molecules perform their function as go-betweens that link the breakdown of food molecules and the release of energy (catabolism) to the energy-requiring biosynthesis of small and large organic molecules (anabolism).

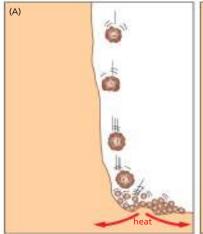

generation to the sites where the energy will be used for biosynthesis and other cell activities (Figure 2-31).

The **activated carriers** store energy in an easily exchangeable form, either as a readily transferable chemical group or as electrons held at a high energy level, and they can serve a dual role as a source of both energy and chemical groups in biosynthetic reactions. For historical reasons, these molecules are also sometimes referred to as *coenzymes*. The most important of the activated carrier molecules are ATP and two molecules that are closely related to each other, NADH and NADPH. As we discuss next, coupled reactions allow cells both to generate such activated carrier molecules and to use them like money to pay for reactions that otherwise could not take place.

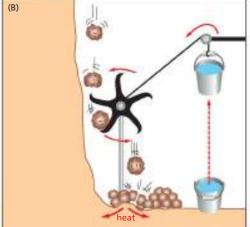

The Formation of an Activated Carrier Is Coupled to an Energetically Favorable Reaction

Coupling mechanisms require enzymes and are fundamental to all the energy transactions of the cell. The nature of a **coupled reaction** is illustrated by a mechanical analogy in **Figure 2–32**, in which an energetically favorable chemical reaction is represented by rocks falling from a cliff. The energy of falling rocks would normally be entirely wasted in the form of heat generated by friction when the rocks hit the ground (see the falling-brick diagram in Figure 2–17). By careful design, however, part of this energy could be used instead to drive a paddle wheel

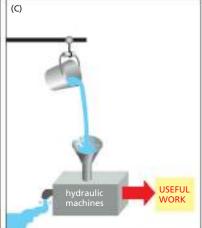

Figure 2–32 A mechanical model illustrating the principle of coupled chemical reactions. The spontaneous reaction shown in (A) could serve as an analogy for the direct oxidation of glucose to CO_2 and H_2O , which produces heat only. In (B), the same reaction is coupled to a second reaction; this second reaction is analogous to the synthesis of activated carrier molecules. The energy produced in (B) is in a more useful form than in (A) and can be used to drive a variety of otherwise energetically unfavorable reactions (C).

kinetic energy of falling rocks is transformed into heat energy only

part of the kinetic energy is used to lift a bucket of water, and a correspondingly smaller amount is transformed into heat

the potential kinetic energy stored in the raised bucket of water can be used to drive hydraulic machines that carry out a variety of useful tasks

that lifts a bucket of water (Figure 2–32B). Because the rocks can now reach the ground only after moving the paddle wheel, we say that the energetically favorable reaction of rock falling has been directly *coupled* to the energetically unfavorable reaction of lifting the bucket of water. Note that because part of the energy is used to do work in Figure 2–32B, the rocks hit the ground with less velocity than in Figure 2–32A, and correspondingly less energy is dissipated as heat.

Similar processes occur in cells, where enzymes play the role of the paddle wheel. By mechanisms that we discuss later in this chapter, enzymes couple an energetically favorable reaction, such as the oxidation of foodstuffs, to an energetically unfavorable reaction, such as the generation of an activated carrier molecule. As in this example, the amount of heat released by the oxidation reaction is reduced by exactly the amount of energy stored in the energy-rich covalent bonds of the activated carrier molecule. And the activated carrier molecule picks up a packet of energy of a size sufficient to power a chemical reaction elsewhere in the cell.

ATP Is the Most Widely Used Activated Carrier Molecule

The most important and versatile of the activated carriers in cells is ATP (adenosine triphosphate). Just as the energy stored in the raised bucket of water in Figure 2–32B can drive a wide variety of hydraulic machines, ATP is a convenient and versatile store, or currency, of energy used to drive a huge variety of chemical reactions in cells. ATP is synthesized by coupling a reaction that is highly energetically favorable to an energetically unfavorable phosphorylation reaction in which a phosphate group is added to ADP (adenosine diphosphate). When required, ATP gives up its energy packet through its energetically favorable hydrolysis to ADP and inorganic phosphate (Figure 2–33). The regenerated ADP is then available to be used for another round of the phosphorylation reaction that forms ATP.

The two outermost phosphate groups in ATP are said to be held to the rest of the molecule by "high-energy" covalent bonds, because each of these phosphoanhydride linkages releases a great deal of free energy when hydrolyzed. The unusually large negative free-energy change for these hydrolysis reactions arises from a number of factors. The release of the terminal phosphate group when ATP forms ADP removes an unfavorable repulsion between adjacent negative charges; in addition, the inorganic phosphate ion released is stabilized both by resonance and by favorable hydrogen-bond formation with water.

The energetically favorable reaction of ATP hydrolysis is coupled to many otherwise unfavorable reactions through which needed molecules are synthesized.

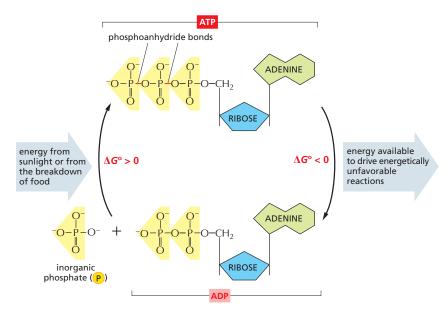

Figure 2–33 The interconversion of ATP and ADP occurs in a cycle. The two outermost phosphates in ATP are held to the rest of the molecule by "highenergy" phosphoanhydride bonds and are readily hydrolyzed or transferred to other molecules. Water can be added to ATP to form ADP and inorganic phosphate. This hydrolysis of the terminal phosphate of ATP yields between 46 and 54 kJ/mole of usable energy, depending on the intracellular conditions. (Although the ΔG° of this reaction is -30.5 kJ/mole, its ΔG inside cells is much more negative, because the ratio of ATP to the products ADP and phosphate is kept so high.)

The formation of ATP from ADP and phosphate reverses the hydrolysis reaction; because this condensation reaction is energetically unfavorable, it must be coupled to a highly energetically favorable reaction to occur.

MBOC7_ptr_ch02_049-114.indd 71 08/12/21 11:25 AM

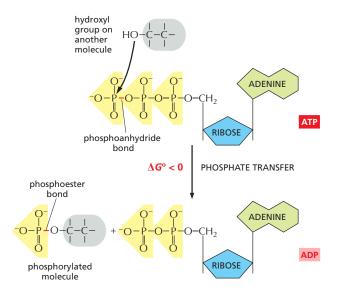

Figure 2–34 An example of a phosphate transfer reaction. Because an energyrich phosphoanhydride bond in ATP is converted to a phosphoester bond, this reaction is energetically favorable, having a large negative ΔG . Reactions of this type are involved in the synthesis of phospholipids and in the initial steps of reactions that catabolize sugars, as well as in many other metabolic pathways.

Many of these coupled reactions involve the transfer of the terminal phosphate in ATP to another molecule, as illustrated by the phosphorylation reaction in **Figure 2-34**.

As the most abundant activated carrier in cells, ATP is the principal energy currency. To give just two examples, it supplies energy for many of the pumps that transport substances into and out of the cell (discussed in Chapter 11), and it powers the molecular motors that enable muscle cells to contract and nerve cells to transport materials from one end of their long axons to another (discussed in Chapter 16).

Energy Stored in ATP Is Often Harnessed to Join Two Molecules Together

We have previously discussed one way in which an energetically favorable reaction can be coupled to an energetically unfavorable reaction, $X \to Y$, so as to enable it to occur. In that scheme, a second enzyme catalyzes the energetically favorable reaction $Y \to Z$, pulling all of the X to Y in the process. But when the required product is Y and not Z, this mechanism is not useful.

A typical biosynthetic reaction is one in which two molecules, A and B, are joined together to produce A–B in the energetically unfavorable *condensation* reaction

$$B-H + A-OH \rightarrow A-B + H_2O$$

There is an indirect pathway that allows B–H and A–OH to form A–B, in which a coupling to ATP hydrolysis makes the reaction go. Here, energy from ATP hydrolysis is first used to convert A–OH to a higher-energy intermediate compound, which then reacts directly with B–H to give A–B. The simplest possible mechanism involves the transfer of a phosphate from ATP to A–OH to make A–O–PO₃, in which case the reaction pathway contains only two steps:

- 1. $A-OH + ATP \rightarrow A-O-PO_3 + ADP$
- 2. $B-H + A-O-PO_3 \rightarrow A-B + phosphate$

Net result: A-OH + ATP + B-H \rightarrow A-B + ADP + phosphate

The condensation reaction, which by itself is energetically unfavorable, is forced to occur by being directly coupled to ATP hydrolysis in an enzyme-catalyzed reaction pathway (Figure 2–35A).

A biosynthetic reaction of exactly this type synthesizes the amino acid glutamine (Figure 2-35B). We will see shortly that similar (but more complex) mechanisms are also used to produce nearly all of the large molecules of the cell.

MBOC7_ptr_ch02_049-114.indd 72 08/12/21 11:25 AM

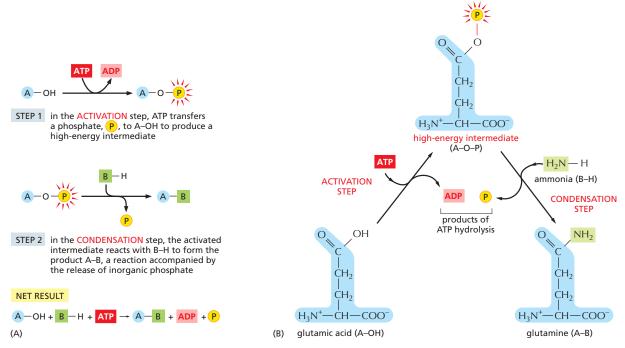

Figure 2–35 An example of an energetically unfavorable biosynthetic reaction driven by ATP hydrolysis. (A) Schematic illustration of the condensation reaction described in the text. In this set of reactions, a phosphate group is first donated by ATP to form a high-energy intermediate, A–O–PO $_3$, which then reacts with the other substrate, B–H, to form the product A–B. (B) Reaction showing the biosynthesis of the amino acid glutamine from glutamic acid. Glutamic acid, which corresponds to the A–OH shown in (A), is first converted to a high-energy phosphorylated intermediate, which corresponds to A–O–PO $_3$. This intermediate then reacts with ammonia (which corresponds to B–H) to form glutamine. In this example, both steps occur on the surface of the same enzyme, glutamine synthetase (not shown). ATP hydrolysis can drive this energetically unfavorable reaction because it produces a favorable free-energy change (ΔG° of -30.5 kJ/mole) that is larger in magnitude than the energy required for the synthesis of glutamine from glutamic acid plus NH $_3$ (ΔG° of +14.2 kJ/mole). For clarity, the glutamic acid side chain is shown in its uncharged form.

NADH and NADPH Are Important Electron Carriers

Other important activated carrier molecules participate in oxidation–reduction reactions and are commonly part of coupled reactions in cells. These activated carriers are specialized to carry electrons held at a high energy level (sometimes called "high-energy" electrons) and hydrogen atoms. The most important of these electron carriers are NAD^+ (nicotinamide adenine dinucleotide) and the closely related molecule $NADP^+$ (nicotinamide adenine dinucleotide phosphate). As part of an enzyme-catalyzed reaction in which a substrate molecule is oxidized, each picks up a "packet of energy" corresponding to two electrons plus a proton (H^+) , and they are thereby converted to NADH (reduced nicotinamide adenine dinucleotide) and NADPH (reduced nicotinamide adenine dinucleotide phosphate), respectively (Figure 2–36). These molecules can therefore be regarded as carriers of hydride ions (the H^+ plus two electrons, or H^-).

Like ATP, NADPH is an activated carrier that participates in many important biosynthetic reactions that would otherwise be energetically unfavorable. The NADPH is produced according to the general scheme shown in Figure 2–36A. During a special set of energy-yielding catabolic reactions, two hydrogen atoms are removed from a substrate molecule. Both electrons but just one hydrogen atom (that is, a hydride ion, ${\rm H}^-$) are added to the nicotinamide ring of NADP+ to form NADPH; the second hydrogen atom is released as a proton $({\rm H}^+)$ into solution. This is a typical oxidation–reduction reaction, in which the substrate is oxidized and NADP+ is reduced.

NADPH readily gives up the hydride ion it carries in a subsequent oxidationreduction reaction, because the nicotinamide ring can achieve a more stable

MBOC7_ptr_ch02_049-114.indd 73 08/12/21 11:25 AM

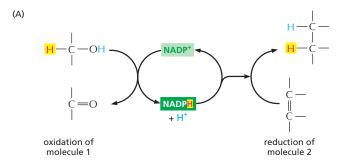

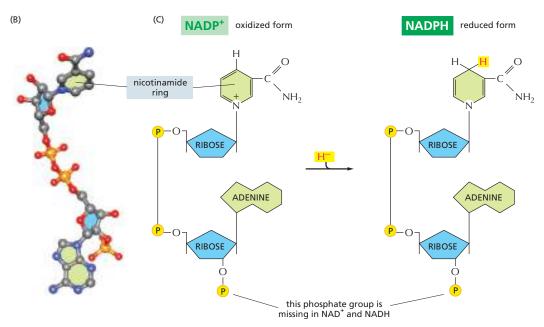

Figure 2–36 NADPH, an important carrier of electrons. (A) NADPH is produced in reactions of the general type shown on the left, in which two hydrogen atoms are removed from a substrate. The oxidized form of the carrier molecule, NADP+, receives one hydrogen atom plus an electron (a hydride ion); the other H atom is released as a proton (H+) into solution. Because NADPH holds its hydride ion in a high-energy linkage, the hydride ion can easily be transferred to other molecules, as shown on the right. (B) and (C) The structures of NADP+ and NADPH. The part of the NADP+ molecule known as the nicotinamide ring accepts the hydride ion, H-, forming NADPH. The molecules NAD+ and NADH are identical in structure to NADP+ and NADPH, respectively, except that they lack the indicated phosphate group.

arrangement of electrons without it. In this subsequent reaction, which regenerates NADP⁺, it is the NADPH that is oxidized and the substrate that is reduced. The NADPH is an effective donor of its hydride ion to other molecules for the same reason that ATP readily transfers a phosphate: in both cases the transfer is accompanied by a large negative free-energy change. One example of the use of NADPH in biosynthesis is shown in Figure 2–37.

The extra phosphate group on NADPH has no effect on the electron-transfer properties of NADPH compared with NADH, being far away from the region involved in electron transfer (see Figure 2–36C). It does, however, give a molecule of NADPH a slightly different shape from that of NADH, making it possible for NADPH and NADH to bind as substrates to completely different sets of enzymes. Thus, the two types of carriers are used to transfer electrons (or hydride ions) between two different sets of molecules.

Why should there be this division of labor? The answer lies in the need to regulate two sets of electron-transfer reactions independently. NADPH operates chiefly with enzymes that catalyze anabolic reactions, supplying the high-energy electrons needed to synthesize energy-rich biological molecules. NADH, by contrast, has a special role as an intermediate in the catabolic system of reactions that generate ATP through the oxidation of food molecules, as we will discuss shortly. The geneses of NADH from NAD⁺ and of NADPH from NADP⁺ occur by different pathways and are independently regulated so that the cell can adjust the supply of electrons for these two contrasting purposes. Inside the cell the ratio of NAD⁺ to NADPH is kept low. This

MBOC7_ptr_ch02_049-114.indd 74 08/12/21 11:25 AM

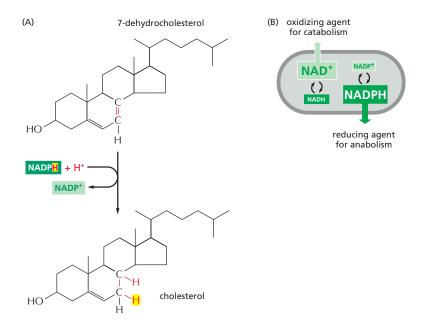

Figure 2-37 NADPH as a reducing agent. (A) The final stage in a biosynthetic route leading to cholesterol. As in many other biosynthetic reactions, the reduction of the C=C bond is achieved by the transfer of a hydride ion from the carrier molecule NADPH, plus a proton (H+) from the solution. (B) Keeping NADPH levels high and NADH levels low alters the redox potential for each of the two redox pairs-NADPH:NADP+ and NADH:NAD-(see Panel 14-1, p. 825). It causes NADPH to be a much stronger electron donor (reducing agent) than NADH, and it causes NAD+ to be a much better electron acceptor (oxidizing agent) than NADP+, as indicated.

provides plenty of NAD $^+$ to act as an oxidizing agent and plenty of NADPH to act as a reducing agent (Figure 2–37B)—as required for their special roles in catabolism and anabolism, respectively.

There Are Many Other Activated Carrier Molecules in Cells

Other activated carriers also pick up and carry a chemical group in an easily transferred, high-energy linkage. For example, coenzyme A carries a readily transferable acetyl group in a thioester linkage and in this activated form is known as **acetyl CoA** (acetyl coenzyme A). Acetyl CoA (Figure 2–38) is used to add two carbon units in the biosynthesis of larger molecules.

In acetyl CoA, as in other carrier molecules, the transferable group makes up only a small part of the molecule. The rest consists of a large organic portion that serves as a convenient "handle," facilitating the recognition of the carrier molecule by specific enzymes. As with acetyl CoA, this handle portion very often contains a nucleotide derivative (usually adenosine diphosphate), a curious fact that may be a relic from an early stage of evolution. It is currently thought that the main catalysts for early life-forms—before DNA or proteins—were RNA molecules (or

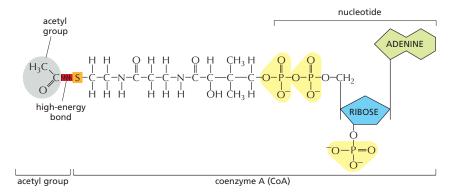

Figure 2–38 The structure of the important activated carrier molecule acetyl CoA. The sulfur atom (orange) forms a thioester bond to acetate. Because this is a high-energy linkage, releasing a large amount of free energy when it is hydrolyzed, the acetate molecule can be readily transferred to other molecules.

MBOC7_ptr_ch02_049-114.indd 75 08/12/21 11:25 AM

TABLE 2-3 Some Activated Carrier Molecules Widely Used in Metabolism

their close relatives), as described in Chapter 6. It is tempting to speculate that many of the carrier molecules that we find today originated in this earlier RNA world, where their nucleotide portions could have been useful for binding them to RNA enzymes (ribozymes).

Thus, ATP transfers phosphate, NADPH transfers electrons and hydrogen, and acetyl CoA transfers two-carbon acetyl groups. FADH₂ (reduced flavin adenine dinucleotide) is used like NADH in electron and proton transfers (Figure 2–39). The reactions of other activated carrier molecules involve the transfer of a methyl, carboxyl, or glucose group for biosyntheses (Table 2–3). These activated carriers are generated in reactions that are coupled to ATP hydrolysis, as in the example in Figure 2–40. Therefore, the energy that enables their groups to be used for biosynthesis ultimately comes from the catabolic reactions that generate ATP. Similar processes occur in the synthesis of the very large molecules of the cell—the nucleic acids, proteins, and polysaccharides—that we discuss next.

The Synthesis of Biological Polymers Is Driven by ATP Hydrolysis

As discussed previously, the macromolecules of the cell constitute most of its dry mass (see Figure 2–7). These molecules are made from subunits (or monomers) that are linked together in a *condensation* reaction, in which the constituents of a

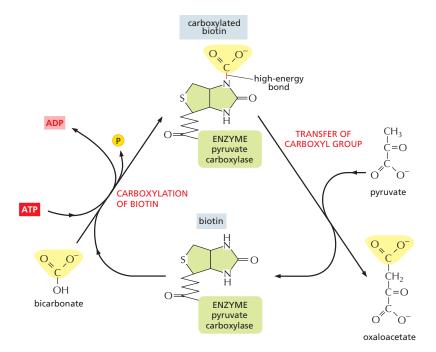

Figure 2–39 FADH₂ is a carrier of hydrogens and high-energy electrons, like NADH and NADPH. (A) Structure of FADH₂, with its hydrogen-carrying atoms highlighted in *yellow*. (B) The formation of FADH₂ from FAD (flavin adenine dinucleotide).

Figure 2–40 A carboxyl group–transfer reaction using an activated carrier molecule. Carboxylated biotin is used by the enzyme pyruvate carboxylase to transfer a carboxyl group in the production of oxaloacetate, a molecule needed for the citric acid cycle. The acceptor molecule for this group-transfer reaction is pyruvate. Other enzymes use biotin, a B-complex vitamin, to transfer carboxyl groups to other acceptor molecules. Note that synthesis of carboxylated biotin requires energy that is derived from ATP—a general feature of many activated carriers.

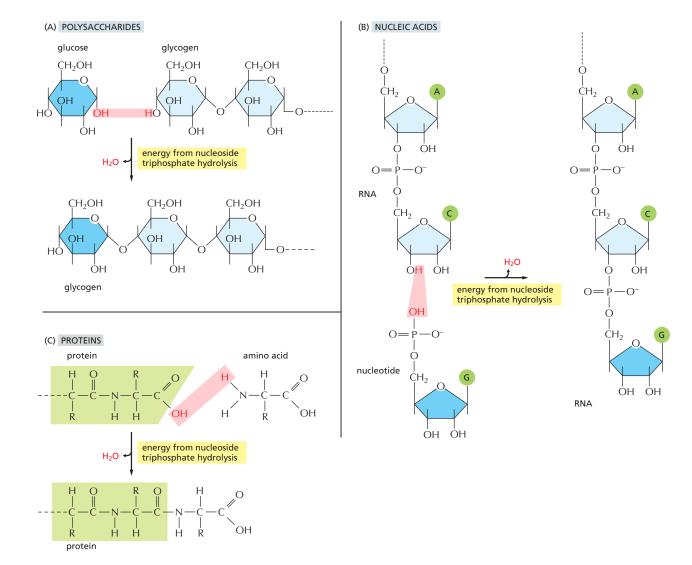

MBOC7_ptr_ch02_049-114.indd 76 08/12/21 11:25 AM

water molecule (OH plus H) are removed from the two reactants. Consequently, the reverse reaction—the breakdown of all three types of polymers—occurs by the enzyme-catalyzed addition of water (*hydrolysis*). This hydrolysis reaction is energetically favorable, whereas the biosynthetic reactions require an energy input (see Figure 2–9).

The nucleic acids (DNA and RNA), proteins, and polysaccharides are all polymers that are produced by the repeated addition of a monomer onto one end of a growing chain. The synthesis reactions for these three types of macromolecules are outlined in Figure 2–41. As indicated, the condensation step in each case depends on energy from nucleoside triphosphate hydrolysis. And yet, except for the nucleic acids, there are no phosphate groups left in the final product molecules. How are the reactions that release the energy of ATP hydrolysis coupled to polymer synthesis?

For each type of macromolecule, an enzyme-catalyzed pathway exists, which resembles that discussed previously for the synthesis of the amino acid glutamine (see Figure 2–35). The principle is exactly the same, in that the –OH group that will be removed in the condensation reaction is first activated by becoming involved in a high-energy linkage to a second molecule. However, the actual mechanisms used to link ATP hydrolysis to the synthesis of proteins and polysaccharides are more complex than that used for glutamine synthesis, inasmuch as more than

Figure 2-41 How energy is used to synthesize macromolecules. Synthesis of a portion of (A) a polysaccharide, (B) a nucleic acid, and (C) a protein is shown here. In each case, synthesis involves a condensation reaction in which water is lost; the atoms involved are shaded in pink. Not shown is the consumption of high-energy nucleoside triphosphates that is required to activate each subunit prior to its addition. In contrast, the reverse reaction—the breakdown of all three types of polymers—occurs through the simple addition of water, or hydrolysis (not shown), which is energetically favorable and does not require an energy carrier.

MBOC7_ptr_ch02_049-114.indd 77 08/12/21 11:25 AM

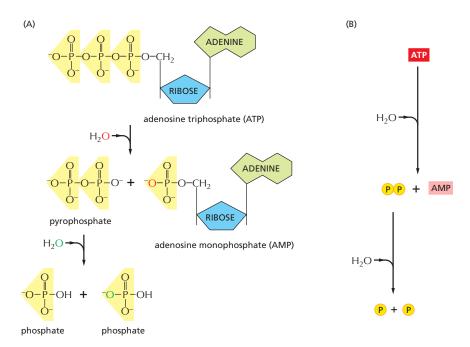

Figure 2–42 An alternative pathway of ATP hydrolysis, in which pyrophosphate is first formed and then hydrolyzed. This route releases about twice as much free energy (approximately –100 kJ/mole) as the reaction shown earlier in Figure 2–33, and it forms AMP instead of ADP. (A) In the two successive hydrolysis reactions, oxygen atoms from the participating water molecules are retained in the products, as indicated, whereas the hydrogen atoms dissociate to form free hydrogen ions (H⁺, not shown). (B) Summary of overall reaction.

one high-energy intermediate is required to generate the final high-energy bond that is broken during the condensation step (discussed in Chapter 6 for protein synthesis).

Each activated carrier has limits in its ability to drive a biosynthetic reaction. The ΔG for the hydrolysis of ATP to ADP and phosphate depends on the concentrations of all of the reactants, but under the usual conditions in a cell it is between -46 and -54 kJ/mole. In principle, this hydrolysis reaction could drive an unfavorable reaction with a ΔG of, perhaps, +40 kJ/mole, provided that a suitable reaction path is available. For some biosynthetic reactions, however, even -50 kJ/mole does not provide enough of a driving force. In these cases, the path of ATP hydrolysis can be altered so that it initially produces AMP and *pyrophosphate*, which is itself then hydrolyzed in a subsequent step (Figure 2–42). The whole process makes available a total free-energy change of about -100 kJ/mole. An important type of biosynthetic reaction that is driven in this way is the synthesis of nucleic acids (polynucleotides) from nucleoside triphosphates, as illustrated on the right side of Figure 2–43.

Note that the repetitive condensation reactions that produce macromolecules can be oriented in one of two ways, which differ in the position of the high-energy bond that drives polymerization. In so-called *polymer-end activation*, the reactive bond required for the condensation reaction is carried on the end of the growing polymer, and it must therefore be regenerated each time that a monomer is added. In this case, each monomer brings with it the reactive bond that will be used in adding the *next* monomer in the series. In *direct-monomer activation*, the reactive bond carried by each monomer is instead used immediately for its own addition (Figure 2–44).

We shall see in later chapters that both of these types of polymerization are used. The synthesis of DNA, RNA, and some simple polysaccharides occurs by direct-monomer activation, for example, whereas the synthesis of proteins occurs by a polymer-end activation process.

Summary

Living cells need to create and maintain order within themselves to survive and grow. This is thermodynamically possible only because of a continual input of energy, part of which must be released from the cells to their environment as heat

MBOC7_ptr_ch02_049-114.indd 78 08/12/21 11:25 AM

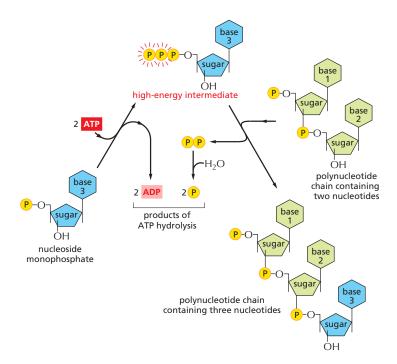

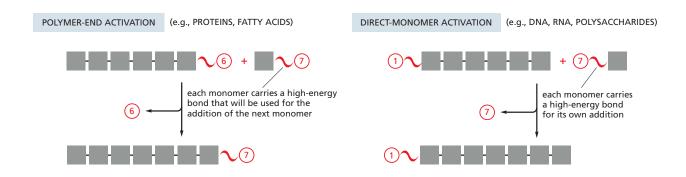

Figure 2-43 Synthesis of a polynucleotide, RNA or DNA, is a multistep process driven by ATP hydrolysis. In the first step, a nucleoside monophosphate (a nucleotide) is activated by the sequential transfer of the terminal phosphate groups from two ATP molecules. The high-energy intermediate formed - a nucleoside triphosphate - exists free in solution until it reacts with the growing end of an RNA or a DNA chain, which leads to release of pyrophosphate. Hydrolysis of the latter to inorganic phosphate is highly favorable and helps to drive the overall reaction in the direction of polynucleotide synthesis. For details, see Chapter 5.

that disorders the surroundings. The only chemical reactions possible are those that increase the total amount of disorder in the universe. The free-energy change for a reaction, ΔG , measures this disorder, and it must be less than zero for a reaction to proceed spontaneously. This ΔG depends both on the intrinsic properties of the reacting molecules and their concentrations, and it can be calculated from these concentrations if either the equilibrium constant (K) for the reaction or its standard free-energy change, ΔG° , is known.

The energy needed for life comes ultimately from the electromagnetic radiation of the Sun, which drives the formation of organic molecules in photosynthetic organisms such as green plants. Animals obtain their energy by eating organic molecules and oxidizing them in a series of enzyme-catalyzed reactions that are coupled to the formation of ATP—a common currency of energy in all cells.

To make possible the continual generation of order in cells, energetically favorable reactions, such as the hydrolysis of ATP, are coupled to energetically unfavorable reactions. In the biosynthesis of macromolecules, ATP is used to form reactive phosphorylated intermediates. Because the energetically unfavorable reaction of biosynthesis now becomes energetically favorable, ATP hydrolysis is said to drive the reaction. Polymeric molecules such as proteins, nucleic acids, and polysaccharides are assembled from small activated precursor molecules by repetitive condensation reactions that are driven in this way. Other reactive

Figure 2–44 Two active-intermediate orientations are utilized for the repetitive condensation reactions that form biological polymers. A polymerend activation mechanism for polymer synthesis is compared with its alternative, direct-monomer activation. As indicated, these two mechanisms are used to produce different types of biological macromolecules.

MBOC7_ptr_ch02_049-114.indd 79 08/12/21 11:25 AM

molecules, called either activated carriers or coenzymes, transfer other chemical groups in the course of biosynthesis: NADPH transfers hydrogen as a proton plus two electrons (a hydride ion), for example, whereas acetyl CoA transfers an acetyl group.

HOW CELLS OBTAIN ENERGY FROM FOOD

The constant supply of energy that cells need to generate and maintain the biological order that keeps them alive comes from the chemical-bond energy in food molecules.

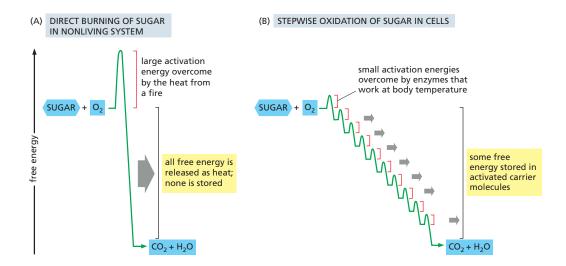

The proteins, lipids, and polysaccharides that make up most of the food we eat must be broken down into smaller molecules before our cells can use them—either as a source of energy or as building blocks for other molecules. Enzymatic digestion breaks down the large polymeric molecules in food into their monomer subunits—proteins into amino acids, polysaccharides into sugars, and fats into fatty acids and glycerol. After digestion, the small organic molecules derived from food enter the cytosol of cells, where their gradual oxidation begins.

Sugars are particularly important fuel molecules, and they are oxidized in small controlled steps to carbon dioxide (CO_2) and water (Figure 2-45). In this section, we trace the major steps in the breakdown, or catabolism, of sugars and show how they produce ATP, NADH, and other activated carrier molecules in animal cells. A very similar pathway also operates in plants, fungi, and many bacteria. As we shall see, the oxidation of fatty acids is equally important for cells. Other molecules, such as proteins, can also serve as energy sources when they are funneled through appropriate enzymatic pathways.

Glycolysis Is a Central ATP-producing Pathway

The major process for oxidizing sugars is the sequence of reactions known as ${\bf glycolysis}$, which produces ATP without the involvement of molecular oxygen (${\bf O}_2$ gas). It occurs in the cytosol of most cells, including many anaerobic microorganisms. Glycolysis probably evolved early in the history of life, before photosynthetic organisms introduced oxygen into the atmosphere. During glycolysis, a glucose molecule with six carbon atoms is converted into two molecules of ${\it pyruvate}$, each of which contains three carbon atoms. For each glucose molecule, two molecules of ATP are hydrolyzed to provide energy to drive the early steps, but four

Figure 2-45 Schematic representation of the controlled stepwise oxidation of sugar in a cell, compared with ordinary burning. (A) If the sugar were oxidized to CO2 and H2O in a single step, it would release an amount of energy much larger than could be captured for useful purposes. (B) In the cell, enzymes catalyze oxidation via a series of small steps in which free energy is transferred in conveniently sized packets to carrier molecules-most often ATP and NADH. Heat is also released, enabling the universe to be disordered sufficiently to make the entire pathway energetically favorable (ΔG is negative). Each step is catalyzed by an enzyme that lowers the activation-energy barrier that must be surmounted by the random collision of molecules to allow the reaction to occur at the temperature inside cells (see Figure 2-24). Note that the total free energy released by the complete oxidative breakdown of glucose to CO2 and H₂O-2880 kJ/mole-is exactly the same in (A) and (B).

MBOC7_ptr_ch02_049-114.indd 80 08/12/21 11:25 AM

molecules of ATP are produced in the later steps. At the end of glycolysis, there is consequently a net gain of two molecules of ATP for each glucose molecule broken down.

Piecing together the complete glycolytic pathway in the 1930s was a major triumph of biochemistry, as the pathway consists of a sequence of 10 separate reactions, each producing a different sugar intermediate and each catalyzed by a different enzyme. These enzymes, like most enzymes, all have names ending in "-ase"—like isomerase and dehydrogenase—which specify the type of reaction they catalyze. The sugar oxidation occurs when electrons are removed by NAD+ (producing NADH) from some of the carbons derived from the glucose molecule. Some of the energy released by this oxidation drives the direct synthesis of ATP molecules from ADP and phosphate, and some remains with the electrons in the activated electron carrier NADH. The pathway is outlined in Figure 2–46 and shown in detail in Panel 2–8 (pp. 108–109) and Movie 2.5.

Two molecules of NADH are formed per molecule of glucose in the course of glycolysis. As we shall see, in aerobic organisms these NADH molecules donate their electrons to the electron-transport chain described in Chapter 14, which enables the $\rm NAD^+$ formed by NADH oxidization to be reused for glycolysis.

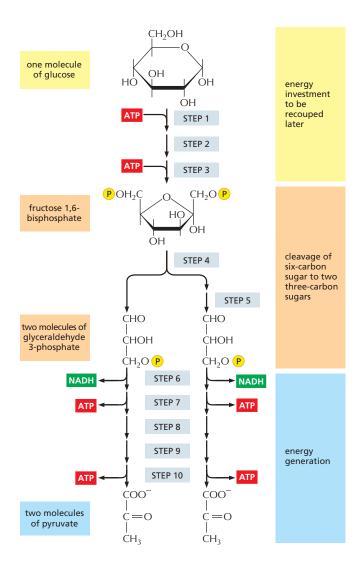

Figure 2-46 An outline of glycolysis. Each of the 10 steps shown is catalyzed by a different enzyme. Note that step 4 cleaves a six-carbon sugar into two three-carbon sugars, so that the number of molecules at every stage after this doubles. Note also that one of the two products of step 4 is modified (isomerized) in step 5 to convert it into a second molecule of glyceraldehyde 3-phosphate, the other product of step 4. As indicated, step 6 begins the energy-generation phase of glycolysis. Because two molecules of ATP are hydrolyzed in the early, energy-investment phase, glycolysis results in the net synthesis of 2 ATP and 2 NADH molecules per molecule of glucose. Glycolysis is also referred to as the Embden-Meyerhof pathway, named for the biochemists who first described it. All the steps of glycolysis are reviewed in Panel 2-8 and Movie 2.5.

MBOC7_ptr_ch02_049-114.indd 81 08/12/21 11:25 AM

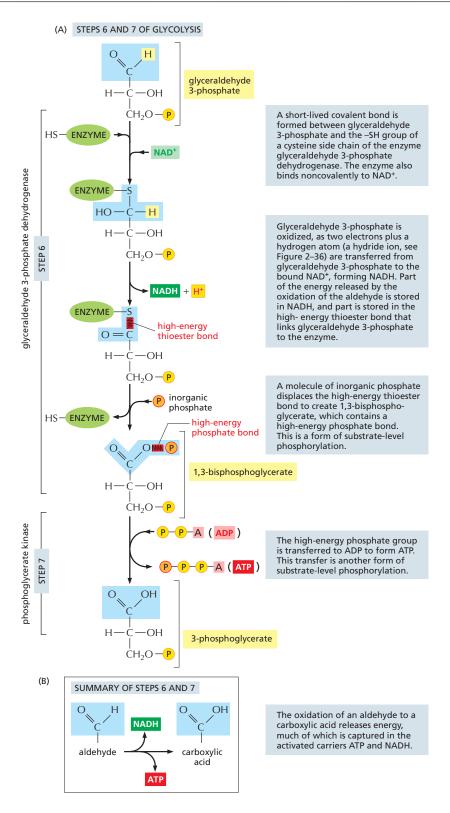

Figure 2-47 How the oxidation of glyceraldehyde 3-phosphate is coupled to the formation of ATP and NADH in steps 6 and 7 of glycolysis. (A) In step 6, the enzyme glyceraldehyde 3-phosphate dehydrogenase couples the energetically favorable oxidation of an aldehyde to the energetically unfavorable formation of a high-energy phosphate bond. At the same time, this oxidation enables energy to be stored in NADH. In step 7, the newly formed high-energy phosphate bond in 1,3-bisphosphoglycerate is transferred to ADP by the enzyme phosphoglycerate kinase, forming a molecule of ATP and leaving a free carboxylic acid group on the oxidized sugar. The part of the molecule that undergoes a change is shaded in blue; the rest of the molecule remains unchanged throughout all these reactions. (B) Summary of the overall chemical change produced by the reactions of steps 6 and 7.

MBOC7_ptr_ch02_049-114.indd 82 08/12/21 11:25 AM

Glycolysis Illustrates How Enzymes Couple Oxidation to Energy Storage

The formation of ATP during glycolysis provides a particularly clear demonstration of how enzymes couple energetically unfavorable reactions with favorable ones, thereby driving the many chemical reactions that make life possible. Two central reactions in glycolysis (steps 6 and 7) convert the three-carbon sugar intermediate glyceraldehyde 3-phosphate (an aldehyde) into 3-phosphoglycerate (a carboxylic acid; see Panel 2–8, pp. 108–109), thus oxidizing an aldehyde group to a carboxylic acid group. This sugar oxidation process releases enough free energy to convert a molecule of ADP to ATP and to transfer two electrons (and a proton) from the aldehyde to NAD+ to form NADH, while still liberating enough heat to the environment to make the overall reaction energetically favorable (ΔG° for the overall reaction is -12.5 kJ/mole).

Figure 2-47 details this remarkable feat of energy harvesting. The chemical reactions are precisely guided by two enzymes to which the sugar intermediates are tightly bound. The first enzyme (glyceraldehyde 3-phosphate dehydrogenase) forms a covalent bond to the sugar aldehyde group through a reactive -SH group on the enzyme and then catalyzes the oxidation of this aldehyde group to a carboxylic acid. This creates a highly reactive enzyme-substrate bond that is displaced by an inorganic phosphate ion to produce a high-energy sugar phosphate intermediate. This intermediate (1,3-bisphosphoglycerate) then binds to the second enzyme (phosphoglycerate kinase), which catalyzes an energetically favorable transfer of its high-energy phosphate to ADP, forming ATP and completing the process of oxidizing a sugar aldehyde to a carboxylic acid.

We have shown this particular oxidation process in some detail because it provides a clear example of enzyme-mediated energy storage through coupled reactions (Figure 2–48). Steps 6 and 7 are the only reactions in glycolysis that create a high-energy phosphate linkage directly from inorganic phosphate. As such, they account for the net yield of two ATP molecules and two NADH molecules per molecule of glucose (see Panel 2–8, pp. 108–109).

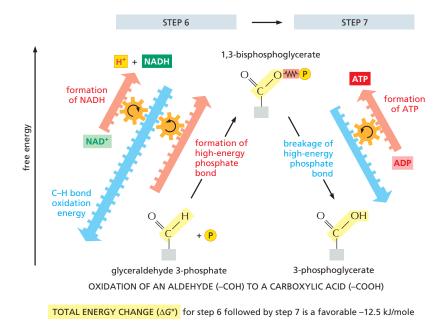

Figure 2-48 How a pair of coupled reactions drives the energetically unfavorable formation of NADH and ATP in steps 6 and 7 of glycolysis. In this diagram, energetically favorable reactions are represented by blue arrows and energetically costly reactions by red arrows. In step 6, the energy released by the energetically favorable oxidation of a C-H bond in glyceraldehyde 3-phosphate (blue arrow) is large enough to drive two energetically costly reactions: the formation of both NADH and a high-energy phosphate bond in 1,3-bisphosphoglycerate (red arrows). The subsequent energetically favorable breakage of that high-energy phosphate bond in step 7 then drives the formation

MBOC7_ptr_ch02_049-114.indd 83 08/12/21 11:25 AM

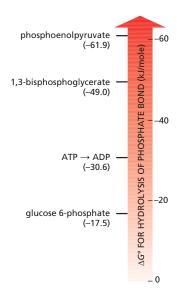

Figure 2–49 Phosphate bonds with different hydrolysis energies. Examples of molecules formed during glycolysis that contain different types of phosphate bonds are shown, along with the standard free-energy change for hydrolysis of those bonds in kJ/mole. The transfer of a phosphate group from one molecule to another is energetically favorable if the standard free-energy change (ΔG°) for hydrolysis of the phosphate bond is more negative for the donor molecule than for the acceptor. (The hydrolysis reactions can be thought of as the transfer of the phosphate group to water.) Thus, a phosphate group is readily transferred from 1,3-bisphospholycerate to ADP to form ATP. Transfer reactions involving the phosphate groups in these molecules are detailed in Panel 2–8 (pp. 108–109). Note that standard conditions often do *not* pertain to living cells, where the relative concentrations of reactants and products will influence the actual change in free energy (see p. 67).

As we have just seen, ATP can be formed readily from ADP when a reaction intermediate is formed with a phosphate bond of higher energy than that of the terminal phosphate bond in ATP. Phosphate bonds can be ordered in energy by comparing the standard free-energy change (ΔG°) for the breakage of each bond by hydrolysis. Figure 2–49 compares the high-energy phosphoanhydride bonds in ATP with the energy of other types of phosphate bonds that are generated during glycolysis.

Fermentations Produce ATP in the Absence of Oxygen

For most animal and plant cells, glycolysis is only a prelude to the final stage of the breakdown of food molecules. In these cells, the pyruvate formed by glycolysis is rapidly transported into the mitochondria, where it is converted into CO_2 plus acetyl CoA, whose acetyl group is then completely oxidized to CO_2 and H_2O .

In contrast, for many anaerobic organisms—which do not utilize molecular oxygen and can grow and divide without it—glycolysis is the principal source of the cell's ATP. Certain animal tissues, such as skeletal muscle, can also continue to function when molecular oxygen is limited. In these anaerobic conditions, the pyruvate and the NADH electrons stay in the cytosol. The pyruvate is converted into products excreted from the cell; for example, into ethanol and CO_2 in the yeasts used in brewing and breadmaking or into lactic acid (lactate) in muscle. In this process, the NADH gives up its electrons and is converted back into NAD $^+$. This is crucial, because a regeneration of NAD $^+$ is required to maintain the reactions of glycolysis (Figure 2–50). Energy-yielding pathways like these are called fermentations.

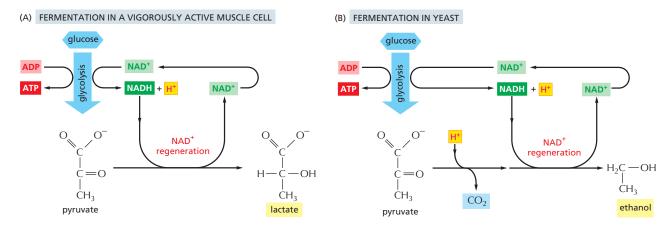

Figure 2–50 Two pathways for the anaerobic breakdown of pyruvate. (A) When there is inadequate oxygen in a muscle cell undergoing vigorous contraction, the pyruvate produced by glycolysis is converted to lactic acid (lactate) as shown. This reaction regenerates the NAD⁺ required in step 6 of glycolysis, but the whole pathway yields much less energy overall than complete oxidation does. (B) In some organisms that can grow anaerobically, such as yeasts, pyruvate is converted via acetaldehyde into carbon dioxide and ethanol. Again, this pathway regenerates NAD⁺ from NADH, as needed for glycolysis to continue. Both (A) and (B) are examples of fermentations.

MBOC7_ptr_ch02_049-114.indd 84 08/12/21 11:25 AM

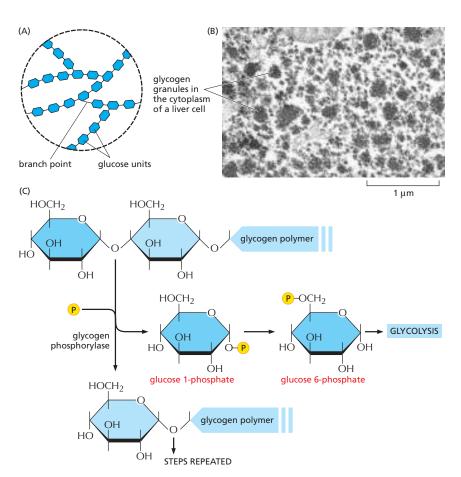

Organisms Store Food Molecules in Special Reservoirs

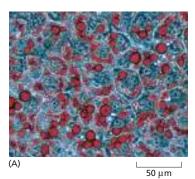

All organisms need to maintain a high ATP/ADP ratio to maintain biological order in their cells. Yet animals have only periodic access to food, and plants need to survive overnight without sunlight, when they are unable to produce sugar from photosynthesis. For this reason, both plants and animals convert sugars and fats to special forms for storage.

To compensate for long periods of fasting, animals store fatty acids as **fat** droplets composed of water-insoluble *triacylglycerols* (also called triglycerides). The triacylglycerols in animals are mostly stored in the cytoplasm of specialized fat cells called adipocytes (**Figure 2–51**). For shorter-term storage, sugar is stored as glucose subunits in the large branched polysaccharide **glycogen**, which is present as small granules in the cytoplasm of many cells, with the largest stores in liver and muscle.

The synthesis and degradation of glycogen are rapidly regulated according to need. When cells need more ATP than they can generate from the food molecules taken in from the bloodstream, they break down glycogen in a reaction that produces glucose 1-phosphate, which is rapidly converted to glucose 6-phosphate for glycolysis (Figure 2–52). During fasting, liver cells release glucose derived from breakdown of their glycogen stores into the bloodstream for use by other cells, while muscle cells hoard their supplies for their own use.

Quantitatively, fat is far more important than glycogen as an energy store for animals, because it provides for more efficient storage. The oxidation of a gram of fat releases about twice as much energy as the oxidation of a gram of glycogen does. Moreover, glycogen differs from fat in binding a great deal of water, producing a sixfold difference in the actual mass of glycogen required to store the same amount of energy as fat. An average adult human stores enough glycogen for only about a day of normal activities but enough fat to last for nearly a month.

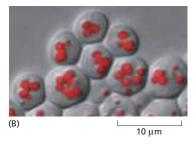

Figure 2–51 Fats stored in the form of lipid droplets in cells. (A) Fat droplets (stained red) in the cytoplasm of developing adipocytes. (B) Lipid droplets (red) in yeast cells, which also use them as a reservoir of energy and as building blocks for membrane lipid biosynthesis. (A, courtesy of Peter Tontonoz and Ronald M. Evans; B, courtesy of Sepp D. Kohlwein.)

Figure 2–52 How animal cells store glucose in the form of glycogen to provide energy in times of need. (A) The structure of glycogen; starch in plants is a very similar branched polymer of glucose but has many fewer branch points. (B) An electron micrograph showing glycogen granules in the cytoplasm of a liver cell; each granule contains both glycogen and the enzymes required for glycogen synthesis and breakdown. (C) The enzyme glycogen when cells need more glucose. (B, courtesy of Robert Fletterick and Daniel S. Friend, by permission of E.L. Bearer.)

MBOC7_ptr_ch02_049-114.indd 85 08/12/21 11:25 AM

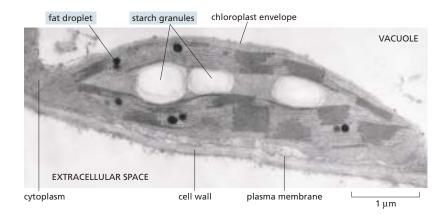

Figure 2–53 Plant cells store both starch and fats in their chloroplasts. An electron micrograph of a single chloroplast in a plant cell shows the starch granules and fat droplets that have been synthesized in the organelle. (Courtesy of K. Plaskitt.)

If our main fuel reservoir had to be carried as glycogen instead of fat, body weight would increase by an average of about 60 pounds.

How do plants store sugars and fats? Plants produce abundant amounts of both ATP and NADPH by the photosynthesis that is carried out in their chloroplasts. But this organelle is isolated from the rest of its plant cell by a membrane that is impermeable to both types of activated carrier molecules. Moreover, the plant contains many cells—such as those in the roots—that lack chloroplasts and therefore cannot produce their own sugars. Thus, sugars are exported from chloroplasts to the mitochondria present in all cells of the plant. Most of the ATP needed for general plant cell metabolism is synthesized in these mitochondria, using exactly the same pathways for the oxidative breakdown of sugars as in nonphotosynthetic organisms; this ATP is then passed to the rest of the cell.

During periods of excess photosynthetic capacity during the day, chloroplasts convert some of the sugars that they make into fats and into **starch**, a polymer of glucose analogous to the glycogen of animals. Both are stored inside the chloroplast until needed for energy-yielding oxidation during periods of darkness (**Figure 2–53**).

The embryos inside plant seeds must live on stored sources of energy for a prolonged period until they germinate and produce leaves that can harvest the energy in sunlight. For this reason, plant seeds often contain especially large amounts of fats and starch—which makes them a major food source for animals, including ourselves (Figure 2–54).

Between Meals, Most Animal Cells Derive Their Energy from Fatty Acids Obtained from Fat

After a meal, most of the energy that an animal needs is derived from sugars obtained from food. Excess sugars, if any, are used to replenish depleted glycogen stores or to synthesize fats as a stable longer-term food store. In the absence

Figure 2–54 Some plant seeds that serve as important foods for humans. Corn, nuts, and peas all contain rich stores of starch and fat that provide the young plant embryo in the seed with energy and building blocks for biosynthesis. (Courtesy of the John Innes Foundation.)

MBOC7_ptr_ch02_049-114.indd 86 08/12/21 11:25 AM

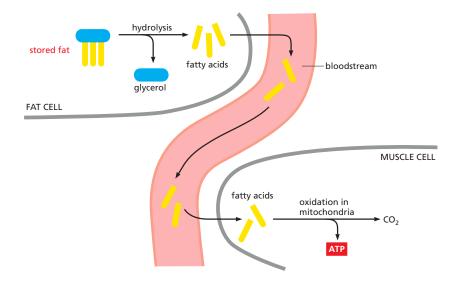

Figure 2–55 How stored fats are mobilized for energy production in animals. Low glucose levels in the blood trigger the hydrolysis of the triacylglycerol molecules in fat droplets to free fatty acids and glycerol. These fatty acids enter the bloodstream, where they bind to the abundant blood protein, serum albumin. Special fatty acid transporters in the plasma membrane of cells that oxidize fatty acids, such as muscle cells, then pass these fatty acids into the cytosol, from which they are moved into mitochondria for energy production.

of another meal, the liver begins to release glucose from its store of glycogen to maintain circulating glucose levels, and the fat stored in adipose tissue is also called into play. By the morning after an overnight fast, the glycogen reserves are exhausted, and fatty acid oxidation generates most of the ATP we need.

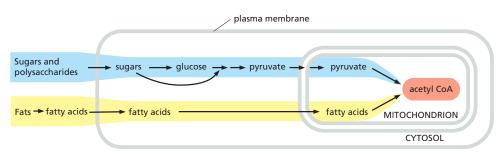

Low glucose levels in the blood trigger the breakdown of fats for energy production. As illustrated in Figure 2–55, the triacylglycerols stored in fat droplets in adipocytes are hydrolyzed to produce fatty acids and glycerol, and the fatty acids released are transferred to cells in the body through the bloodstream. Notably, the brain must rely on circulating glucose—or *ketone bodies* when available—because fatty acids are poorly utilized by the brain.

What are ketone bodies? During prolonged periods of fasting, when the circulating supply of glucose is mostly maintained by its synthesis from amino acids derived from the breakdown of proteins in muscle, the liver assumes its role as a central metabolic hub to convert fatty acids to the energy-rich molecules acetoacetate and β -hydroxybutyrate. These ketone bodies are released into the bloodstream to serve as an alternative fuel in heart and brain cells, where they are oxidized through the citric acid cycle to generate ATP. By thereby meeting most of the energy needs of the brain and heart, this process partially spares protein breakdown. Consumption of a diet very low in carbohydrate (a *ketogenic diet*) leads to the production of ketone bodies and can enable weight loss in most individuals. A spontaneous breakdown of acetoacetate to acetone generates the bad breath often associated both with such diets and with prolonged fasting.

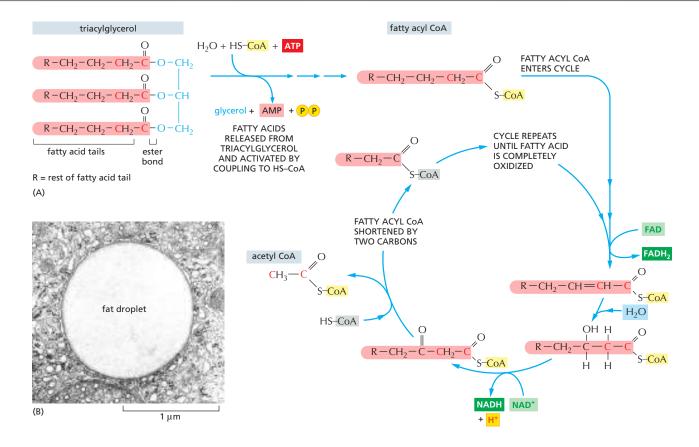

Sugars and Fats Are Both Degraded to Acetyl CoA in Mitochondria

The fatty acids imported from the bloodstream are moved into mitochondria, where all of their oxidation takes place (Figure 2–56). Each molecule of fatty acid (as the activated molecule *fatty acyl CoA*) is broken down completely by a cycle

Figure 2–56 Pathways for the production of acetyl CoA from sugars and fats. The mitochondrion in eukaryotic cells is where acetyl CoA is produced from both types of food molecules. It is therefore the place where most of the cell's oxidation reactions occur and where most of its ATP is made. Amino acids (not shown) can also enter mitochondria to be converted there into acetyl CoA or another intermediate of the citric acid cycle. The structure and function of mitochondria are discussed in detail in Chapter 14.

MBOC7_ptr_ch02_049-114.indd 87 08/12/21 11:25 AM

of reactions that trims two carbons at a time from its carboxyl end, generating one molecule of acetyl CoA for each turn of the cycle. A molecule of NADH and a molecule of FADH₂ are also produced in this process (Figure 2–57).

As was shown in Figure 2–56, in eukaryotes the pyruvate that was produced by glycolysis from sugars in the cytosol is likewise transported into mitochondria, where it is rapidly decarboxylated by a giant complex of three enzymes, called the *pyruvate dehydrogenase complex*. The products are a molecule of CO_2 (a waste product), a molecule of NADH, and acetyl COA (see Panel 2–9, pp. 110–111).

Sugars and fats are the major energy sources for most nonphotosynthetic organisms, including humans. Most of the useful energy that can be extracted from their oxidation remains stored in the acetyl CoA molecules that are produced from both sources. In the *citric acid cycle* of reactions, the acetyl group (-COCH₃) in acetyl CoA is completely oxidized to CO₂ and H₂O. This cycle, to be described next, therefore plays a critical, central role in the energy metabolism of aerobic organisms.

The Citric Acid Cycle Generates NADH by Oxidizing Acetyl Groups to CO₂

In the nineteenth century, biologists noticed that in the absence of air, cells produce lactic acid (for example, in muscle) or ethanol (for example, in yeast), while in its presence they consume O_2 and produce CO_2 and H_2O instead. Efforts to define the pathways of aerobic metabolism eventually focused on the oxidation of pyruvate and led in 1937 to the discovery of the **citric acid cycle**, also known as the *tricarboxylic acid cycle* or the *Krebs cycle*. The citric acid cycle accounts for about two-thirds of the total oxidation of carbon compounds in most cells, and its major end products are CO_2 and high-energy electrons in the form of NADH. The CO_2 is released as a waste product, while the high-energy electrons from NADH are passed to a membrane-bound

Figure 2-57 How the oxidation of fatty acids produces acetyl CoA. (A) Fats are stored in the form of triacylglycerol, the glycerol portion of which is shown in blue. Three fatty acid chains (shaded in red) are linked to this glycerol through ester bonds that can be hydrolyzed by enzymes called lipases to allow the fatty acids to enter the bloodstream (see Figure 2-55). Once the fatty acids enter mitochondria (see Figure 2-56), they are coupled to coenzyme A in a reaction requiring ATP. These activated fatty acids (fatty acyl CoA molecules) are then oxidized in a cycle containing four enzymes, which are not shown. As indicated, each turn of the cycle shortens the fatty acyl CoA molecule by two carbons (red) and generates one molecule each of the energy-rich molecules FADH₂, NADH, and acetyl CoA. (B) Fats are insoluble in water and spontaneously form large lipid droplets. This electron micrograph shows a lipid droplet in the cytoplasm of a specialized fat cell, an adipocyte. (B, courtesy of Daniel S. Friend and by permission of E.L. Bearer.)

MBOC7_ptr_ch02_049-114.indd 88 08/12/21 11:25 AM

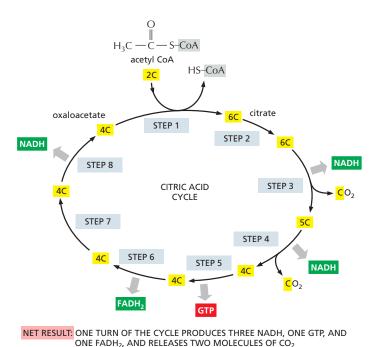

Figure 2–58 Simple overview of the citric acid cycle. The reaction of acetyl CoA with oxaloacetate starts the cycle by producing citrate (citric acid). In each turn of the cycle, two molecules of CO₂ are produced as waste products, plus three molecules of NADH, one molecule of GTP, and one molecule of FADH₂. The number of carbon atoms in each intermediate is shown in a *yellow box*. For details, see Panel 2–9 (pp. 110–111).

electron-transport chain that will be discussed in Chapter 14, eventually combining with O_2 to produce H_2O .

The citric acid cycle itself does not use gaseous O_2 (it uses oxygen atoms from H_2O). But the cycle does require O_2 in subsequent reactions to keep it going. This is because there is no other efficient way for the NADH to get rid of its electrons and thus regenerate the NAD $^+$ that the cycle requires.

The citric acid cycle takes place inside mitochondria in eukaryotic cells. The process begins when the acetyl group is transferred from acetyl CoA to a four-carbon molecule, *oxaloacetate*, to form the six-carbon tricarboxylic acid, *citric acid*, for which the subsequent cycle of reactions is named. This citric acid molecule is then gradually oxidized, allowing the energy of oxidation to be harnessed to produce activated carrier molecules. The chain of eight reactions forms a cycle because at the end the oxaloacetate is regenerated to enter a new turn of the cycle, as shown in outline in Figure 2–58.

We have thus far highlighted only one of the three types of activated carrier molecules that are produced by the citric acid cycle: NADH, the reduced form of the NAD $^+$ /NADH electron carrier system (see Figure 2–36). In addition to three molecules of NADH, each turn of the cycle also produces one molecule of FADH $_2$ from FAD (see Figure 2–39) and one molecule of GTP, guanosine triphosphate, from GDP. The structure of GTP is illustrated in Figure 2–59. GTP is a close relative

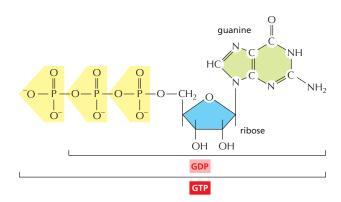

Figure 2–59 The structure of GTP, guanosine triphosphate. GTP and GDP are close relatives of ATP and ADP, respectively.

MBOC7_ptr_ch02_049-114.indd 89 08/12/21 11:25 AM

of ATP, and the transfer of its terminal phosphate group to ADP produces one ATP molecule in each cycle.

Panel 2-9 (pp. 110–111) and Movie 2.6 present the complete citric acid cycle. Water, rather than molecular oxygen, supplies the extra oxygen atoms required to make CO_2 from the acetyl groups entering the citric acid cycle. As illustrated in the Panel, three molecules of water are taken up in each cycle, and the oxygen atoms of some of them are ultimately used to make CO_2 .

In addition to pyruvate and fatty acids, some amino acids pass from the cytosol into mitochondria, where they are also converted into acetyl CoA or one of the other intermediates of the citric acid cycle. As we discuss next, in mitochondria the large amount of energy stored in the electrons of NADH and FADH2 is utilized for ATP production through the process of *oxidative phosphorylation*, which is the only step in the oxidative catabolism of foodstuffs that directly requires gaseous oxygen (O2) from the atmosphere. Thus, in the eukaryotic cell, the mitochondrion is the center toward which all energy-yielding processes lead, whether they begin with sugars, fats, or proteins.

Electron Transport Drives the Synthesis of the Majority of the ATP in Most Cells

Most chemical energy is released in the last stage in the degradation of a food molecule. This process begins when NADH and $FADH_2$ transfer the electrons that they obtained by oxidizing food-derived organic molecules to an **electron-transport chain** embedded in the inner membrane of the mitochondrion. As the electrons pass along this long chain of specialized electron acceptor and donor molecules, they fall to successively lower energy states, being finally passed to molecules of oxygen gas (O_2) that have diffused into the mitochondrion, reducing the oxygen to produce water. The electrons have now reached a very low energy level, and all the available energy has been extracted from the oxidized food molecule.

The energy released by this chain of electron transfers is used to pump H⁺ ions (protons) across the membrane—from the innermost mitochondrial compartment (the matrix) to the intermembrane space (and then to the cytosol). The resulting electrochemical proton gradient across the inner mitochondrial membrane serves as a major source of energy for cells, being tapped like a battery to drive a variety of energy-requiring reactions. The most prominent of these reactions is the generation of ATP by the phosphorylation of ADP, as part of a process known as **oxidative phosphorylation** (see Figure 14-12). This harnessing of chemical energy through membrane-based electron transfers is one of the most remarkable achievements of cell evolution—as such, we shall devote an entire chapter to it (Chapter 14).

Many Biosynthetic Pathways Begin with Glycolysis or the Citric Acid Cycle

Catabolic reactions, such as those of glycolysis and the citric acid cycle, produce both energy for the cell and the building blocks from which many other organic molecules are made. Thus far, we have emphasized energy production rather than the provision of starting materials for biosynthesis. But many of the intermediates formed in glycolysis and the citric acid cycle are siphoned off by such anabolic pathways, in which the intermediates are converted by a series of enzyme-catalyzed reactions into amino acids, nucleotides, lipids, and other small organic molecules that the cell needs. The oxaloacetate and α -ketoglutarate produced during the citric acid cycle, for example (see Panel 2–9, pp. 110–111), are transferred from the mitochondrial matrix back to the cytosol, where they serve as precursors for the production of many essential molecules, such as the amino acids aspartate and glutamate, respectively. An idea of the extent of these anabolic pathways can be gathered from

MBOC7_ptr_ch02_049-114.indd 90 08/12/21 11:25 AM

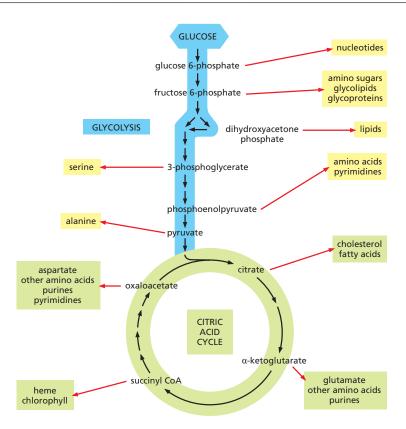

Figure 2–60 Glycolysis and the citric acid cycle provide the precursors needed to synthesize many important biological molecules. The amino acids, nucleotides, lipids, sugars, and other molecules—shown here as products—in turn serve as the precursors for the many macromolecules of the cell. Each black arrow in this diagram denotes a single enzyme-catalyzed reaction; the red arrows generally represent pathways with many steps that are required to produce the indicated products.

Figure 2-60, which illustrates some of the branches leading from the central catabolic reactions to biosyntheses.

Animals Must Obtain All the Nitrogen and Sulfur They Need from Food

So far we have concentrated mainly on carbohydrate metabolism and have not yet considered the metabolism of nitrogen or sulfur. These two elements are important constituents of biological macromolecules. Nitrogen and sulfur atoms pass from compound to compound and between organisms and their environment in a series of reversible cycles.

Although molecular nitrogen constitutes nearly 80% of Earth's atmosphere, nitrogen is chemically unreactive as a gas. Only a few living species are able to incorporate it into organic molecules, a process called **nitrogen fixation**. Nitrogen fixation occurs both in certain microorganisms and by some geophysical processes, such as lightning discharge. It is essential to the biosphere as a whole, for without it life could not exist on this planet. Only a small fraction of the nitrogenous compounds in today's organisms, however, is due to fresh products of nitrogen fixation from the atmosphere. Most organic nitrogen has been in circulation for some time, passing from one living organism to another. Thus, present-day nitrogen-fixing reactions can be said to perform a "topping-up" function for the total nitrogen supply.

Vertebrates receive virtually all of their nitrogen from their dietary intake of proteins and nucleic acids. In the body, these macromolecules are broken down to amino acids and the components of nucleotides, and the nitrogen they contain is used to produce new proteins and nucleic acids—or other molecules. About

MBOC7_ptr_ch02_049-114.indd 91 08/12/21 11:25 AM

half of the 20 amino acids found in proteins are essential amino acids for vertebrates (Figure 2–61), which means that they cannot be synthesized from other ingredients of the diet. The other amino acids can be so synthesized, using a variety of raw materials that include the intermediates of the citric acid cycle just described. The essential amino acids are made by plants and other organisms, usually by long and energetically expensive pathways that have been lost in the course of vertebrate evolution.

The nucleotides needed to make RNA and DNA are synthesized using specialized biosynthetic pathways. All of the nitrogens in the purine and pyrimidine bases (as well as some of the carbons) are derived from the plentiful amino acids glutamine, aspartic acid, and glycine, whereas the ribose and deoxyribose sugars are derived from glucose. There are no "essential nucleotides" that must be provided in the diet.

As we have seen, the amino acids derived from food that are not used in biosynthesis can be oxidized to generate metabolic energy. Most of their carbon and hydrogen atoms eventually form $\rm CO_2$ or $\rm H_2O$, whereas their nitrogen atoms are shuttled through various forms and eventually appear as urea, which is excreted. Each amino acid is processed differently, and a whole constellation of enzymatic reactions exists for their catabolism.

Sulfur is abundant on Earth in its most oxidized form, sulfate (SO_4^{2-}) . To be useful for life, sulfate must be reduced to sulfide (S^{2-}) , the oxidation state of sulfur required for the synthesis of essential biological molecules, including the amino acids methionine and cysteine, coenzyme A, and the iron–sulfur centers essential for electron transport. The sulfur-reduction process begins in bacteria, fungi, and plants, where a special group of enzymes use ATP and reducing power to create a sulfate assimilation pathway. Humans and other animals cannot reduce sulfate and must therefore acquire the sulfur they need for their metabolism in the food that they eat.

Metabolism Is Highly Organized and Regulated

One can get a sense of the intricacy of a cell as a chemical machine from the relation of glycolysis and the citric acid cycle to the other metabolic pathways sketched out in Figure 2–62. This diagram represents only some of the enzymatic pathways in a human cell. It is obvious that our discussion of cell metabolism has dealt with only a tiny fraction of the broad field of cell chemistry.

All these reactions occur in a cell that is less than 0.1 mm in diameter, and each requires a different enzyme. The same molecule can often be part of many different pathways. Pyruvate, for example, is a substrate for half a dozen or more different enzymes, each of which modifies it chemically in a different way. One enzyme converts pyruvate to acetyl CoA, another to oxaloacetate; a third enzyme changes pyruvate to the amino acid alanine, a fourth to lactate, and so on. All of these different pathways compete for the same pyruvate molecule, and similar competitions for thousands of other small molecules go on at the same time.

The situation is further complicated in a multicellular organism. Different cell types require somewhat different sets of enzymes. And different tissues make distinct contributions to the chemistry of the organism as a whole. All types of cells have their distinctive metabolic traits, and they cooperate extensively in the normal state, as well as in response to stress and starvation. One might think that the whole system would need to be so finely balanced that any minor upset, such as a temporary change in dietary intake, would be disastrous.

In fact, the metabolic balance of a cell is amazingly stable. Whenever the balance is perturbed, the cell reacts so as to restore the initial state. The cell can adapt and continue to function during starvation or disease. Mutations of many kinds can damage or even eliminate particular reaction pathways, and yet—provided that certain minimum requirements are met—the cell survives. It does so because an elaborate network of *control mechanisms* regulates and coordinates the rates of all of its reactions. These controls rest, ultimately, on the remarkable abilities

THE ESSENTIAL AMINO ACIDS

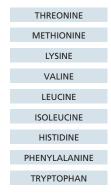

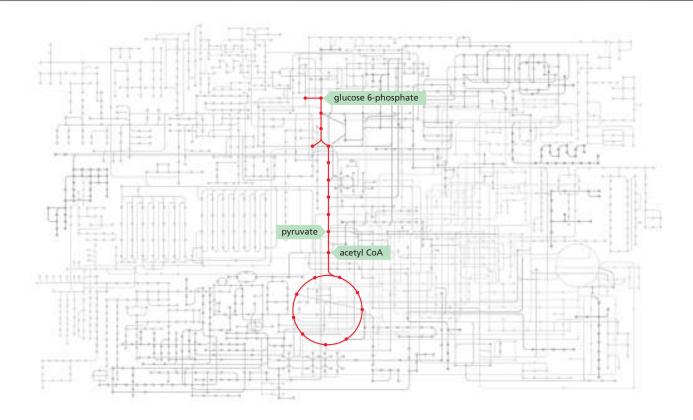

Figure 2–61 The nine essential amino acids. These cannot be synthesized by human cells and so must be supplied in the diet

MBOC7_ptr_ch02_049-114.indd 92 08/12/21 11:25 AM

of proteins to change their shape and their chemistry in response to changes in their immediate environment.

The principles that underlie how proteins are built and the chemistry behind their regulation are clearly central to all of biology. And it is proteins that will be our next concern.

Summary

Food molecules are broken down by controlled stepwise oxidation to provide chemical energy in the form of ATP and NADH. Following the breakdown of large food molecules to their simple subunits, three main sets of reactions act in series, the products of each being the starting material for the next: glycolysis (which occurs in the cytosol), the citric acid cycle (in the mitochondrial matrix), and oxidative phosphorylation (on the inner mitochondrial membrane). The intermediate products of glycolysis and the citric acid cycle are used both as sources of metabolic energy and to produce many of the small molecules used as the raw materials for biosynthesis. Cells store sugar molecules as glycogen in animals and starch in plants; both plants and animals also use fats extensively as a food store. These storage materials in turn serve as a major source of food for humans, along with the proteins that comprise the majority of the dry mass of most of the cells in the foods we eat.

Figure 2–62 Glycolysis and the citric acid cycle are at the center of an elaborate set of metabolic pathways in human cells. Some 2000 metabolic reactions are shown schematically with the reactions of glycolysis and the citric acid cycle in *red*. Many other reactions either lead into these two central pathways—delivering small molecules to be catabolized with production of energy—or they lead outward as in Figure 2–60 to supply carbon compounds for the purpose of biosynthesis. MBOC7_ptr_ch02_049-114.indd 93 08/12/21 11:25 AM

CARBON SKELETONS

Carbon has a unique role in the cell because of its ability to form strong covalent bonds with other carbon atoms. Thus carbon atoms can join to form:

chains

also written as

branched trees

also written as

rings

also written as

COVALENT BONDS

A covalent bond forms when two atoms come very close together and share one or more of their outer-shell electrons. Each atom forms a fixed number of covalent bonds in a defined spatial arrangement.

SINGLE BONDS: two electrons shared per bond

DOUBLE BONDS: four electrons shared per bond

The precise spatial arrangement of covalent bonds influences the three-dimensional structure and chemistry of molecules. In this review Panel, we see how covalent bonds are used in a variety of biological molecules.

Atoms joined by two or more covalent bonds cannot rotate freely around the bond axis. This restriction has a major influence on the three-dimensional shape of many macromolecules.

C-H COMPOUNDS

Carbon and hydrogen together make stable compounds (or groups) called hydrocarbons. These are nonpolar, do not form hydrogen bonds, and are generally insoluble in water.

methane

part of the hydrocarbon "tail" of a fatty acid molecule

H₃C

ALTERNATING DOUBLE BONDS

A carbon chain can include double bonds. If these are on alternate carbon atoms, the bonding electrons move within the molecule, stabilizing the structure by a phenomenon called *resonance*.

the truth is somewhere between these two structures

Alternating double bonds in a ring can generate a very stable structure.

often written as

MBOC7_ptr_ch02_049-114.indd 94 08/12/21 11:25 AM

C-O COMPOUNDS

Many biological compounds contain a carbon covalently bonded to an oxygen. For example,

alcohol

H

COH

The -OH is called a hydroxyl group.

The C=O is called a carbonyl group.

Carboxylic acid

The -COOH is called a carboxyl group. In water, this loses an H⁺ ion to become -COO⁻.

Esters are formed by combining an acid and an alcohol.

C-N COMPOUNDS

Amines and amides are two important examples of compounds containing a carbon linked to a nitrogen.

Amines in water combine with an H⁺ ion to become positively charged.

$$-\overset{\mid}{C}-\overset{\mid}{N}\overset{+}{H}\overset{+}{H}^{+} \;\; \Longrightarrow \;\; -\overset{\mid}{C}\overset{\mid}{N}\overset{+}{N}\overset{+}{H}$$

Amides are formed by combining an acid and an amine. Unlike amines, amides are uncharged in water. An example is the peptide bond that joins amino acids in a protein.

Nitrogen also occurs in several ring compounds, including important constituents of nucleic acids: purines and pyrimidines.

SULFHYDRYL GROUP The $-\stackrel{!}{C}-SH$ is called a sulfhydryl group. In the amino acid cysteine, the sulfhydryl group may exist in the reduced form $-\stackrel{!}{C}-SH$ or more rarely in an oxidized, cross-bridging form $-\stackrel{!}{C}-S-S-\stackrel{!}{C}-$

PHOSPHATES

Inorganic phosphate is a stable ion formed from phosphoric acid, H_3PO_4 . It is also written as \ref{P} .

Phosphate esters can form between a phosphate and a free hydroxyl group. Phosphate groups are often covalently attached to proteins in this way.

The combination of a phosphate and a carboxyl group, or two or more phosphate groups, produces an acid anhydride. Because compounds of this type release a large amount of free energy when the bond is broken by hydrolysis in the cell, they are often said to contain a *high-energy* bond.

$$-c \bigvee_{OH}^{O} + HO - P - O^{-} \longrightarrow_{H_{2}O}^{H_{2}O} - c \bigvee_{O}^{O} \longrightarrow_{P - O^{-}}^{O}$$

high-energy acyl phosphate bond (carboxylic-phosphoric acid anhydride) found in some metabolites

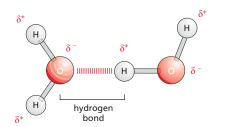

high-energy phosphoanhydride bond found in molecules such as ATP

also written as

HYDROGEN BONDS

Because they are polarized, two adjacent H₂O molecules can form a noncovalent linkage known as a hydrogen bond. Hydrogen bonds have only about 1/20 the strength of a covalent bond.

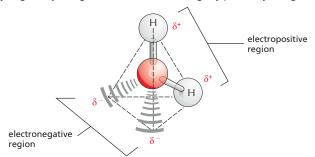

Hydrogen bonds are strongest when the three atoms lie in a straight line.

bond lengths hydrogen bond 0.17 nm O H 0.10 nm covalent bond

WATER

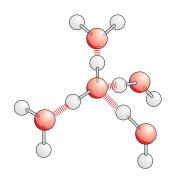

Two atoms connected by a covalent bond may exert different attractions for the electrons of the bond. In such cases, the bond is polar, with one end slightly negatively charged (δ^-) and the other slightly positively charged (δ^+).

Although a water molecule has an overall neutral charge (having the same number of electrons and protons), the electrons are asymmetrically distributed, making the molecule polar. The oxygen nucleus draws electrons away from the hydrogen nuclei, leaving the hydrogen nuclei with a small net positive charge. The excess of electron density on the oxygen atom creates weakly negative regions at the other two corners of an imaginary tetrahedron. On these pages, we review the chemical properties of water and see how water influences the behavior of biological molecules.

WATER STRUCTURE

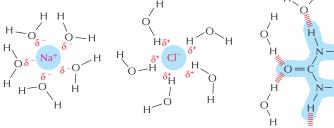

Molecules of water join together transiently in a hydrogen-bonded lattice. Even at 37°C, 15% of the water molecules are joined to four others in a short-lived assembly known as a flickering cluster.

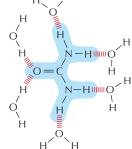

The cohesive nature of water is responsible for many of its unusual properties, such as high surface tension, high specific heat capacity, and high heat of vaporization.

HYDROPHILIC MOLECULES

Substances that dissolve readily in water are termed hydrophilic. They include ions and polar molecules that attract water molecules through electrical charge effects. Water molecules surround each ion or polar molecule and carry it into solution.

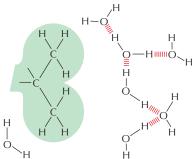

Ionic substances such as sodium chloride dissolve because water molecules are attracted to the positive (Na+) or negative (CI⁻) charge of each ion.

Polar substances such as urea dissolve because their molecules form hydrogen bonds with the surrounding water molecules.

HYDROPHOBIC MOLECULES

Substances that contain a preponderance of nonpolar bonds are usually insoluble in water and are termed hydrophobic. Water molecules are not attracted to such hydrophobic molecules and so have little tendency to surround them and bring them into solution.

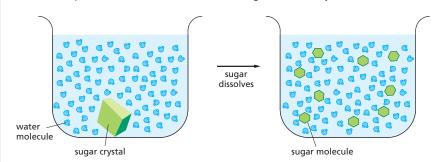

Hydrocarbons, which contain many C-H bonds, are especially hydrophobic.

MBOC7_ptr_ch02_049-114.indd 96 08/12/21 11:25 AM

WATER AS A SOLVENT

Many substances, such as household sugar (sucrose), dissolve in water. That is, their molecules separate from each other, each becoming surrounded by water molecules.

When a substance dissolves in a liquid, the mixture is termed a solution. The dissolved substance (in this case sugar) is the solute, and the liquid that does the dissolving (in this case water) is the solvent. Water is an excellent solvent for hydrophilic substances because of its polar bonds.

ACIDS

Substances that release hydrogen ions (protons) into solution are called acids.

Many of the acids important in the cell are not completely dissociated, and they are therefore weak acids; for example, the carboxyl group (-COOH), which dissociates to give a hydrogen ion in solution.

$$-c$$
OH
 $+$
 $+$
 $-c$
O
O

carboxyl group (weak acid)

Note that this is a reversible reaction.

HYDROGEN ION EXCHANGE

Positively charged hydrogen ions (H^+) can spontaneously move from one water molecule to another, thereby creating two ionic species.

$$\begin{array}{c} H \\ \\ H \end{array} \begin{array}{c} H \\ \\ H \end{array} \begin{array}{c}$$

often written as:
$$H_2O \rightleftharpoons H^+ + OH^-$$

hydrogen hydroxyl ion ion

Because the process is rapidly reversible, hydrogen ions are continually shuttling between water molecules. Pure water contains equal concentrations of hydronium ions and hydroxyl ions (both 10^{-7} M).

рΗ H⁺ conc. рΗ The acidity of a solution is defined by the concentration (conc.) 10^{-1} of hydronium ions (H₃O⁺) it 10^{-2} possesses, generally ACIDIC 10^{-3} abbreviated as H+. 10^{-4} For convenience, we 10^{-5} use the pH scale, where 10^{-6} 10^{-7} $pH = -log_{10}[H^+]$ 10⁻⁸ 10^{-9} For pure water 10⁻¹⁰ 10^{-11} 11 $[H^+] = 10^{-7}$ moles/liter 10⁻¹² 12 10^{-13} 13 pH = 7.0 10^{-14}

BASES

Substances that reduce the number of hydrogen ions in solution are called bases. Some bases, such as ammonia, combine directly with hydrogen ions.

$$NH_3$$
 + H^+ \longrightarrow NH_4^+ ammonia hydrogen ion ammonium ion

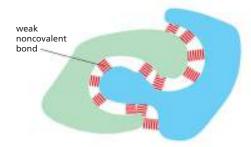

Other bases, such as sodium hydroxide, reduce the number of H^+ ions indirectly, by producing OH^- ions that then combine directly with H^+ ions to make $\mathrm{H}_2\mathrm{O}$.

Many bases found in cells are partially associated with H^+ ions and are termed weak bases. This is true of compounds that contain an amino group ($-NH_2$), which has a weak tendency to reversibly accept an H^+ ion from water, thereby increasing the concentration of free OH^- ions.

$$-NH_2 + H^+ \longrightarrow -NH_3^+$$

WEAK NONCOVALENT CHEMICAL BONDS

Organic molecules can interact with other molecules through three types of short-range attractive forces known as noncovalent bonds: van der Waals attractions, electrostatic attractions, and hydrogen bonds. The repulsion of hydrophobic groups from water is also important for these interactions and for the folding of biological macromolecules.

Weak noncovalent bonds have less than 1/20 the strength of a strong covalent bond. They are strong enough to provide tight binding only when many of them are formed simultaneously.

HYDROGEN BONDS

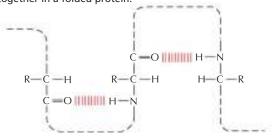

As already described for water (see Panel 2-2, pp. 96-97), hydrogen bonds form when a hydrogen atom is "sandwiched" between two electron-attracting atoms (usually oxygen or nitrogen).

Hydrogen bonds are strongest when the three atoms are in a straight line:

Examples in macromolecules:

Amino acids in a polypeptide chain can be hydrogen-bonded together in a folded protein.

Two bases, G and C, are hydrogen bonded in a DNA double helix.

VAN DER WAALS ATTRACTIONS

If two atoms are too close together, they repel each other very strongly. For this reason, an atom can often be treated as a sphere with a fixed radius. The characteristic "size" for each atom is specified by a unique van der Waals radius. The contact distance between any two noncovalently bonded atoms is the sum of their van der Waals radii.

0.12 nm radius

radius

radius

radius

At very short distances, any two atoms show a weak bonding interaction due to their fluctuating electrical charges. The two atoms will be attracted to each other in this way until the distance between their nuclei is approximately equal to the sum of their van der Waals radii. Although they are individually very weak, such van der Waals attractions can become important when two macromolecular surfaces fit together very closely, because many atoms are involved.

Note that when two atoms form a covalent bond, the centers of the two atoms (the two atomic nuclei) are much closer together than the sum of the two van der Waals radii. Thus,

0.4 nm two nonbonded carbon atoms

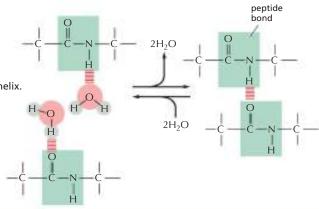

0.15 nm two carbon atoms held by a single covalent bond

0.13 nm two carbon atoms held by a double covalent bond

HYDROGEN BONDS IN WATER

Any two atoms that can form hydrogen bonds to each other can alternatively form hydrogen bonds to water molecules. Because of this competition with water molecules, the hydrogen bonds formed in water between two peptide bonds, for example, are relatively weak.

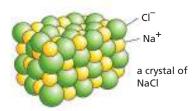

ELECTROSTATIC ATTRACTIONS

Electrostatic attractions occur both between fully charged groups (ionic bond) and between partially charged groups on polar molecules.

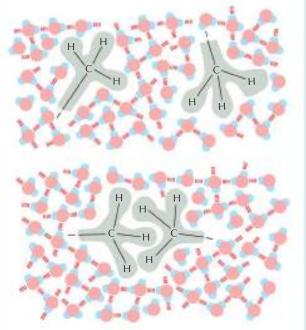

The force of attraction between the two partial charges, δ^+ and δ^- , falls off rapidly as the distance between the charges increases.

In the absence of water, ionic bonds are very strong. They are responsible for the strength of such minerals as marble and agate and for crystal formation in common table salt, NaCl.

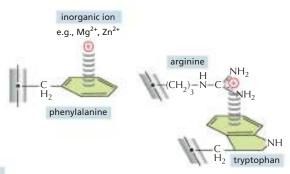

HYDROPHOBIC FORCES

Water forces hydrophobic groups together in order to minimize their disruptive effects on the water network formed by the hydrogen bonds between water molecules. Hydrophobic groups held together in this way are sometimes said to be held together by "hydrophobic bonds," even though the attraction is actually caused by a repulsion from water.

CATION- π INTERACTIONS

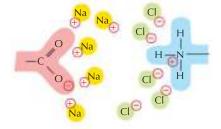

The structure of a typical protein reveals that it contains several cation— π (pi) interactions, these electrostatic attractions being about half as abundant as the electrostatic attractions between positively and negatively charged amino-acid side chains. In this energetically favorable interaction, a cation is paired with the aromatic (π) electrons of either a tryptophan, tyrosine, or phenylalanine side chain. As shown, the cation can either be an inorganic ion or a positively charged lysine or arginine side chain. A tryptophanarginine pair is the most common, as illustrated here.

ELECTROSTATIC ATTRACTIONS IN WATER

Charged groups are shielded by their interactions with water molecules. Electrostatic attractions are therefore quite weak in water.

Inorganic ions in solution can also cluster around charged groups and further weaken these electrostatic attractions.

Despite being weakened by water and inorganic ions, electrostatic attractions are very important in biological systems.

100

MONOSACCHARIDES

Monosaccharides usually have the general formula $(CH_2O)_n$, where n can be 3, 4, 5, 6, 7, or 8, and have two or more hydroxyl groups. They contain either an aldehyde group $(-c \leqslant_H^0)$ and are called aldoses or a ketone group (>c=0) and are called ketoses.

	3-carbon (TRIOSES)	5-carbon (PENTOSES)	6-carbon (HEXOSES)
ALDOSES	H—C—OH H—C—OH H glyceraldehyde	H—C—OH H—C—OH H—C—OH H—C—OH H—ribose	H—C—OH HO—C—H H—C—OH H—C—OH H—C—OH H—C—OH
KETOSES	H H-C-OH C=O H-C-OH H dihydroxyacetone	H H—C—OH C=O H—C—OH H—C—OH H—C—OH H ribulose	H H-C-OH C=O HO-C-H H-C-OH H-C-OH H-C-OH H h-C-OH

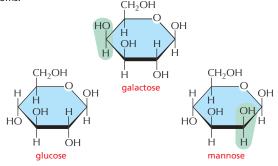

RING FORMATION

In aqueous solution, the aldehyde or ketone group of a sugar molecule tends to react with a hydroxyl group of the same molecule, thereby closing the molecule into a ring.

Note that each carbon atom has a number.

ISOMERS

Many monosaccharides differ only in the spatial arrangement of atoms; that is, they are isomers. For example, glucose, galactose, and mannose have the same formula ($C_6H_{12}O_6$) but differ in the arrangement of groups around one or two carbon atoms

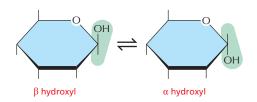

These small differences make only minor changes in the chemical properties of the sugars. But the differences are recognized by enzymes and other proteins and therefore can have major biological effects.

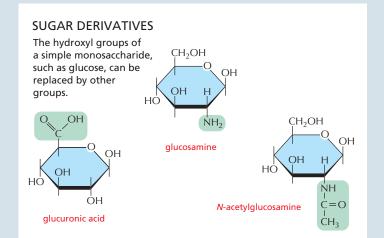

MBOC7_ptr_ch02_049-114.indd 100 08/12/21 11:25 AM

α AND β LINKS

The hydroxyl group on the carbon that carries the aldehyde or ketone can rapidly change from one position to the other. These two positions are called α and $\beta.$

As soon as one sugar is linked to another, the α or β form is frozen.

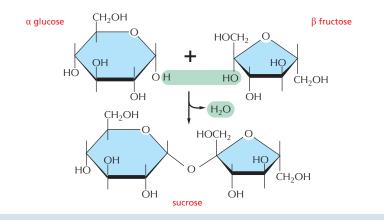

DISACCHARIDES

The carbon that carries the aldehyde or the ketone can react with any hydroxyl group on a second sugar molecule to form a disaccharide. Three common disaccharides are

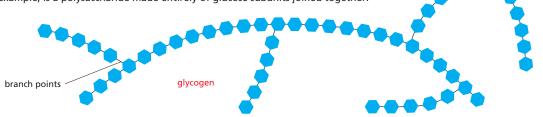

maltose (glucose + glucose) lactose (galactose + glucose) sucrose (glucose + fructose)

The reaction forming sucrose is shown here.

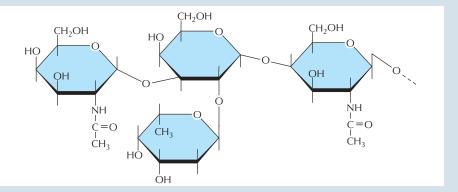

OLIGOSACCHARIDES AND POLYSACCHARIDES

Large linear and branched molecules can be made from simple repeating sugar subunits. Short chains are called oligosaccharides, and long chains are called polysaccharides. Glycogen, for example, is a polysaccharide made entirely of glucose subunits joined together.

COMPLEX OLIGOSACCHARIDES

In many cases, a sugar sequence is nonrepetitive. Many different molecules are possible. Such complex oligosaccharides are usually linked to proteins or to lipids, as is this oligosaccharide, which is part of a cell-surface molecule that defines a particular blood group.

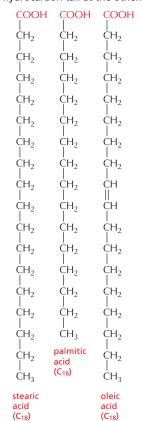

MBOC7_ptr_ch02_049-114.indd 101 08/12/21 11:25 AM

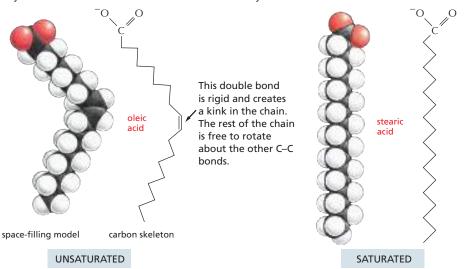

102

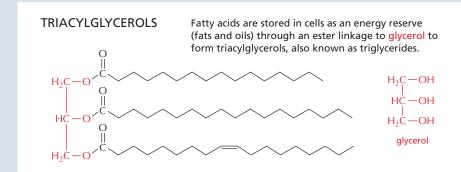

FATTY ACIDS

All fatty acids have a carboxyl group at one end and a long hydrocarbon tail at the other.

Hundreds of different kinds of fatty acids exist. Some have one or more double bonds in their hydrocarbon tail and are said to be <u>unsaturated</u>. Fatty acids with no double bonds are <u>saturated</u>.

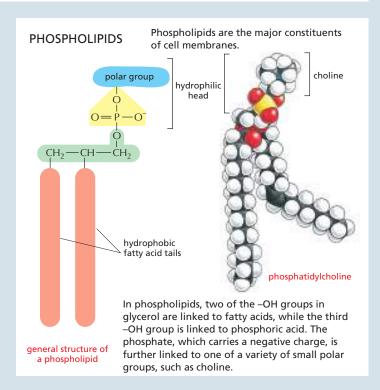

CARBOXYL GROUP

If free, the carboxyl group of a fatty acid will be ionized.

But more often it is linked to other groups to form either esters

or amides.

MBOC7_ptr_ch02_049-114.indd 102 08/12/21 11:25 AM

LIPID AGGREGATES

Fatty acids have a hydrophilic head and a hydrophobic tail.

surface film micelle

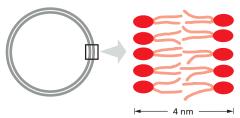

In water, they can form either a surface film or small, spherical micelles.

Their derivatives can form larger aggregates held together by hydrophobic forces:

Triacylglycerols form large, spherical fat droplets in the cell cytoplasm.

> 200 nm or more

Phospholipids and glycolipids form self-sealing lipid bilayers, which are the basis for all cell membranes.

OTHER LIPIDS

Lipids are defined as water-insoluble molecules that are soluble in organic solvents. Two other common types of lipids are steroids and polyisoprenoids. Both are made from isoprene units.

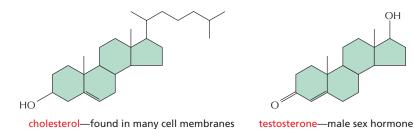

$$CH_3$$
 $C-CH=CH_2$
 CH_2 isoprene

ОН

galactose

STEROIDS

Steroids have a common multiple-ring structure.

GLYCOLIPIDS

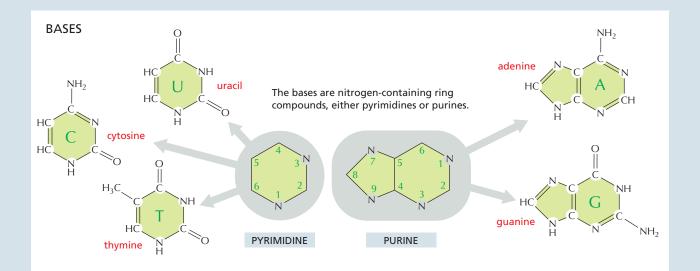

Like phospholipids, these compounds are composed of a hydrophobic region, containing two long hydrocarbon tails, and a polar region, which contains one or more sugars. Unlike phospholipids, there is no phosphate.

POLYISOPRENOIDS

Long-chain polymers of isoprene

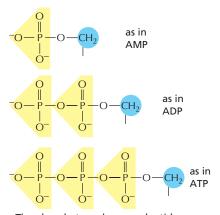

dolichol phosphate—used to carry activated sugars in the membraneassociated synthesis of glycoproteins and some polysaccharides

PHOSPHATES

104

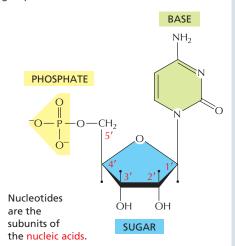

The phosphates are normally joined to the C5 hydroxyl of the ribose or deoxyribose sugar (designated 5'). Mono-, di-, and triphosphates are common.

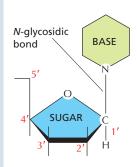

The phosphate makes a nucleotide negatively charged.

NUCLEOTIDES

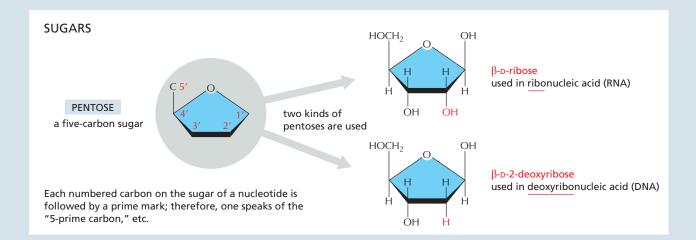

A nucleotide consists of a nitrogen-containing base, a five-carbon sugar, and a phosphate group.

BASE-SUGAR LINKAGE

The base is linked to the same carbon (C1) used in sugar–sugar bonds.

MBOC7_ptr_ch02_049-114.indd 104 08/12/21 11:25 AM

NOMENCLATURE

A nucleoside or nucleotide is named according to its nitrogenous base.

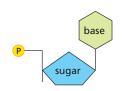

BASE	NUCLEOSIDE	ABBR.
adenine	adenosine	Α
guanine	guanosine	G
cytosine	cytidine	С
uracil	uridine	U
thymine	thymidine	Т

Single-letter abbreviations are used variously as shorthand for (1) the base alone, (2) the nucleoside, or (3) the whole nucleotide— the context will usually make clear which of the three entities is meant. When the context is not sufficient, we will add the terms "base," "nucleoside," "nucleotide," or—as in the examples below—use the full 3-letter nucleotide code.

AMP = adenosine monophosphate
dAMP = deoxyadenosine monophosphate
UDP = uridine diphosphate
ATP = adenosine triphosphate

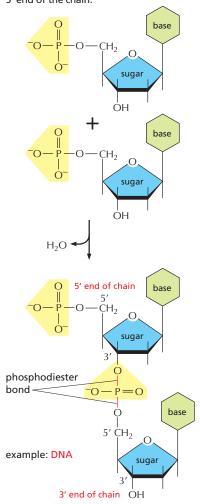

BASE + SUGAR = NUCLEOSIDE

BASE + SUGAR + PHOSPHATE = NUCLEOTIDE

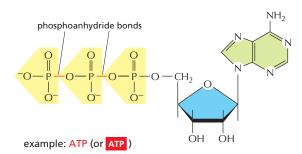

NUCLEIC ACIDS

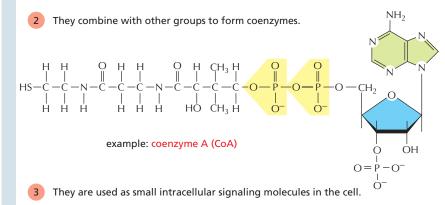

To form nucleic acid polymers, nucleotides are joined together by phosphodiester bonds between the 5' and 3' carbon atoms of adjacent sugar rings. The linear sequence of nucleotides in a nucleic acid chain is abbreviated using a one-letter code, such as AGCTT, starting with the 5' end of the chain.

NUCLEOTIDES AND THEIR DERIVATIVES HAVE MANY OTHER FUNCTIONS

As nucleoside di- and triphosphates, they carry chemical energy in their easily hydrolyzed phosphoanhydride bonds.

example: cyclic AMP (cAMP)

O=POOH

THE IMPORTANCE OF FREE ENERGY FOR CELLS

Life is possible because of the complex network of interacting chemical reactions occurring in every cell. In viewing the metabolic pathways that comprise this network, one might suspect that the cell has had the ability to evolve an enzyme to carry out any reaction that it needs. But this is not so. Although enzymes are powerful catalysts, they can promote only those reactions that are thermodynamically possible; other reactions proceed in cells only because they are coupled to very favorable reactions that drive them.

The question of whether a reaction can occur spontaneously, or instead needs to be coupled to another reaction, is central to cell biology. The answer is obtained by reference to a quantity called the *free energy*. In this Panel, we shall explain some of the fundamental ideas—derived from a special branch of chemistry and physics called *thermodynamics*—that are required for understanding what free energy is and why it is so important to cells.

ENERGY RELEASED BY CHANGES IN CHEMICAL BONDING IS CONVERTED INTO HEAT

An enclosed system is defined as a collection of molecules that does not exchange matter with the rest of the universe (e.g., the "cell in a box" shown above). Any such system will contain molecules with a total energy E. This energy will be distributed in a variety of ways: some as the translational energy of the molecules, some as their vibrational and rotational energies, but most as the bonding energies between the individual atoms that make up the molecules. Suppose that a reaction occurs in the system. The first law of thermodynamics places a constraint on what types of reactions are possible: it states that "in any process, the total energy of the universe remains constant.' For example, suppose that reaction $A \rightarrow B$ occurs somewhere in the box and releases a great deal of chemical-bond energy. This energy will initially increase the intensity of molecular motions (translational, vibrational, and rotational) in the system, which is equivalent to raising its temperature. However, these increased motions will soon be transferred out of the system by a series

of molecular collisions that heat up first the walls of the box and then the outside world (represented by the sea in our example). In the end, the system returns to its initial temperature, by which time all the chemical-bond energy released in the box has been converted into heat energy and transferred out of the box to the surroundings. According to the first law, the change in the energy in the box ($\Delta E_{\rm box}$, which we shall denote as ΔE) must be equal and opposite to the amount of heat energy transferred, which we shall designate as h; that is, $\Delta E = -h$. Thus, the energy in the box (E) decreases when heat leaves the system.

E also can change during a reaction as a result of work being done on the outside world. For example, suppose that there is a small increase in the volume (ΔV) of the box during a reaction. Because the walls of the box must push against the constant pressure (P) in the surroundings in order to expand, this does work on the outside world and requires energy. The energy used is $P(\Delta V)$, which according to the first law must decrease the energy in the box (E) by the same amount. In most reactions, chemical-bond energy is converted into both work and heat. Enthalpy (H) is a composite function that includes both of these (H = E + PV). To be rigorous, it is the change in enthalpy (ΔH) in an enclosed system, and not the change in energy, that is equal to the heat transferred to the outside world during a reaction. Reactions in which H decreases release heat to the surroundings and are said to be "exothermic," while reactions in which H increases absorb heat from the surroundings and are said to be "endothermic." Thus, $-h = \Delta H$. However, the volume change is negligible in most biological reactions, so to a good approximation

 $-h = \Delta H \approx \Delta E$

THE SECOND LAW OF THERMODYNAMICS

Consider a container in which 1000 coins are all lying heads-up. If the container is shaken vigorously, subjecting the coins to the types of random motions that all molecules experience due to their frequent collisions with other molecules, one will end up with about half the coins oriented heads-down. The reason for this reorientation is that there is only a single way in which the original orderly state of the coins can be reinstated (every coin must lie heads-up), whereas there are many different ways (about 10²⁹⁸) to achieve a disorderly state in which there is an equal mixture of heads and tails; in fact, there are more ways

to achieve a 50–50 state than to achieve any other state. Each state has a probability of occurrence that is proportional to the number of ways it can be realized. The second law of thermodynamics states that "systems will change spontaneously from states of lower probability to states of higher probability." Because states of lower probability are more ordered than states of higher probability, the second law can be restated: "the universe constantly changes so as to become more disordered."

MBOC7_ptr_ch02_049-114.indd 106 08/12/21 11:25 AM

THE ENTROPY, S

The second law (but not the first law) allows one to predict the direction of a particular reaction. But to make it useful for this purpose, one needs a convenient measure of the probability or, equivalently, the degree of disorder of a state. The entropy (S) is such a measure. It is a logarithmic function of the probability. Thus the change in entropy (ΔS) that occurs when the reaction $A \rightarrow B$ converts 1 mole of A into 1 mole of B is

$$\Delta S = R \ln p_R/p_A$$

where p_A and p_B are the probabilities of the two states A and B, R is the gas constant (8.31 J K⁻¹ mole⁻¹), and ΔS is measured in entropy units (eu).

For 1000 coins, the relative probability of all heads (state A) versus half heads and half tails (state B) is equal to the ratio of the number of different ways that the two results can be obtained. One can calculate that $p_{\rm A}=1$ and $p_{\rm B}=1000!(500!\times500!)=10^{298}$. Therefore, the entropy change for the reorientation of the coins

when their container is vigorously shaken and an equal mixture of heads and tails is obtained is R In (10^{298}), or about 1370 eu per mole of such containers (6×10^{23} containers). Because ΔS defined above is positive for the transition from state A to state B ($p_B/p_A > 1$), reactions with an *increase* in S (i.e., for which $\Delta S > 0$) are favored and will occur spontaneously.

Heat energy causes the random commotion of molecules. Because the transfer of heat from an enclosed system to its surroundings increases the number of different arrangements that the molecules in the outside world can have, it increases their entropy. It can be shown that the release of a fixed quantity of heat energy has a greater disordering effect at low temperature than at high temperature, and that the value of ΔS for the surroundings, as described above ($\Delta S_{\rm sea}$), is precisely equal to h, the amount of heat transferred to the surroundings from the system, divided by the absolute temperature (T):

$$\Delta S_{\text{sea}} = h/T$$

THE GIBBS FREE ENERGY, G

When dealing with an enclosed biological system, one would like to have a simple way of predicting whether a given reaction will or will not occur spontaneously in the system. We have seen that the crucial question is whether the entropy change for the universe is positive or negative when that reaction occurs. In our idealized system, the cell in a box, there are two separate components to the entropy change of the universe—the entropy change for the system enclosed in the box and the entropy change for the surrounding "sea"—and both must be added together before any prediction can be made. For example, it is possible for a reaction to absorb heat and thereby decrease the entropy of the sea ($\Delta S_{\rm sea}$ < 0) and at the same time cause such a large degree of disordering inside the box ($\Delta S_{\text{box}} > 0$) that the total $\Delta S_{\rm universe}$ = $\Delta S_{\rm sea}$ + $\Delta S_{\rm box}$ is greater than zero. In this case, the reaction will occur spontaneously, even though the sea gives up heat to the box during the reaction. An example of such a reaction is the dissolving of sodium chloride in a beaker containing water (the "box"), which is a spontaneous process even though the temperature of the water drops as the salt goes into solution.

Chemists have found it useful to define a number of new "composite functions" that describe *combinations* of physical properties of a system. The properties that can be combined include the temperature (7), pressure (P), volume (V), energy (E), and entropy (S). The enthalpy (H) is one such composite function. But by far the most useful composite function for biologists is the *Gibbs free energy*, G. It serves as an accounting device that allows one to deduce the entropy change of the universe resulting from a chemical reaction in the box, while avoiding any separate consideration of the entropy change in the sea. The definition of G is

$$G = H - TS$$

where, for a box of volume V, H is the enthalpy described earlier (E+PV), T is the absolute temperature, and S is the entropy. Each of these quantities applies to the inside of the box only. The change in free energy during a reaction in the box (the G of the products minus the G of the starting materials) is denoted as ΔG and, as we shall now demonstrate, it is a direct measure of the amount of disorder that is created in the universe when the reaction occurs.

At constant temperature the change in free energy (ΔG) during a reaction equals $\Delta H - T \Delta S$. Remembering that $\Delta H = -h$, the heat absorbed from the sea, we have

$$-\Delta G = -\Delta H + T \Delta S$$
$$-\Delta G = h + T \Delta S, \text{ so } -\Delta G/T = h/T + \Delta S$$

But h/T is equal to the entropy change of the sea (ΔS_{sea}), and the ΔS in the above equation is ΔS_{box} . Therefore

$$-\Delta G/T = \Delta S_{\text{sea}} + \Delta S_{\text{box}} = \Delta S_{\text{universe}}$$

We conclude that the free-energy change is a direct measure of the entropy change of the universe. A reaction will proceed in the direction that causes the change in the free energy (ΔG) to be less than zero, because in this case there will be a positive entropy change in the universe when the reaction occurs.

For a complex set of coupled chemical reactions involving many different molecules, the total free-energy change can be computed simply by adding up the free energies of all the different molecular species after the reaction and comparing this value with the sum of free energies before the reaction. For common substances, the required free-energy values can be found from published tables. In this way, one can predict the direction of a reaction and thereby readily check the feasibility of any proposed mechanism. (Thus, for example, from the magnitude of the electrochemical proton gradient across the inner mitochondrial membrane and the ΔG for ATP hydrolysis inside the mitochondrion, one can be certain that the ATP synthase enzyme requires that more than one proton pass through it for each molecule of ATP that it synthesizes.)

The value of ΔG for a reaction is a direct measure of how far the reaction is from equilibrium. The large negative value for ATP hydrolysis in a cell merely reflects the fact that cells keep the ATP hydrolysis reaction as much as 10 orders of magnitude away from equilibrium. If a reaction reaches equilibrium, $\Delta G = 0$, that reaction then proceeds at precisely equal rates in the forward and backward directions. For ATP hydrolysis, equilibrium is reached when the vast majority of the ATP has been hydrolyzed, as occurs in a dead cell.

For each step, the part of the molecule that undergoes a change is shadowed in *blue*, and the name of the enzyme that catalyzes the reaction is in a *yellow* box. Reactions represented by double arrows (⇒) are readily reversible, whereas those represented by single arrows (→) are effectively irreversible. To watch a video of the reactions of glycolysis, see Movie 2.5.

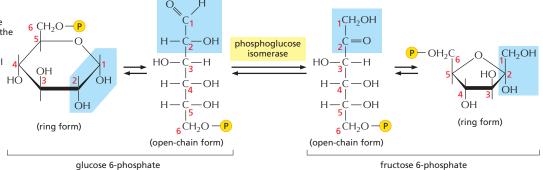

STEP 1

108

Glucose is phosphorylated by ATP to form a sugar phosphate. The negative charge of the phosphate prevents passage of the sugar phosphate through the plasma membrane, trapping glucose inside the cell.

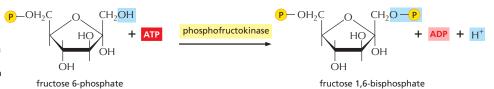

STEP 2

A readily reversible rearrangement of the chemical structure (isomerization) moves the carbonyl oxygen from carbon 1 to H carbon 2, forming a ketose from an aldose sugar. (See Panel 2–4, pp. 100–101.)

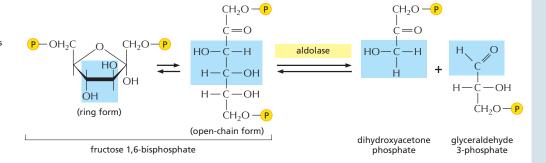

STEP 3

The new hydroxyl group on carbon 1 is phosphorylated by ATP, in preparation for the formation of two three-carbon sugar phosphates. The entry of sugars into glycolysis is controlled at this step, through regulation of the enzyme phosphofructokinase.

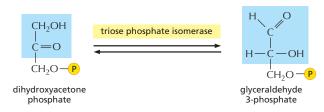

STEP 4

The six-carbon sugar is cleaved to produce two three-carbon molecules. Only the glyceraldehyde 3-phosphate can proceed immediately through glycolysis.

STEP 5

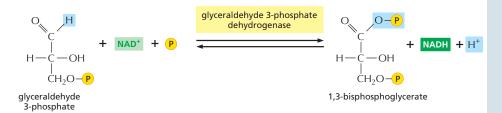

The other product of step 4, dihydroxyacetone phosphate, is isomerized to form a second molecule of glyceraldehyde 3-phosphate.

MBOC7_ptr_ch02_049-114.indd 108 08/12/21 11:25 AM

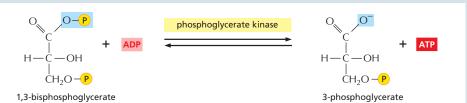

STEP 6

The two molecules of glyceraldehyde 3-phosphate produced in steps 4 and 5 are oxidized. The energy-generation phase of glycolysis begins, as NADH and a new high-energy anhydride linkage to phosphate are formed (see Figure 2–47).

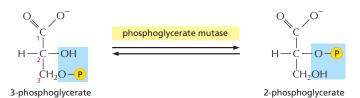

STEP 7

The transfer to ADP of the high-energy phosphate group that was generated in step 6 forms ATP.

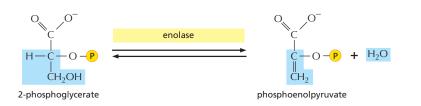

STEP 8

The remaining phosphate ester linkage in 3-phosphoglycerate, which has a relatively low free energy of hydrolysis is moved from carbon 3 to carbon 2 to form 2-phosphoglycerate.

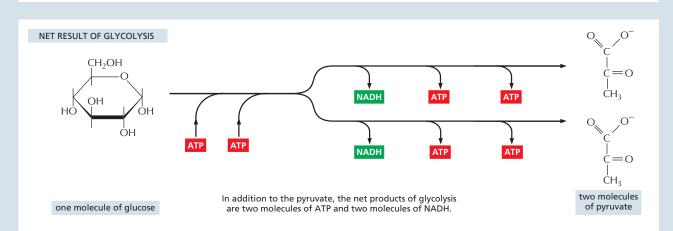

STEP 9

The removal of water from 2-phosphoglycerate creates a high-energy enol phosphate linkage.

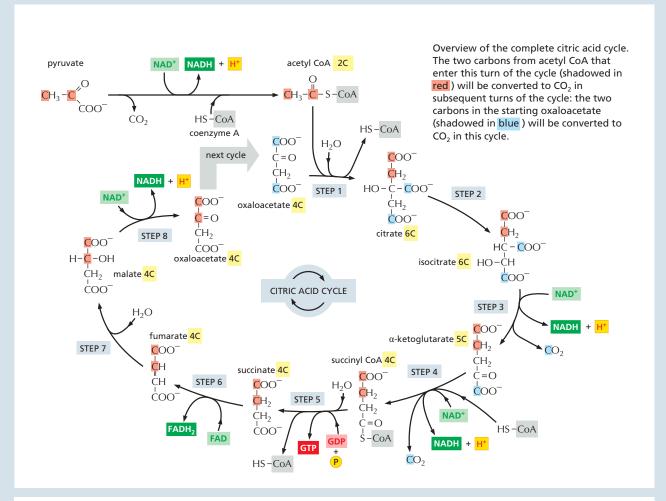

STEP 10

The transfer to ADP of the high-energy phosphate group that was generated in step 9 forms ATP, completing glycolysis.

MBOC7_ptr_ch02_049-114.indd 109 08/12/21 11:25 AM

Details of these eight steps are shown below. In this part of the Panel, for each step, the part of the molecule that undergoes a change is shadowed in blue, and the name of the enzyme that catalyzes the reaction is in a yellow box.

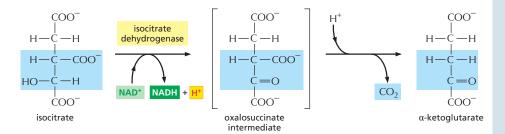

To watch a video of the reactions of the citric acid cycle, see Movie 2.6.

STEP 1 COO After the enzyme removes COO citrate a proton from the CH₃ group on acetyl CoA, the ĊH₂ synthaseĊH₂ S-CoA negatively charged CH₂⁻ forms a bond to a carbonyl COO ĊH₂ carbon of oxaloacetate. ĊH₂ ĊH₂ The subsequent loss by hydrolysis of the coenzyme A (HS–CoA) drives the COO COO ĊOO reaction strongly forward. acetyl CoA oxaloacetate S-citryl-CoA citrate intermediate

MBOC7_ptr_ch02_049-114.indd 110 08/12/21 11:25 AM

STEP 3

In the first of four oxidation steps in the cycle, the carbon carrying the hydroxyl group is converted to a carbonyl group. The immediate product is unstable, losing CO_2 while still bound to the enzyme.

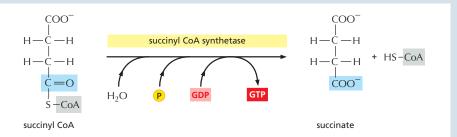

STEP 4

The α -ketoglutarate dehydrogenase complex closely resembles the large enzyme complex that converts pyruvate to acetyl CoA, the pyruvate dehydrogenase complex. It likewise catalyzes an oxidation that produces NADH, CO₂, and a high-energy thioester bond to coenzyme A (CoA).

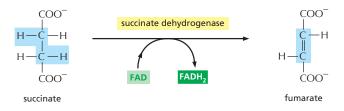

STEP 5

An inorganic phosphate displaces the CoA, forming a high-energy phosphate linkage to succinate. This phosphate is then passed to GDP to form GTP. (In bacteria and plants, ATP is formed instead.)

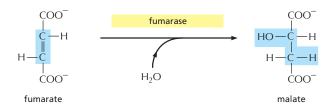

STEP 6

In the third oxidation step of the cycle, FAD accepts two hydrogen atoms from succinate.

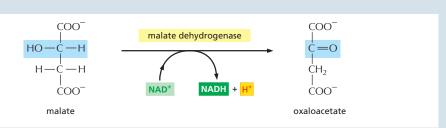

STEP 7

The addition of water to fumarate places a hydroxyl group next to a carbonyl carbon.

STEP 8

In the last of four oxidation steps in the cycle, the carbon carrying the hydroxyl group is converted to a carbonyl group, regenerating the oxaloacetate needed for step 1.

MBOC7_ptr_ch02_049-114.indd 111 08/12/21 11:25 AM

PROBLEMS

Which statements are true? Explain why or why not.

- 2-1 A 10^{-8} M solution of HCl has a pH of 8.
- **2–2** Most of the interactions between macromolecules could be mediated just as well by covalent bonds as by noncovalent bonds.
- **2–3** Animals and plants use oxidation to extract energy from food molecules.
- **2–4** If an oxidation occurs in a reaction, it must be accompanied by a reduction.
- **2–5** Linking the energetically unfavorable reaction $A \to B$ to a second, favorable reaction $B \to C$ will shift the equilibrium constant for the first reaction.
- **2–6** The criterion for whether a reaction proceeds spontaneously is ΔG , not ΔG° , because ΔG takes into account the concentrations of the substrates and products.
- **2–7** The oxygen consumed during the oxidation of glucose in animal cells is returned as CO_2 to the atmosphere.

Discuss the following problems.

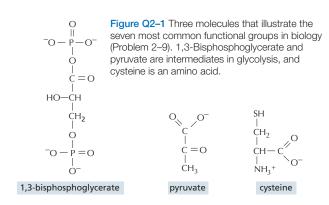

2-8 During an all-out sprint, muscles produce a high concentration of lactic acid, which lowers the pH of the blood and of the cytosol. The lower pH inside the cell reduces the rate of ATP production and contributes to the fatigue that sprinters experience well before their fuel reserves are exhausted. The main blood buffer against pH changes is the bicarbonate/CO₂ system.

$$pK_1 = pK_2 = pK_3 =$$

$$CO_2 \rightleftharpoons CO_2 \rightleftharpoons H_2CO_3 \rightleftharpoons H^+ + HCO_3 - \rightleftharpoons H^+ + CO_3^2 -$$
(gas) (dissolved)

To improve their performance, would you advise sprinters to hold their breath or to breathe rapidly just before the race? Why?

- **A.** Breathe rapidly to decrease the pH of the blood.
- B. Breathe rapidly to increase the pH of the blood.
- C. Hold their breath to decrease the pH of the blood.
- D. Hold their breath to increase the pH of the blood.
- **2–9** The three molecules in **Figure Q2–1** contain the seven most common functional groups in biology. Most molecules in the cell are built from these functional groups. Indicate and name the functional groups in these molecules.

- **2–10** The molecular weight of ethanol (CH_3CH_2OH) is 46 and its density is 0.789 g/cm³.
- A. What is the molarity of ethanol in beer that is 5% ethanol by volume? [Alcohol content of beer varies from about 4% (lite beer) to 8% (stout beer).]
- B. The legal limit for a driver's blood alcohol content varies, but 80 mg of ethanol per 100 mL of blood (usually referred to as a blood alcohol level of 0.08) is typical. What is the molarity of ethanol in a person at this legal limit?
- C. How many 12-oz (355-mL) bottles of 5% beer could a 70-kg person drink and remain under the legal limit? A 70-kg person contains about 40 liters of water. Ignore the metabolism of ethanol and assume that the water content of the person remains constant and that ethanol distributes evenly in that volume.
- **2–11** A histidine side chain is known to play an important role in the catalytic mechanism of an enzyme; however, it is not clear whether histidine is required in its protonated (charged) or unprotonated (uncharged) state. To answer this question, you measure enzyme activity over a range of pH, with the results shown in **Figure Q2–2**. Which form of histidine is required for enzyme activity?

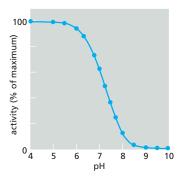

Figure Q2-2 Enzyme activity as a function of pH (Problem 2-11).

MBOC7_ptr_ch02_049-114.indd 112 08/12/21 11:25 AM

PROBLEMS 113

- **2–12** The organic chemistry of living cells is said to be special for two reasons: it occurs in an aqueous environment, and it accomplishes some very complex reactions. But do you suppose it is really all that much different from the organic chemistry carried out in the top laboratories in the world? Why or why not?
- **2–13** Polymerization of tubulin subunits into microtubules occurs with an increase in the orderliness of the subunits. Yet tubulin polymerization occurs with an increase in entropy (decrease in order). How can that be?
- **2–14** "Diffusion" sounds slow—and over everyday distances it is—but on the scale of a cell it is very fast. The average instantaneous velocity of a particle in solution—that is, the velocity between the very frequent collisions—is

$$v = (kT/m)^{1/2}$$

where $k = 1.38 \times 10^{-16}$ g cm²/K sec², T = temperature in K (37°C is 310 K), and m = mass in g/molecule.

Calculate the instantaneous velocity of a water molecule (molecular mass = 18 daltons), a glucose molecule (molecular mass = 180 daltons), and a myoglobin molecule (molecular mass = 15,000 daltons) at 37° C.

- **2–15** Each phosphoanhydride bond between the phosphate groups in ATP is a high-energy linkage with a ΔG° value of -30.5 kJ/mole. Hydrolysis of this bond in cells normally liberates usable energy in the range of 45 to 55 kJ/mole. Why do you think a range of values for released energy is given for ΔG , rather than a precise number, as for ΔG° ?
- A. ΔG cannot be accurately measured and can only be estimated as a range of values.
- B. Differences in the concentrations of ATP, ADP, and phosphate can significantly change ΔG .
- **C.** The specific enzyme catalyzing hydrolysis determines how much energy is released.
- D. The temperature fluctuations occurring inside the cell can significantly change ΔG .
- **2–16** A 70-kg adult human (154 lb) could meet his or her entire energy needs for one day by eating 3 moles of glucose (540 g). (We do not recommend this.) Each molecule of glucose generates 30 molecules of ATP when it is oxidized to CO₂. The concentration of ATP is maintained in cells at about 2 mM, and a 70-kg adult has about 25 liters of intracellular fluid. Given that the ATP concentration remains constant in cells, calculate how many times per day, on average, each ATP molecule in the body is hydrolyzed and resynthesized.
- **2–17** What is the "packet of energy" that NADH and NADPH carry?
- A. A hydride ion (two electrons and one proton)
- B. A hydrogen atom (one electron and one proton)
- C. A hydrogen ion (one proton and no electrons)
- D. A hydronium ion (a protonated water molecule)

2–18 Cancer cells can increase the rate of glycolysis up to 200-fold relative to normal differentiated cells. This effect, known as the Warburg effect after its discoverer, is exploited in an imaging technique that is commonly used to detect tumors. An individual is dosed with a molecule labeled with a radioactive isotope of fluorine (¹⁸F). The labeled molecule is preferentially taken up by cancer cells and is detected by positron emission tomography (PET) scanning. Which one of the following molecules would you label with ¹⁸F to detect tumors via the Warburg effect?

A. Acetyl CoA

B. Glucose

C. Lactate

D. Pyruvate

2–19 Does a Snickers candy bar (65 g, 1360 kJ) provide enough energy to climb from Zermatt (elevation 1660 m) to the top of the Matterhorn (4478 m; Figure Q2–3), or might you need to stop at Hörnli Hut (3260 m) to eat another one? Imagine that you and your gear have a mass of 75 kg and that all of your work is done against gravity (that is, you are just climbing straight up). Remember from your introductory physics course that

work (J) = mass (kg)
$$\times$$
 g (m/sec²) \times height gained (m)

where g is acceleration due to gravity (9.8 m/sec²). One joule is 1 kg m²/sec². What assumptions made here will greatly underestimate how much candy you need?

Figure Q2–3 The Matterhorn (Problem 2–19). (Earth Trotter Photos/Shutterstock.)

2–20 Assuming that there are 5×10^{13} cells in the human body and that ATP is turning over at a rate of 10^9 ATP molecules per minute in each cell, how many watts is the human body consuming? (A watt is a joule per second.) Assume that hydrolysis of ATP yields $50 \, \text{kJ/mole}$.

CHAPTER

3

Proteins

When we look at a cell through a microscope or analyze its electrical or biochemical activity, we are, in essence, observing proteins. Proteins constitute most of a cell's dry mass. They are not only the cell's building blocks; they also execute the majority of the cell's functions. Proteins that are enzymes provide the intricate molecular surfaces inside a cell that catalyze its many chemical reactions. Proteins embedded in the plasma membrane form channels and pumps that control the passage of small molecules into and out of the cell. Other proteins carry messages from one cell to another or act as signal integrators that relay sets of signals inward from the plasma membrane to the cell nucleus. Yet others serve as tiny molecular machines with moving parts: kinesin, for example, propels organelles through the cytoplasm; topoisomerase can untangle knotted DNA molecules. Other specialized proteins act as antibodies, toxins, hormones, antifreeze molecules, elastic fibers, ropes, or sources of luminescence. Before we can hope to understand how genes work, how muscles contract, how nerves conduct electricity, how embryos develop, or how our bodies function, we must attain a deep understanding of proteins.

THE ATOMIC STRUCTURE OF PROTEINS

From a chemical point of view, proteins are by far the most structurally complex and functionally sophisticated molecules known. This is perhaps not surprising, once we realize that the structure and chemistry of each protein have been developed and fine-tuned over billions of years of evolutionary history. The theoretical calculations of population geneticists reveal that, over evolutionary time periods, a surprisingly small selective advantage is enough to cause a randomly altered protein sequence to spread through a population of organisms. Yet, even to experts, the remarkable versatility of proteins can seem truly amazing.

In this section, we consider how the location of each amino acid in a protein's long string of amino acids determines its three-dimensional shape. Later in the chapter, we use this understanding of protein structure at the atomic level to describe how the precise shape of each protein molecule determines its function in a cell.

The Structure of a Protein Is Specified by Its Amino Acid Sequence

There are 20 different types of amino acids in proteins that are encoded directly in an organism's DNA, each with different chemical properties. Every **protein** molecule consists of a long unbranched chain of these amino acids, each linked to its neighbor through a covalent *peptide bond* (**Figure 3–1A**). Proteins are therefore also known as *polypeptides*. Each type of protein has a unique sequence of amino acids, and there are many thousands of different proteins in a cell.

The repeating sequence of atoms along the core of the polypeptide chain is referred to as the **polypeptide backbone**. Attached to this repetitive backbone are those portions of the amino acids that are not involved in making

116 Chapter 3: Proteins

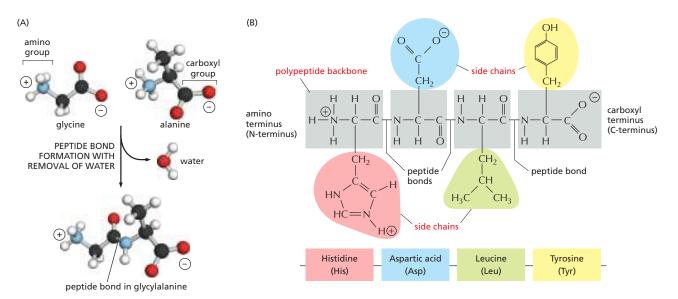

Figure 3–1 The components of a protein. (A) Formation of a peptide bond. This covalent bond forms when the carbon atom of the carboxyl group of one amino acid (such as glycine) shares electrons with the nitrogen atom from the amino group of a second amino acid (such as alanine). As indicated, a molecule of water is eliminated in this condensation reaction (see Figure 2–9). In this model, carbon atoms are *black*, nitrogen *blue*, oxygen *red*, and hydrogen *white*. (B) A two-dimensional representation of a short section of polypeptide backbone with its attached side chains. Each type of protein differs in its sequence and number of amino acids; it is the sequence of the chemically different side chains that makes each protein distinct. The two ends of a polypeptide chain are chemically different: the end carrying the free amino group (NH₂, which takes up a proton at neutral pH to become NH₃+) is the amino terminus, or N-terminus, and the end carrying the free carboxyl group (COOH, which loses a proton at neutral pH to become COO⁻) is the carboxyl terminus, or C-terminus. Note that, for simplicity, in many figures in this textbook, NH₂ and COOH are used to denote these termini, instead of their actual ionized forms. The amino acid sequence of a protein is always presented in the N-to-C direction, reading from left to right.

a peptide bond; these are the 20 different amino acid **side chains** that give each amino acid its unique properties (**Figure 3-1B**). Some of these side chains are nonpolar and hydrophobic ("water-fearing"), others are negatively or positively charged, some can readily form covalent bonds, and so on. **Panel 3-1** (pp. 118-119) shows their atomic structures, and **Figure 3-2** lists their abbreviations.

AMINO ACID			SIDE CHAIN		AMINO ACID		SIDE CHAIN	
Aspartic acid	Asp	D	acidic (negative charge)		Alanine	Ala	Α	nonpolar
Glutamic acid	Glu	Е	acidic (negative charge)		Glycine	Gly	G	nonpolar
Arginine	Arg	R	basic (positive charge)		Valine	Val	V	nonpolar
Lysine	Lys	K	basic (positive charge)		Leucine	Leu	L	nonpolar
Histidine	His	Н	basic (positive charge)		Isoleucine	lle	1	nonpolar
Asparagine	Asn	N	uncharged polar		Proline	Pro	Р	nonpolar
Glutamine	Gln	Q	uncharged polar		Phenylalanine	Phe	F	nonpolar
Serine	Ser	S	uncharged polar		Methionine	Met	M	nonpolar
Threonine	Thr	Т	uncharged polar		Tryptophan	Trp	W	nonpolar
Tyrosine	Tyr	Υ	uncharged polar		Cysteine	Cys	C	nonpolar
POLAR AMINO ACIDS NONPOLAR AMINO ACIDS								

Figure 3–2 The 20 amino acids commonly found in proteins. Each amino acid has a three-letter and a one-letter abbreviation. There are equal numbers of polar and nonpolar side chains; however, some side chains listed here as polar are large enough to have some nonpolar properties (for example, Thr, Tyr, Arg, Lys). For atomic structures, see Panel 3–1 (pp. 118–119).

MBOC7_ptr_ch03_115-182.indd 116 02/12/21 2:16 PM

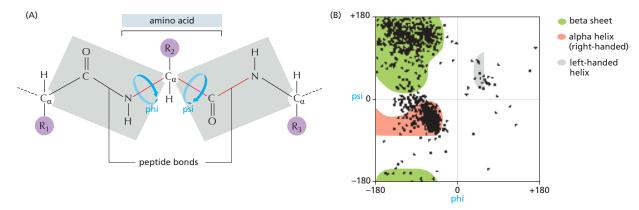

Figure 3–3 Steric limitations on the bond angles in a polypeptide chain. (A) Each amino acid contributes three bonds (red) to the backbone of the chain. Because it has a partial double-bond character, the peptide bond is planar (gray shading) and does not permit free rotation. By contrast, rotation can occur about the C_{α} –C bond, whose angle of rotation is called psi (Ψ), and about the N–C $_{\alpha}$ bond, whose angle of rotation is called phi (φ). By convention, an R group is often used to denote an amino acid side chain (purple circles). (B) The conformation of the main-chain atoms in a protein is determined by one pair of φ and Ψ angles for each amino acid; because of steric restrictions, most of the possible pairs of φ and Ψ angles do not occur. In this so-called Ramachandran plot, each dot represents an observed pair of angles in a protein. The three differently shaded clusters of dots reflect three different secondary structures repeatedly found in proteins. Most prominent are the alpha helix and the beta sheet, as will be described in the text. (B, from J. Richardson, Adv. Prot. Chem. 34:174–175, 1981. With permission from Elsevier.)

As discussed in Chapter 2, atoms behave almost as if they were hard spheres with a definite radius (their *van der Waals radius*). Other constraints limit the possible bond angles in a polypeptide chain, and this—plus the requirement that no two atoms overlap—severely restricts the possible three-dimensional arrangements (or *conformations*) of proteins. As illustrated in Figure 3–3, these steric restrictions (which include a delocalization of electrons in the peptide bond that makes that linkage planar) confine the energy minima for the bond angles in polypeptides to a narrow range. But a long flexible chain such as a protein can still fold in an enormous number of different ways.

The folding of a protein chain is determined by many different sets of weak *noncovalent bonds* that form between one part of the chain and another. These involve atoms in the polypeptide backbone, as well as atoms in the amino acid side chains. There are three types of these weak bonds: *hydrogen bonds, electrostatic attractions,* and *van der Waals attractions,* as explained in Chapter 2 (see p. 51). Individual noncovalent bonds are 30–300 times weaker than the typical covalent bonds that create biological molecules. But many weak bonds acting in parallel can hold two regions of a polypeptide chain tightly together. It is the combined strength of large numbers of these noncovalent bonds that stabilizes each protein's folded shape (Figure 3–4).

A fourth weak force—a hydrophobic clustering force—also has a central role in determining the shape of a protein. As described in Chapter 2, hydrophobic molecules, including the nonpolar side chains of particular amino acids, tend to be forced together in an aqueous environment in order to minimize their disruptive effect on the hydrogen-bonded network of water molecules (see Panel 2-2, pp. 96-97). Therefore, an important factor governing the folding of any protein is the distribution of its polar and nonpolar amino acids. The nonpolar (hydrophobic) side chains in a protein—belonging to such amino acids as phenylalanine, leucine, valine, and tryptophan—tend to cluster in the interior of the molecule (just as hydrophobic oil droplets coalesce in water to form one large droplet). This enables these side chains to avoid contact with the water that surrounds them inside a cell. In contrast, polar groups—such as those belonging to arginine, glutamine, and histidine—tend to arrange themselves near the outside of the molecule, where they can form hydrogen bonds with water and with other polar molecules (Figure 3-5). Any polar amino acids that are left buried within the protein are usually hydrogen-bonded to other polar amino acids or to the polypeptide backbone.

OPTICAL ISOMERS

The α -carbon atom is asymmetric, allowing for two mirror-image (or stereo-) isomers, L and D.

Proteins contain exclusively L-amino acids.

PEPTIDE BONDS

In proteins, amino acids are joined together by an amide linkage, called a peptide bond.

The four atoms involved in each peptide bond form a rigid planar unit (red box). There is no rotation around the C-N bond.

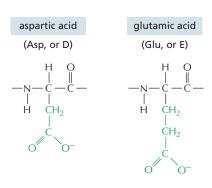

H₂O

Proteins are long polymers of amino acids linked by peptide bonds, and they are always written with the N-terminus toward the left. Peptides are shorter, usually fewer than 50 amino acids long. The sequence of this tripeptide is histidine-cysteine-valine.

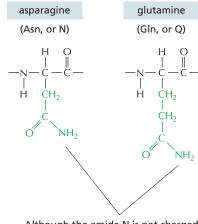

ŞH peptide bond amino terminus, or \circ ĊH₂ carboxyl terminus, or CH_3 These two single bonds allow rapid rotation, so that long chains of amino acids are very flexible.

120 Chapter 3: Proteins

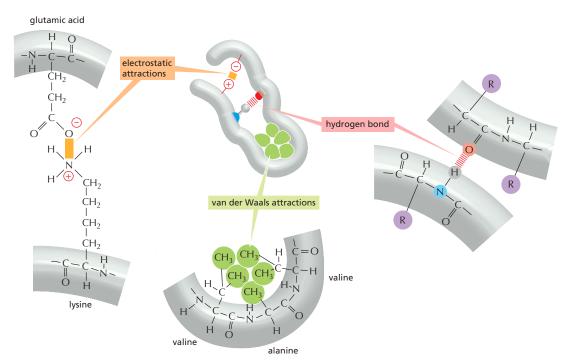

Figure 3–4 Three types of noncovalent bonds help proteins fold. Although a single one of these bonds is quite weak, many of them often act together to create a strong bonding arrangement, as in the example shown. As in the previous figure, R is used as a general designation for an amino acid side chain.

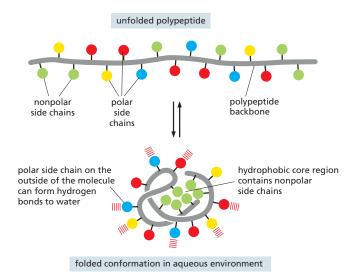

Figure 3–5 How a protein folds into a compact conformation. The polar amino acid side chains tend to lie on the outside of the protein, where they can interact with water; the nonpolar amino acid side chains are buried on the inside forming a tightly packed hydrophobic core of atoms that are hidden from water. In this highly schematic drawing, the protein contains only 17 amino acids; actual proteins are generally much larger.

MBOC7_ptr_ch03_115-182.indd 120 02/12/21 2:17 PM

Proteins Fold into a Conformation of Lowest Energy

As a result of all of these interactions, most proteins have a particular three-dimensional structure, which is determined by the order of the amino acids in a protein's chain. The final folded structure, or **conformation**, of any polypeptide chain is generally the one that minimizes its free energy. Biologists have studied protein folding in a test tube using highly purified proteins. Treatment with certain solvents, which disrupt the noncovalent interactions holding the folded chain together, unfolds, or *denatures*, a protein. This treatment converts the protein into a flexible polypeptide chain that has lost its natural shape. When the denaturing solvent is removed, the protein often refolds spontaneously, or *renatures*, into its original conformation. This indicates that the amino acid sequence contains all of the information needed for specifying the three-dimensional shape of a protein, a critical point for understanding cell biology.

Most proteins fold up into a single stable conformation. However, this conformation is very dynamic, experiencing constant fluctuations caused by thermal energy. In addition, a protein's conformation can change when the protein interacts with other molecules in the cell. This change in shape is often crucial to the function of the protein, as we explain in detail later.

Although a protein chain can fold into its correct conformation without outside help, special proteins called *molecular chaperones* often assist in protein folding (see Chapter 6). Molecular chaperones bind to partly folded polypeptide chains and help them progress along the most energetically favorable folding pathway. In the crowded conditions of the cytoplasm, chaperones are required to prevent the temporarily exposed hydrophobic regions in newly synthesized protein chains from associating with each other to form protein aggregates. However, the final three-dimensional shape of the protein is still specified by its amino acid sequence: chaperones simply make reaching the folded state more reliable.

The α Helix and the β Sheet Are Common Folding Motifs

When we compare the three-dimensional structures of many different protein molecules, it becomes clear that, although the overall conformation of each protein is unique, two regular folding patterns are often found within them. Both patterns were discovered 70 years ago from studies of hair and silk. The first folding pattern to be described, called the α helix, was found in the protein α -keratin, which forms the filaments in hair. Within a year of the discovery of the α helix, a second folded structure, called a β sheet, was found in the protein *fibroin*, the major constituent of silk. These two patterns are common because they result from hydrogen-bonding between the N-H and C=O groups in the polypeptide backbone, without involving the side chains of the amino acids. Thus, although incompatible with some amino acid side chains, many different amino acid sequences can form them. In each case, the protein chain adopts a regular, repeating conformation. Figure 3-6 illustrates the detailed structures of these two important conformations, which in ribbon models of proteins are represented by a helical ribbon and by a set of aligned arrows, respectively.

The cores of many proteins contain extensive regions of β sheet. As shown in **Figure 3–7**, these β sheets can form either from neighboring segments of the polypeptide backbone that run in the same orientation (parallel chains) or from a polypeptide backbone that folds back and forth upon itself, with each section of the chain running in the direction opposite to that of its immediate neighbors (antiparallel chains). Both types of β sheet produce a very rigid structure, held together by hydrogen bonds that connect the peptide bonds in neighboring chains (see Figure 3–6C).

MBOC7_ptr_ch03_115-182.indd 121 02/12/21 2:17 PM

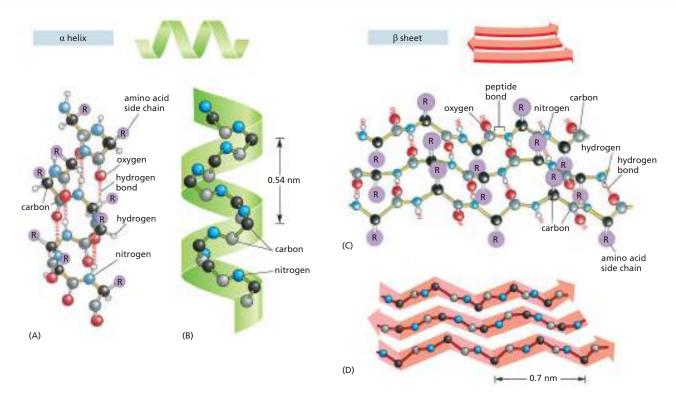

Figure 3–6 The regular conformation of the polypeptide backbone in the α helix and the β sheet. The α helix (alpha helix) is shown in (A) and (B). The N—H of every peptide bond is hydrogen-bonded to the C=O of a neighboring peptide bond located four peptide bonds away in the same chain. Note that all of the N—H groups point up in this diagram and that all of the C=O groups point down (toward the C-terminus); this gives a polarity to the helix, with the C-terminus having a partial negative and the N-terminus a partial positive charge (Movie 3.1). The β sheet (beta sheet) is shown in (C) and (D). In this example, adjacent peptide chains run in opposite (antiparallel) directions. Hydrogen-bonding between peptide bonds in different strands holds the individual polypeptide chains (strands) together in a β sheet, and the amino acid side chains in each strand alternately project above and below the plane of the sheet. By convention, when arrows are used to represent a β sheet, the arrowheads point toward the C-terminus (Movie 3.2). (A) and (C) show all the atoms in the polypeptide backbone, but the amino acid side chains are truncated and denoted by R. (It has long been a convention to use R in this way.) In contrast, (B) and (D) show only the carbon and nitrogen backbone atoms.

An α helix is generated when a single polypeptide chain twists around on itself to form a rigid cylinder. A hydrogen bond forms between every fourth peptide bond, linking the C=O of one peptide bond to the N—H of another (see Figure 3-6A). This gives rise to a regular helix with a complete turn every 3.6 amino acids.

Regions of α helix are abundant in proteins located in cell membranes, such as transport proteins and receptors. As we discuss in Chapter 10, those portions of a transmembrane protein that cross the lipid bilayer usually cross as α helices composed largely of amino acids with nonpolar side chains. The polypeptide backbone, which is hydrophilic, is hydrogen-bonded to itself in the α helix and shielded from the hydrophobic lipid environment of the membrane by its protruding nonpolar side chains (see Figure 10–19).

In other proteins, α helices can wrap around each other to form a particularly stable structure, known as a **coiled-coil**. This structure can form when the two (or in some cases, three or four) α helices have most of their nonpolar (hydrophobic) side chains on one side, so that they can twist around each other with these side chains facing inward (**Figure 3–8**). Long rodlike coiled-coils provide the structural framework for many elongated proteins. Examples are α -keratin, which forms the intracellular fibers that reinforce the outer layer of the skin and its appendages, and the myosin molecules responsible for muscle contraction.

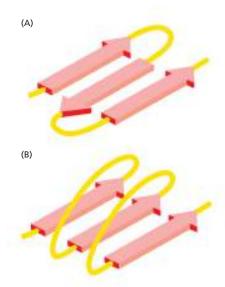

Figure 3–7 Two types of β sheet structures. (A) An antiparallel β sheet (see Figure 3–6C). (B) A parallel β sheet. Both of these structures are common in proteins.

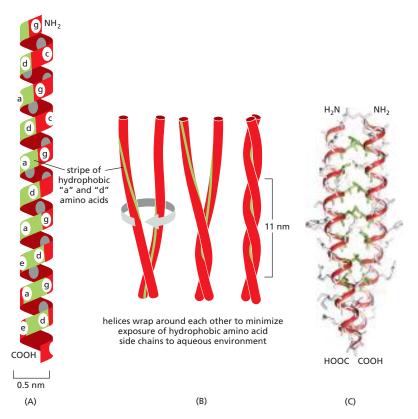

Figure 3–8 A coiled-coil. (A) A single α helix, with successive amino acid side chains labeled in a sevenfold sequence, "abcdefg" (from top to bottom). Amino acids "a" and "d" in such a sequence lie close together on the cylinder surface, forming a "stripe" (green) that winds slowly around the α helix. Proteins that form coiled-coils typically have nonpolar amino acids at positions "a" and "d." Consequently, as shown in (B), the two α helices can wrap around each other with the nonpolar side chains of one α helix interacting with the nonpolar side chains of the other. (C) The atomic structure of a coiled-coil determined by x-ray crystallography. The α -helical backbone is shown in red and the nonpolar side chains in green, while the more hydrophilic amino acid side chains, shown in gray, are left exposed to the aqueous environment (Movie 3.3). Coiled-coils can also form from three α helices. (PDB code: 3NMD.)

Four Levels of Organization Are Considered to Contribute to Protein Structure

Scientists have found it useful to define four levels of organization that successively generate the structure of a protein. The first level is the protein's amino acid sequence, which is known as its **primary structure**; this sequence is unique for each protein, as determined by the gene that encodes that protein. At the next level, those stretches of the polypeptide chain that form α helices and β sheets constitute the protein's **secondary structure**. The full three-dimensional organization of a polypeptide chain—including its α helices, β sheets, and the many twists and turns that form between its N- and C-termini—is referred to as the protein's **tertiary structure**. And finally, if a protein molecule is formed as a complex of more than one polypeptide chain, its complete conformation is designated as its **quaternary structure**.

Because even a small protein molecule is built from thousands of atoms linked together by precisely oriented covalent and noncovalent bonds, biologists are aided in visualizing these extremely complicated structures by computer-based three-dimensional displays. The student resource site that accompanies this book contains computer-generated images of selected proteins, which can be displayed and rotated on the screen in a variety of formats (Movie 3.4).

MBOC7_ptr_ch03_115-182.indd 123 02/12/21 2:17 PM

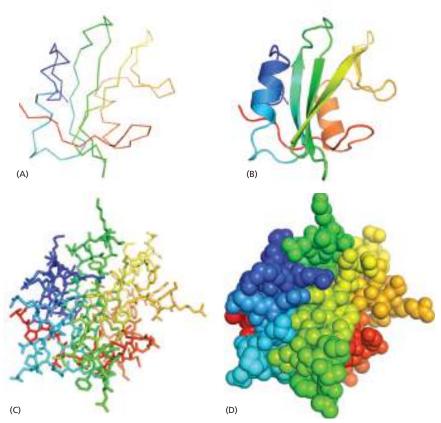

Figure 3–9 Four representations that are commonly used to describe the structure of a protein. Constructed from a string of 100 amino acids, the SH2 domain is part of many different proteins. Here, its structure is displayed as (A) a polypeptide backbone model, (B) a ribbon model, (C) a wire model that includes the amino acid side chains, and (D) a space-filling model (Movie 3.4). Each image is colored in a way that allows the polypeptide chain to be followed from its N-terminus (purple) to its C-terminus (red). (PDB code: 1SHA.)

Protein Domains Are the Modular Units from Which Larger Proteins Are Built

Proteins come in a wide variety of shapes, and most are between 50 and 2000 amino acids long. Large proteins usually consist of a set of smaller *protein domains* that are joined together. A **domain** is a structural unit that folds more or less independently, being formed from perhaps 40 to 350 contiguous amino acids, and it is a modular unit from which larger proteins are constructed.

To display a protein structure in three dimensions, several different representations are conventionally used, each of which emphasizes distinct features. As an example, **Figure 3–9** presents four representations of an important protein structure called the *SH2 domain*. The SH2 domain is present in many different proteins in eukaryotic cells, where it responds to cell signals to cause selected protein molecules to bind to each other, thereby altering cell behavior (see Chapter 15). Contributing to the tertiary structure of this domain are two α helices and a three-stranded, antiparallel β sheet, which are its critical secondary structure elements (see Figure 3–9B).

Figure 3–10 presents ribbon models of three differently organized protein domains. As these examples illustrate, the central core of a domain can be constructed from α helices, from β sheets, or from various combinations of these two fundamental folding elements.

MBOC7_ptr_ch03_115-182.indd 124 02/12/21 2:17 PM

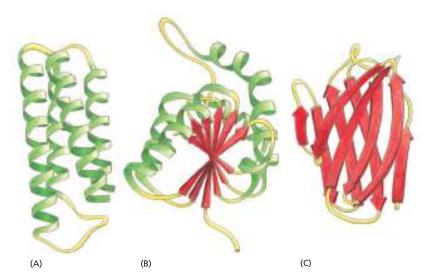

Figure 3–10 Ribbon models of three different protein domains. (A) Cytochrome b_{562} , a single-domain protein involved in electron transport in mitochondria. This protein is composed almost entirely of α helices. (B) The NAD-binding domain of the enzyme lactate dehydrogenase, which is composed of a mixture of α helices and parallel β sheets. (C) The variable domain of an immunoglobulin (antibody) light chain, composed of a sandwich of two antiparallel β sheets. In these examples, the α helices are shown in *green*, while strands organized as β sheets are denoted by *red arrows*. Note how the polypeptide chain generally traverses back and forth across the entire domain, making sharp turns (Movie 3.5) only at the protein surface. It is the protruding loop regions (*yellow*) that often form the binding sites for other molecules.

The different domains of a protein are often associated with different functions. Figure 3–11 shows an example—the Src protein kinase, which functions in signaling pathways inside vertebrate cells (Src is pronounced "sarc"). This protein is considered to have three domains: its SH2 and SH3 domains have regulatory roles—responding to signals that turn the kinase on and off—while its C-terminal domain is responsible for the kinase catalytic activity. Later in the chapter, we shall return to this protein to explain how proteins can form molecular switches that transmit information throughout cells.

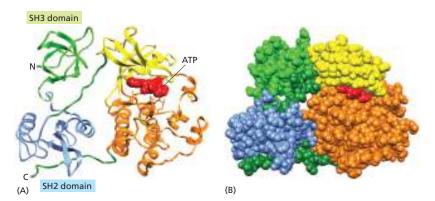

Figure 3–11 A protein formed from multiple domains. In the Src protein shown, a C-terminal domain with two lobes (*yellow* and *orange*) forms the core protein kinase enzyme, while its SH2 and SH3 domains perform regulatory functions. Note that both the SH2 and SH3 domains derive their names from this protein, being abbreviations for "Src homology 2" and "Src homology 3," respectively. (A) A ribbon model, with ATP substrate in *red*. (B) A space-filling model, with ATP substrate in *red*. Note that the site that binds ATP is positioned at the interface of the two lobes that form the kinase domain. The human genome encodes about 300 different SH3 domains and 120 SH2 domains. The structure of the SH2 domain was illustrated in Figure 3–9. (PDB code: 2SRC.)

MBOC7_ptr_ch03_115-182.indd 125 02/12/21 2:17 PM

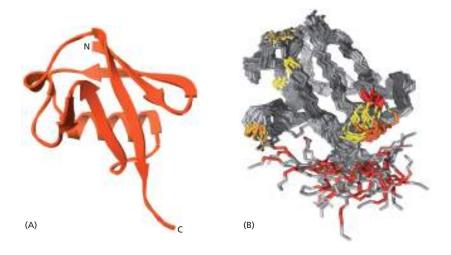

Figure 3-12 A folded protein molecule exists as an ensemble of closely related substructures, or conformers, as displayed here for ubiquitin. (A) A ribbon model that displays the structure of ubiquitin. Ubiquitin is a small protein widely used in cells, often being covalently attached to larger proteins, as described in Chapters 6 and 15. (B) In this diagram, a set of backbone conformations determined for ubiquitin has been overlaid to reveal regions that rapidly transition between different substructures. Superimposed on these structures are the rates of motion of the protein's atoms, as observed in NMR residual dipolar coupling experiments. A color code has been used to indicate the magnitude of these rates, which are largest for red, with orange and yellow also being high. (A, PDB code 1UBI; B, from O.F. Lange et al., Science 320:1471-1475, 2008. With permission from AAAS.)

Proteins Also Contain Unstructured Regions

The smallest protein molecules contain only a single domain, whereas larger proteins can contain several dozen domains, often connected to each other by short, relatively unstructured lengths of polypeptide chain that can act as flexible hinges between domains. The ubiquity of such intrinsically disordered sequences, which continually bend and flex due to thermal buffeting, became appreciated only after bioinformatics methods were developed that could recognize them from their amino acid sequences. Current estimates suggest that a third of all eukaryotic proteins also possess longer, *intrinsically disordered regions (IDRs)*—greater than 30 amino acids in length—in their polypeptide chains. These intrinsically disordered regions can be very long, and they have important functions in cells, as discussed later in this chapter.

All Protein Structures Are Dynamic, Interconverting Rapidly Between an Ensemble of Closely Related Conformations Because of Thermal Energy

Even though a protein has folded into a conformation of lowest free energy, this conformation is always being subjected to thermal bombardment from the Brownian motions of the many molecules that constantly collide with it. Thus the atoms in the protein are always moving, which causes neighboring regions of the protein to oscillate in concerted ways. These motions can now be precisely traced using special NMR techniques, as illustrated in Figure 3–12 for the small protein ubiquitin.

From recent studies combining many types of analyses, we know that protein function exploits these rapid fluctuations—as when a loop on the surface of a protein flips out to expose a binding site for a second molecule. In fact, the function of a protein is generally dependent on that protein's dynamic character, as we explain later when we discuss protein function in detail.

Function Has Selected for a Tiny Fraction of the Many Possible Polypeptide Chains

Because each of the 20 amino acids is chemically distinct and each can, in principle, occur at any position in a protein chain, there are $20 \times 20 \times 20 \times 20 = 160,000$ different possible polypeptide chains four amino acids long, or 20^n different possible polypeptide chains n amino acids long. For a typical protein length of about 300 amino acids, a cell could theoretically make more than 10^{390} (20^{300}) different polypeptide chains. This is such an enormous number that to produce

MBOC7_ptr_ch03_115-182.indd 126 02/12/21 2:17 PM

just one molecule of each kind would require many more atoms than exist in the universe.

Only a very small fraction of this vast set of conceivable polypeptide chains would adopt a stable three-dimensional conformation—by some estimates, less than one in a billion. And yet the majority of proteins present in cells do adopt unique and stable conformations. How is this possible? The answer lies in natural selection. A protein with an unpredictably variable structure and biochemical activity is unlikely to help the survival of a cell that contains it. Such proteins would therefore have been eliminated by natural selection through the enormously long trial-and-error process that underlies biological evolution.

Because evolution has selected for protein function in living organisms, present-day proteins have chemical properties that enable the protein to perform a particular catalytic or structural function in the cell. Proteins are so precisely built that the change of even a few atoms in one amino acid can sometimes disrupt the structure of the whole molecule so severely that all function is lost. And, as discussed later in this chapter, when certain rare protein misfolding accidents occur, the results can be disastrous for the organisms that contain them.

Proteins Can Be Classified into Many Families

Once a protein had evolved that folded up into a stable conformation with useful properties, its structure was often modified during evolution to enable it to perform new functions. As we will discuss in Chapter 4, this process has been greatly accelerated by genetic mechanisms that duplicate genes accidentally, which allows gene copies to evolve independently to perform new functions. Because this type of event occurred frequently in the past, present-day proteins can be grouped into protein families, each family member having an amino acid sequence and a three-dimensional conformation that resemble those of the other family members.

Consider, for example, the *serine proteases*, a large family of protein-cleaving (proteolytic) enzymes that includes the digestive enzymes chymotrypsin, trypsin, and elastase, as well as several proteases involved in blood clotting. When the protease portions of any two of these enzymes are compared, parts of their amino acid sequences are found to match. The similarity of their three-dimensional conformations is even more striking: most of the detailed twists and turns in their polypeptide chains, which are several hundred amino acids long, are virtually identical (**Figure 3–13**). The many different serine proteases nevertheless have distinct enzymatic activities, each cleaving different proteins or the peptide bonds between different types of amino acids. Each therefore performs a distinct function in an organism.

The story we have told for the serine proteases could be repeated for hundreds of other protein families. In general, the structure of the different members of a protein family has been more highly conserved than has the amino acid sequence. In many cases, the amino acid sequences have diverged so far that we cannot be certain of a family relationship between two proteins without determining their three-dimensional structures. The yeast $\alpha 2$ protein and the Drosophila engrailed protein, for example, are both transcription regulatory proteins in the homeodomain family (discussed in Chapter 7). Because they are identical in only 17 of the 60 amino acids of their homeodomain, their relationship became certain only by comparing their three-dimensional structures (Figure 3–14). Many similar examples show that two proteins with more than 25% identity in their amino acid sequences usually share the same overall structure.

The various members of a large protein family often have distinct functions. Mutation is a random process. Some of the amino acid changes that make family members different were selected in the course of evolution because they resulted in useful changes in biological activity; these give the individual family members the different functional properties they have today. Other amino acid changes were effectively "neutral," having neither a beneficial nor a damaging effect on

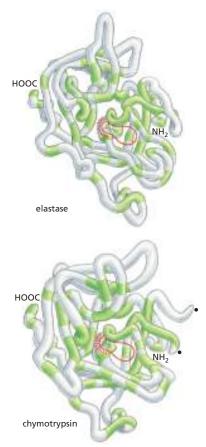

Figure 3-13 A comparison of the conformations of two serine proteases. The backbone conformations of elastase and chymotrypsin. Although only those amino acids in the polypeptide chain shaded in green are the same in the two proteins, the two conformations are very similar nearly everywhere. The active site of each enzyme is circled in red; this is where the peptide bonds of the proteins that serve as substrates are bound and cleaved by hydrolysis. The serine proteases derive their name from the amino acid serine. whose side chain is part of the active site of each enzyme and directly participates in the cleavage reaction. The two dots on the right side of the chymotrypsin molecule mark the new ends created when this enzyme cuts its own backbone.

128 Chapter 3: Proteins

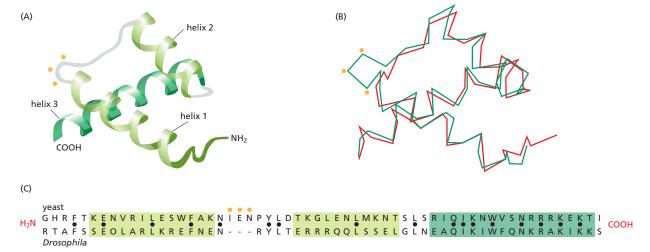

Figure 3–14 A comparison of a class of DNA-binding domains, called homeodomains, in a pair of proteins from two organisms separated by more than a billion years of evolution. (A) A ribbon model of the structure common to both proteins. (B) A trace of the α -carbon positions. The three-dimensional structures shown were determined by x-ray crystallography for the yeast α 2 protein (green) and the Drosophila engrailed protein (red). (C) A comparison of amino acid sequences for the region of the proteins shown in A and B. Black dots mark sites with identical amino acids. Green shading has been used to mark the three α helices shown in A. Orange dots indicate the position of a three-amino-acid insert in the α 2 protein. (Adapted from C. Wolberger et al., Cell 67:517–528, 1991.)

the basic structure and function of the protein. In addition, because mutation is random, there must also have been many deleterious changes that altered the three-dimensional structure of these proteins sufficiently to make them useless. Such faulty proteins would have been readily lost during evolution.

Protein families are readily recognized when the genome of any organism is sequenced; for example, the determination of the DNA sequence for the entire human genome has revealed that we contain about 20,000 protein-coding genes. Through sequence comparisons, we can assign the products of more than half of our protein-coding genes to known protein structures belonging to more than 500 different protein families. Most of the proteins in each family have evolved to perform somewhat different functions, as for the enzymes elastase and chymotrypsin illustrated previously in Figure 3–13. These family members are sometimes called *paralogs* to distinguish them from *orthologs*—those evolutionarily related proteins that have the same function in different organisms (such as the mouse elastase and human elastase enzymes).

The current database of known protein sequences contains more than 100 million entries, and it is growing very rapidly as more and more genomes are sequenced—revealing huge numbers of new genes that encode proteins. The encoded polypeptides range widely in size, from 6 amino acids to a gigantic protein of 34,000 amino acids (titin, a structural protein in muscle).

As described in Chapters 8 and 9, because of the powerful techniques of x-ray crystallography, nuclear magnetic resonance (NMR), and cryo-electron microscopy, we now know the three-dimensional shapes, or conformations, of more than 100,000 of these proteins. By carefully comparing the conformations of these proteins, structural biologists (that is, experts on the structure of biological molecules) have concluded that there are a limited number of ways in which protein domains usually fold up in nature—estimated to be about 2000, if we consider all organisms. For most of these so-called *protein folds*, representative structures have been determined.

Protein comparisons are important because related structures often imply related functions. Many years of experimentation can be saved by discovering that a new protein has an amino acid sequence similarity with a protein of known

MBOC7_ptr_ch03_115-182.indd 128 02/12/21 2:17 PM

function. Such sequence relationships, for example, first indicated that certain genes that cause mammalian cells to become cancerous encode protein kinases (discussed in Chapter 20).

Some Protein Domains Are Found in Many Different Proteins

As previously stated, most proteins are composed of a series of protein domains in which different regions of the polypeptide chain fold independently to form compact structures. Such multidomain proteins are believed to have originated from the accidental joining of the DNA sequences that encode each domain, creating a new gene. In an evolutionary process called *domain shuffling*, many large proteins have evolved through the joining of preexisting domains in new combinations (Figure 3–15). Novel binding surfaces have often been created at the juxtaposition of domains, and many of the functional sites where proteins bind to small molecules are found to be located there.

A subset of protein domains has been especially mobile during evolution; these seem to have particularly versatile structures and are sometimes referred to as *protein modules*. The structure of one such module, the SH2 domain, was featured in Figure 3–9. Three other abundant protein domains are illustrated in Figure 3–16.

Each of these three domains has a stable core structure formed from strands of β sheets, from which less-ordered loops of polypeptide chain protrude. The loops are ideally situated to form binding sites for other molecules, as most clearly demonstrated for the immunoglobulin fold, which forms the basis for antibody molecules. Such β sheet-based domains may have achieved their evolutionary success because they provide a convenient framework for the generation of new binding sites for ligands, requiring only small changes to their protruding loops (see Figure 3–40).

A second feature of these protein domains that explains their utility is the ease with which they can be integrated into other proteins. Two of the three domains illustrated in Figure 3–16 have their N- and C-terminal ends at opposite poles of the domain. When the DNA encoding such a domain undergoes tandem duplication, which is not unusual in the evolution of genomes (discussed in Chapter 4), the duplicated domains with this *in-line* arrangement can be readily linked in series to form extended structures—either with themselves or with

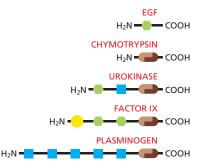

Figure 3-15 Domain shuffling. An extensive shuffling of blocks of protein sequence (protein domains) has occurred during protein evolution. Those portions of a protein denoted by the same shape and color in this diagram are evolutionarily related. Serine proteases such as chymotrypsin are formed from two domains (brown). In the three other proteases shown, which are highly regulated and more specialized. these two protease domains are connected to one or more domains that are similar to domains found in epidermal growth factor (EGF; green), to a calcium-binding protein (vellow), or to a kringle domain (blue). Chymotrypsin is illustrated in Figure 3-13.

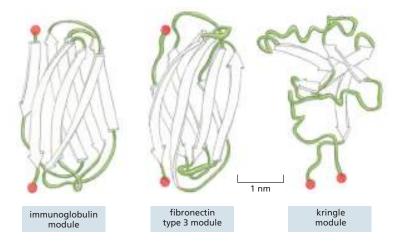

Figure 3–16 The three-dimensional structures of three commonly used protein domains. In these ribbon diagrams, β -sheet strands are shown as *arrows*, and the N- and C-termini are indicated by *red spheres*. Many more such "protein modules" exist in nature. (Adapted from D.J. Leahy et al., *Science* 258:987–991, 1992. With permission from AAAS.)

MBOC7_ptr_ch03_115-182.indd 129 02/12/21 2:17 PM

130

other in-line domains (**Figure 3-17**). Stiff extended structures composed of a series of domains are especially common in extracellular matrix molecules and in the extracellular portions of cell-surface receptor proteins. Other frequently used domains, including the SH2 domain and the kringle domain in Figure 3-16, are of a *plug-in* type, with their N- and C-termini close together. After genomic rearrangements, such domains are usually accommodated as an insertion into a loop region of a second protein.

A comparison of the relative frequency of domain utilization in different eukaryotes reveals that for many common domains, such as protein kinases, this frequency is similar in organisms as diverse as yeast, plants, worms, flies, and humans. But there are some notable exceptions, such as the major histocompatibility complex (MHC) antigen-recognition domain (see Figure 24–36) that is present in 57 copies in humans, but absent in the other four organisms just mentioned. Domains such as these have specialized functions that are not shared with the other eukaryotes; they are assumed to have been strongly selected for during recent evolution to produce the multiple copies observed.

The Human Genome Encodes a Complex Set of Proteins, Revealing That Much Remains Unknown

The result of sequencing the human genome has been surprising, because it reveals that our chromosomes contain only about 20,000 protein-coding genes. On the basis of this number alone, we would appear to be no more complex than the tiny mustard weed, *Arabidopsis*, and only about 1.3-fold more complex than a nematode worm. The genome sequences also reveal that vertebrates have inherited nearly all of their protein domains from invertebrates—with only 7% of identified human domains being vertebrate specific.

Each of our proteins is on average more complicated, however (Figure 3–18). Domain shuffling during vertebrate evolution has given rise to many novel combinations of protein domains, with the result that there are nearly twice as many combinations of domains found in human proteins as in a worm or a fly. This extra variety in our proteins greatly increases the range of protein-protein interactions possible, but how it contributes to making us human is not known.

The complexity of living organisms is staggering, and it is quite sobering to note that we currently lack even the tiniest hint of what the function might be for more than 10,000 of the proteins that have been identified through examining the human genome. There are certainly enormous challenges ahead for the next generation of cell biologists, with no shortage of fascinating mysteries to solve.

Protein Molecules Often Contain More Than One Polypeptide Chain

The same weak noncovalent bonds that enable a protein chain to fold into a specific conformation also allow proteins to bind to each other to produce larger structures in the cell. Any region of a protein's surface that can interact with another molecule through sets of noncovalent bonds is called a **binding site**. A protein can contain binding sites for various large and small molecules. If a binding site recognizes the surface of a second protein, the tight binding of two folded polypeptide chains at this site creates a larger protein molecule with a precisely defined geometry. Each polypeptide chain in such a protein is called

Figure 3–18 Domains in a group of evolutionarily related proteins that have a similar function. In general, there is a tendency for the proteins in more complex organisms, such as humans, to contain additional domains compared to a less complex organism such as yeast—as is the case for the DNA-binding protein compared here.

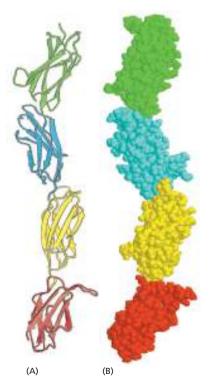

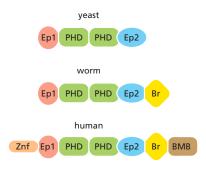

Figure 3–17 An extended structure formed from a series of protein domains. Four fibronectin type 3 domains (see Figure 3–16) from the extracellular matrix molecule fibronectin are illustrated in (A) ribbon and (B) space-filling models. (Adapted from D.J. Leahy et al., *Cell* 84:155–164, 1996.)

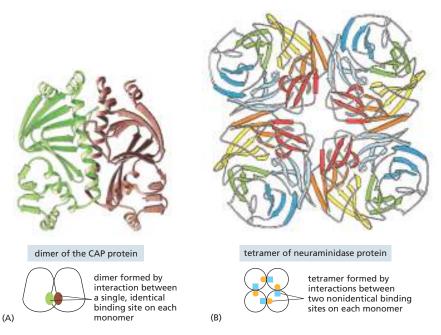

Figure 3–19 Many protein molecules contain multiple copies of the same protein subunit. (A) A symmetrical dimer. The CAP protein, a bacterial transcription regulatory protein, is a complex of two identical polypeptide chains. (B) A symmetrical homotetramer. The enzyme neuraminidase exists as a ring of four identical polypeptide chains. For both A and B, a small schematic below the structure emphasizes how the repeated use of the same binding interaction forms the structure. In A, the use of the same binding site on each monomer (represented by brown and green ovals) causes the formation of a symmetrical dimer. In B, a pair of nonidentical binding sites (represented by orange circles and blue squares) causes the formation of a symmetrical tetramer.

a **protein subunit**. And the precise way that these subunits are arranged creates the protein's *quaternary structure*—as introduced previously.

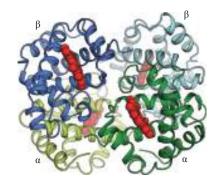

In the simplest case, two identical, folded polypeptide chains form a symmetrical complex of two protein subunits (called a *dimer*) that is held together by interactions between two identical binding sites. (Figure 3–19A). Symmetrical protein complexes that are formed from more than two copies of the same polypeptide chain are also commonly found in cells (Figure 3–19B).

Many other proteins contain two or more types of polypeptide chains. *Hemoglobin,* the protein that carries oxygen in red blood cells, contains two identical α -globin subunits and two identical β -globin subunits, symmetrically arranged (Figure 3–20). Such multisubunit proteins can be very large (Movie 3.6).

Some Globular Proteins Form Long Helical Filaments

The proteins that we have discussed so far are *globular proteins*, in which the polypeptide chain folds up into a compact shape like a ball with an irregular surface. Some of these protein molecules can nevertheless assemble to form filaments that may span the entire length of a cell. Most simply, a long chain of identical protein molecules can be constructed if each molecule has a

Figure 3–20 Hemoglobin is a protein formed as a symmetrical assembly using two each of two different subunits. This abundant, oxygen-carrying protein in red blood cells contains two copies of α -globin (*green*) and two copies of β -globin (*blue*). Each of these four polypeptide chains contains a heme molecule (*red*), which is the site that binds oxygen (O₂). Thus, each molecule of hemoglobin carries four molecules of oxygen. (PDB code: 2DHB.)

MBOC7_ptr_ch03_115-182.indd 131 02/12/21 2:17 PM

Figure 3–21 Protein assemblies. (A) A protein with just one binding site can form a dimer with another identical protein. (B) Identical proteins with two different binding sites often form a long helical filament. (C) If the two binding sites are disposed appropriately in relation to each other, the protein subunits may form a closed ring instead of a helix. (For an example of A, see Figure 3–19A; for an example of B, see Figure 3–22; for an example of C, see Figure 14–32.)

binding site complementary to another region of the surface of the same molecule (Figure 3–21). An actin filament, for example, is a long helical structure produced from many molecules of the protein *actin* (Figure 3–22). Actin is a globular protein that is very abundant in eukaryotic cells, where it forms one of the major filament systems of the cytoskeleton (discussed in Chapter 16).

We will encounter many helical structures in this book. Why is a helix such a common structure in biology? As we have seen, biological structures are often formed by linking similar subunits into long, repetitive chains. If all the subunits are identical, the neighboring subunits in the chain can often fit together in only one way, adjusting their relative positions to minimize the free energy of the contact between them. As a result, each subunit is positioned in exactly the same way in relation to the next, so that subunit 3 fits onto subunit 2 in the same way that subunit 2 fits onto subunit 1, and so on. Because it is very rare for subunits to join up in a straight line, this arrangement generally results in a helix—a regular structure that resembles a spiral staircase, as illustrated in Figure 3–23. Depending on the twist of the staircase, a helix is said to be either right-handed or left-handed (see Figure 3–23E). Handedness is not affected by turning the helix upside down, but it is reversed if the helix is reflected in the mirror.

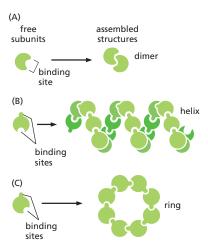

The observation that helices occur commonly in biological structures holds true whether the subunits are small molecules linked together by covalent bonds (for example, the amino acids in an α helix) or large protein molecules that are linked by noncovalent forces (for example, the actin molecules in actin filaments). This is not surprising. A helix is an unexceptional structure, and it is generated simply by placing many similar subunits next to each other, each in the same strictly repeated relationship to the one before; that is, with a fixed rotation followed by a fixed translation along the helix axis.

Protein Molecules Can Have Elongated, Fibrous Shapes

Enzymes tend to be globular proteins: even though many are large and complicated, with multiple subunits, most have an overall rounded shape. In Figure 3–22, we saw that a globular protein can associate to form long filaments. But some functions require that an individual protein molecule span a large distance. These *fibrous proteins* generally have a relatively simple, elongated three-dimensional structure.

One large family of intracellular fibrous proteins consists of α -keratin, introduced when we described the α helix. Keratin filaments are extremely stable and are the main component in long-lived structures such as hair, horn, and nails. An α -keratin molecule is a dimer of two identical subunits, with the long α helices of each subunit forming a coiled-coil (see Figure 3–8). The coiled-coil regions are capped at each end by globular domains containing binding sites. This enables this type of protein to assemble into ropelike *intermediate filaments*—an important component of the cytoskeleton that creates the cell's internal structural framework (see Figure 16–62).

Fibrous proteins are especially abundant outside the cell, where they are a main component of the gel-like *extracellular matrix* that helps to bind collections of cells together to form tissues. Cells secrete extracellular matrix proteins into their surroundings, where they often assemble into sheets or long fibrils. *Collagen* is the most abundant of these proteins in animal tissues. A collagen molecule consists of three long polypeptide chains, each containing the nonpolar amino acid glycine at every third position. This regular structure allows the chains to wind around

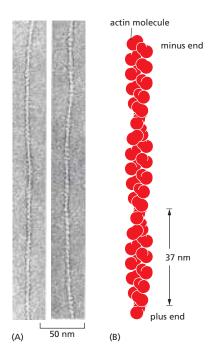

Figure 3–22 Globular actin monomers assemble to produce an actin filament. (A) Transmission electron micrographs of negatively stained actin filaments. (B) The helical arrangement of actin molecules in an actin filament. (A, courtesy of Roger Craig.)

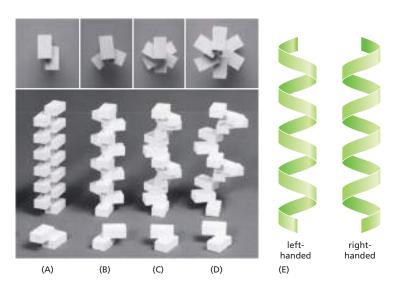

Figure 3-23 Some properties of a helix. (A-D) A helix forms when a series of subunits (here represented by rectangular bricks) bind to each other in a regular way. At the top, each of these helices is viewed from directly above the helix and seen to have two (A), three (B), and six (C and D) subunits per helical turn. Note that the helix in D has a wider path than that in C but the same number of subunits per turn. (E) As discussed in the text, a helix can be either right-handed or left-handed. As a reference, it is useful to remember that standard metal screws, which insert when turned clockwise, are right-handed. Note that a helix retains the same handedness when it is turned upside down.

one another to generate a long, regular triple helix (Figure 3–24). Many collagen molecules then bind to one another side-by-side and end-to-end to create long overlapping arrays—thereby generating the extremely tough collagen fibrils that give connective tissues their tensile strength, as described in Chapter 19.

Covalent Cross-Linkages Stabilize Extracellular Proteins

Many protein molecules are either attached to the outside of a cell's plasma membrane or secreted to form part of the extracellular matrix. All such proteins are directly exposed to extracellular conditions. To help maintain their structures, the polypeptide chains in such proteins are often stabilized by covalent cross-linkages. These linkages can either tie together two amino acids in the same protein or join together many polypeptide chains in a large protein complex—as for the collagen fibrils just described.

A variety of such cross-links exist, but the most common are covalent sulfursulfur bonds. These *disulfide bonds* (also called *S-S bonds*) form as cells prepare newly synthesized proteins for export. As described in Chapter 12, their formation is catalyzed in the endoplasmic reticulum by an enzyme that links together

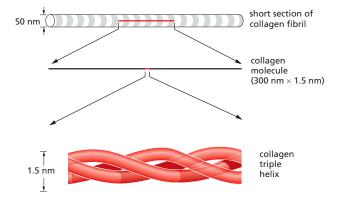

Figure 3–24 The fibrous protein collagen. The collagen molecule is a triple helix formed by three extended protein chains that wrap around one another *(bottom)*. In the extracellular space, many rodlike collagen molecules become covalently linked together through their lysine side chains to form collagen fibrils *(top)* that have the tensile strength of steel. The striping on the collagen fibril is caused by the regular repeating arrangement of the collagen molecules within the fibril.

MBOC7_ptr_ch03_115-182.indd 133 02/12/21 2:17 PM

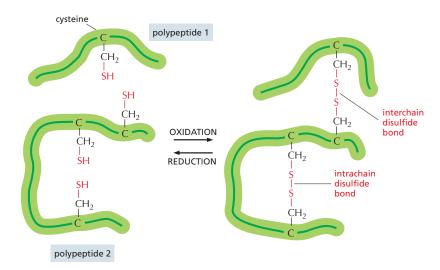

Figure 3–25 Disulfide bonds. Covalent disulfide bonds form between adjacent cysteine side chains. These crosslinkages can join either two parts of the same polypeptide chain or two different polypeptide chains. Because the energy required to break one covalent bond is much larger than the energy required to break even a whole set of noncovalent bonds (see Table 2–1, p. 51), a disulfide bond can have a major stabilizing effect on a protein (Movie 3.7).

the -SH groups of two cysteine side chains that are adjacent in the folded protein (Figure 3-25). Disulfide bonds do not change the conformation of a protein but instead act as atomic staples to reinforce its most favored conformation. For example, lysozyme—an enzyme in tears that dissolves bacterial cell walls—retains its antibacterial activity for a long time because it is stabilized by such cross-linkages.

Disulfide bonds generally fail to form in the cytosol, where a high concentration of reducing agents converts S–S bonds back to cysteine –SH groups. Apparently, proteins do not require this type of reinforcement in the relatively mild environment inside the cell.

Protein Molecules Often Serve as Subunits for the Assembly of Large Structures

The same principles that enable a protein molecule to associate with itself to form rings or a long filament also operate to generate structures that are formed from a set of different macromolecules, such as enzyme complexes, ribosomes, viruses, and membranes. These much larger objects are not made as single, giant, covalently linked molecules. Instead they are formed by the noncovalent assembly of many separately manufactured molecules, which serve as the *subunits* of the final structure.

The use of smaller subunits to build larger structures has several advantages:

- 1. A large structure built from one or a few repeating smaller subunits requires only a small amount of genetic information.
- Both assembly and disassembly can be readily controlled reversible processes, because the subunits associate through multiple bonds of relatively low energy.

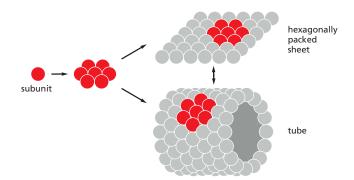

Figure 3–26 Single protein subunits form protein assemblies that feature multiple protein–protein contacts. Hexagonally packed globular protein subunits are shown here forming either flat sheets or tubes. Such large structures are not considered to be single "molecules." Instead, like the actin filament described previously, they are viewed as assemblies formed of many different molecules.

MBOC7_ptr_ch03_115-182.indd 134 02/12/21 2:17 PM

3. Errors in the synthesis of the structure can be more easily avoided, because correction mechanisms can operate during the course of assembly to exclude malformed subunits.

To focus on a well-studied example, we can consider how a virus forms from a mixture of proteins and nucleic acids. Some protein subunits are found to assemble into flat sheets in which the subunits are arranged in hexagonal patterns, but with a slight change in the geometry of the individual subunits, a hexagonal sheet can be converted into a tube (Figure 3–26) or, with more changes, into a hollow sphere. Protein tubes and spheres that bind specific RNA and DNA molecules in their interior form the coats of viruses.

The formation of closed structures, such as rings, tubes, or spheres, provides additional stability because it increases the number of noncovalent bonds between the protein subunits. Moreover, because such a structure is created by mutually dependent, cooperative interactions between subunits, a relatively small change that affects each subunit individually can cause the structure to assemble or disassemble. These principles are dramatically illustrated in the protein coat, or *capsid*, of many simple viruses, which takes the form of a hollow sphere based on an icosahedron (Figure 3–27). Capsids are often made of hundreds of identical protein subunits that enclose and protect the viral nucleic acid (Figure 3–28). The protein in such a capsid must have a particularly adaptable

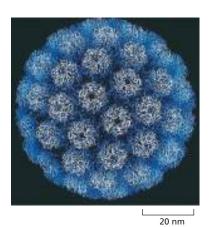

Figure 3–27 The protein capsid of a virus. The structure of the simian virus SV40 capsid has been determined by x-ray crystallography and, as for the capsids of many other viruses, it is known in atomic detail. (Courtesy of Robert Grant, Stephan Crainic, and James M. Hogle.)

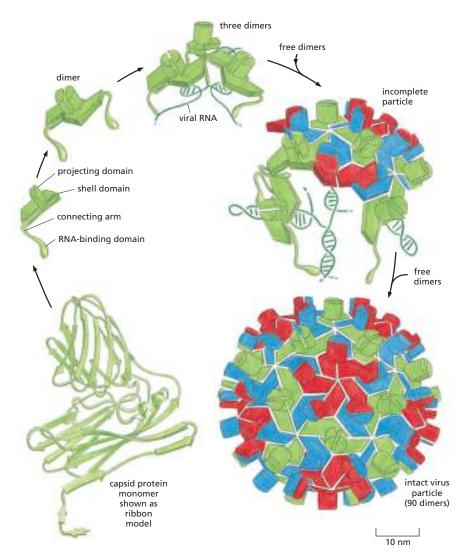

Figure 3–28 The structure of a spherical virus. In viruses, many copies of a single protein subunit often pack together to create a spherical shell (a capsid). This capsid encloses the viral genome, composed of either RNA or DNA. For geometric reasons, no more than 60 identical subunits can pack together in a precisely symmetrical way. If slight irregularities are allowed, however, more subunits can be used to produce a larger capsid that retains icosahedral symmetry. The tomato bushy stunt virus (TBSV) shown here, for example, is a spherical virus about 33 nm in diameter formed from 180 identical copies of a 386-amino-acid capsid protein (90 dimers) plus an RNA genome of 4500 nucleotides. To construct such a large capsid, the protein must be able to fit into three somewhat different environments. This requires three slightly different conformations, each of which is differently colored in the virus particle shown here. The postulated pathway of assembly is shown; the precise threedimensional structure has been determined by x-ray diffraction. (Courtesy of Steve Harrison.)

MBOC7_ptr_ch03_115-182.indd 135 02/12/21 2:17 PM

Figure 3–29 The structure of tobacco mosaic virus (TMV). (A) An electron micrograph of the viral particle, which consists of a single long RNA molecule enclosed in a cylindrical protein coat composed of identical protein subunits. (B) A model showing part of the structure of TMV. An RNA molecule of 6395 nucleotides, present as a single strand, is packaged in a helical coat constructed from 2130 copies of a coat protein 158 amino acids long. Fully infective viral particles can self-assemble in a test tube from purified RNA and protein molecules. (A, courtesy of Robley Williams; B, courtesy of Richard J. Feldmann.)

structure: not only must it make several different kinds of contacts to create the sphere, it must also change this arrangement to let the nucleic acid out to initiate viral replication once the virus has entered a cell.

Many Structures in Cells Are Capable of Self-Assembly

The information for forming many of the complex assemblies of macromolecules in cells must be contained in the subunits themselves, because purified subunits can spontaneously assemble into the final structure under the appropriate conditions. The first large macromolecular aggregate shown to be capable of self-assembly from its component parts was *tobacco mosaic virus* (*TMV*). This virus is a long rod in which a cylinder of protein is arranged around a helical RNA core, which constitutes the viral genome (**Figure 3–29**). If the dissociated RNA and protein subunits are mixed together in solution, they recombine to form fully active viral particles. The assembly process is unexpectedly complex and includes the formation of double rings of protein, which serve as intermediates that add to the growing viral coat.

Another complex macromolecular aggregate that can reassemble from its component parts is the bacterial ribosome. This structure is composed of about 55 different protein molecules and 3 different ribosomal RNA (rRNA) molecules. Incubating a mixture of the individual components under appropriate conditions in a test tube causes them to spontaneously re-form the original structure. Most important, such reconstituted ribosomes are able to catalyze protein synthesis. As might be expected, the reassembly of ribosomes follows a specific pathway: after certain proteins have bound to the RNA, this complex is then recognized by other proteins, and so on, until the structure is complete.

It is still not clear how some of the more elaborate self-assembly processes are regulated. Many structures in the cell, for example, have a precisely defined length that appears to be many times greater than that of their component macromolecules. How such length determination is achieved is in many cases a mystery. In the simplest case, a long core protein or other macromolecule provides a scaffold that determines the extent of the final assembly. This is the mechanism that determines the length of the TMV particle, where the RNA chain provides the core. Similarly, a core protein interacting with actin is thought to determine the length of the thin filaments in muscle.

Assembly Factors Often Aid the Formation of Complex Biological Structures

Not all cellular structures held together by noncovalent bonds self-assemble. A cilium, or a myofibril of a muscle cell, for example, cannot form spontaneously from a solution of its component macromolecules. In these cases, part of the assembly information is provided by special enzymes and other proteins that

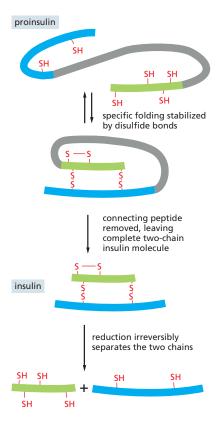

Figure 3–30 Proteolytic cleavage in insulin assembly. The polypeptide hormone insulin cannot spontaneously re-form efficiently if its disulfide bonds are disrupted. It is synthesized as a larger protein (proinsulin) that is cleaved by a proteolytic enzyme after the protein chain has folded into a specific shape. Excision of part of the proinsulin polypeptide chain removes some of the information needed for the protein to fold spontaneously into its normal conformation. For this reason, once insulin has been denatured and its two polypeptide chains have separated, its ability to reassemble is lost.

perform the function of templates, serving as *assembly factors* that guide construction but take no part in the final assembled structure.

Even relatively simple structures may lack some of the ingredients necessary for their own assembly. In the formation of certain bacterial viruses, for example, the head, which is composed of many copies of a single protein subunit, is assembled on a temporary scaffold composed of a second protein that is produced by the virus. Because the second protein is absent from the final viral particle, the head structure cannot spontaneously reassemble once it has been taken apart. Other examples are known in which proteolytic cleavage is an essential and irreversible step in the normal assembly process. This is even the case for some small protein assemblies, including the structural protein collagen and the hormone insulin (Figure 3–30). From these relatively simple examples, it seems certain that the assembly of a structure as complex as a cilium will involve a temporal and spatial ordering that is imparted by numerous other components.

When Assembly Processes Go Wrong: The Case of Amyloid Fibrils

A special class of protein structure, utilized for some normal cell functions, can also contribute to human diseases when not controlled. These are self-propagating, very stable β -sheet aggregates called **amyloid fibrils**. These fibrils are built from a series of identical polypeptide chains that become layered one over the other to create a continuous stack of β strands, with each of the β strands oriented perpendicular to a fibril axis (**Figure 3–31**). In a fibril, two of these stacks of β strands are paired with each other to form a long *cross-beta filament*, with many hundreds of monomers producing an unbranched fibrous structure that can be several micrometers long and 5–15 nm in width (**Figure 3–32**). A surprisingly large fraction of proteins have the potential to adopt such structures,

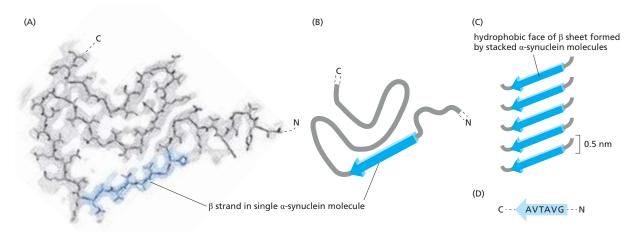

Figure 3–31 How an amyloid fibril forms from a protein associated with Parkinson's disease. Illustrated here is the structure of one-half of an amyloid fibril that is formed by the protein α -synuclein, whose abnormal aggregates contribute to Parkinson's disease. The conformation of the α -synuclein monomer is shown as an atomic model in (A) and schematically in (B), with the β strand that will form the cross-beta spine of the filament colored *blue* (only 57 of α -synuclein's 140 amino acids are shown). (C) How the monomer associates to form a long sheet of stacked β strands. As illustrated in Figure 3–32, a second, identical sheet of β strands pairs with this one to form a two-sheet motif that runs the entire length of the fibril. (D) The amino acid sequence that creates a hydrophobic zipper joining the two sheets, forming the cross-beta spine of the fibril. (From R. Guerrero-Ferreira et al., *eLife* 7:e36402, 2018.)

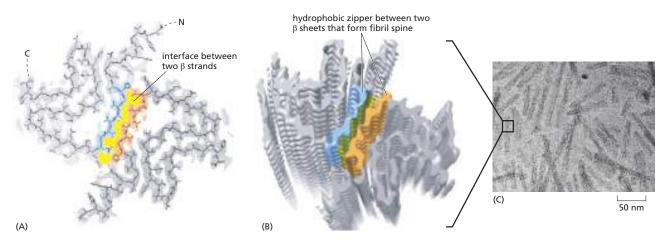

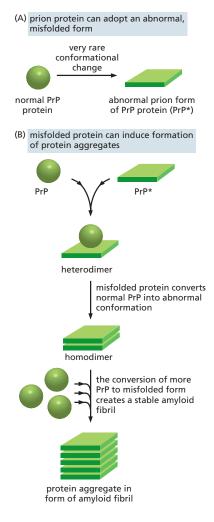

Figure 3–32 The structure of an amyloid fibril. (A) How two monomers of α -synuclein pair to create an amyloid fibril. (B) A three-dimensional rendering of a section of the complete fibril, as determined by cryo-electron microscopy. (C) Electron micrograph of α -synuclein amyloid fibrils. The α -synuclein protein, like some other amyloid-forming proteins, can form several different variants of amyloid fibrils from the same polypeptide chain—only one of which is illustrated here. (From R. Guerrero-Ferreira et al., *eLife* 7:e36402, 2018. This article is distributed under a Creative Commons Attribution 4.0 International license.)

because only a short segment of the polypeptide chain is needed to form the spine of the fibril; in addition, the spine can accommodate a variety of amino acid sequences. Nevertheless, very few proteins will actually form this structure inside cells.

In humans, the quality-control mechanisms governing proteins gradually decline with age, occasionally permitting normal proteins to form pathological aggregates. In extreme cases, the accumulation of such amyloid fibrils in the cell interior can kill the cells and damage tissues. Because the brain is composed of a highly organized collection of nerve cells that cannot regenerate, the brain is especially vulnerable to this sort of cumulative damage. Thus, although amyloid fibrils may form in different tissues and are known to cause pathologies in several sites in the body, the most severe amyloid pathologies are neurodegenerative diseases. For example, an abnormal formation of amyloid fibrils is thought to play a central causative role in both Alzheimer's and Parkinson's diseases.

Prion diseases are a special type of these pathologies. They have attained special notoriety because, unlike Parkinson's or Alzheimer's, prion diseases can readily spread from one organism to another, providing that the second organism eats a tissue containing the protein aggregate. A set of closely related diseases—scrapie in sheep, Creutzfeldt–Jakob disease (CJD) in humans, kuru in humans, and bovine spongiform encephalopathy (BSE) in cattle—are caused by a misfolded, aggregated form of a particular protein called PrP (for prion protein). PrP is normally located on the outer surface of the plasma membrane, most prominently in neurons, and it has the unfortunate property of forming amyloid fibrils that are "infectious" because they convert normally folded molecules of PrP to the same pathological form (Figure 3–33). This property creates a positive feedback loop that propagates the abnormal form of PrP, called PrP*, and allows the pathological

Figure 3–33 Prion diseases are caused by proteins whose misfolding is infectious. (A) Schematic illustration of the type of conformational change in the prion protein (PrP) that produces material for an amyloid fibril. (B) The self-infectious nature of the protein aggregation that is central to prion diseases. The misfolded version of the protein, called PrP*, induces the normal PrP protein it contacts to change its conformation, as shown. PrP* is extremely stable, and if eaten, it can produce amyloid fibrils that disrupt brain-cell function, causing a deadly neurodegenerative disorder. Some of the abnormal amyloid fibrils that form in common noninfectious neurodegenerative disorders, including Parkinson's and Alzheimer's diseases, appear to propagate from cell to cell within the brain in a similar way.

conformation to spread rapidly from cell to cell in the brain, eventually causing death. It can be dangerous to eat the tissues of animals that contain PrP*, as witnessed by the spread of BSE (commonly referred to as "mad cow disease") from cattle to humans. Fortunately, in the absence of PrP*, PrP is extraordinarily difficult to convert to its abnormal form.

A closely related *protein-only inheritance* has been observed in yeast cells. The ability to study infectious proteins in yeast has clarified another remarkable feature of prions. These protein molecules can form several distinctively different types of amyloid fibrils from the same polypeptide chain. Moreover, each type of aggregate can be infectious, forcing normal protein molecules to adopt the same type of abnormal structure. Thus, several different "strains" of infectious particles can arise from the same polypeptide chain.

Recent data suggest that at least some of the abnormal amyloids that form in common human neurological diseases promote the disease by spreading from cell to cell in the brain in a "prion-like" manner, with the abnormally folded form of the protein being taken up by neighboring cells to seed a more widespread formation of the same abnormal structures (for example, α -synuclein in Parkinson's disease, tau protein in Alzheimer's disease). Drugs and antibody treatments are currently being designed in attempts to block these spreading events—and thereby reduce the terrible human toll created by these widespread, common diseases.

Amyloid Structures Can Also Perform Useful Functions in Cells

Amyloid fibrils were initially studied because they cause disease. But the same type of structure is now known to be exploited by cells for useful functions. Eukaryotic cells, for example, store many different peptide and protein hormones that they will secrete in specialized *secretory vesicles*, which package a high concentration of their cargo in dense cores with a regular structure (see Figure 13–43). We now know that these structured cores consist of amyloid fibrils, which in this case have a structure that causes them to dissolve to release soluble cargo after being secreted by exocytosis to the cell exterior (Figure 3–34A). Many bacteria use the amyloid structure in a very different way, secreting proteins that form long amyloid fibrils that project from the cell exterior to help bind bacterial neighbors into biofilms (Figure 3–34B). Because these biofilms help bacteria to survive in adverse environments (including in humans treated with antibiotics), new drugs that specifically disrupt the fibrous networks formed by bacterial amyloids have promise for treating human infections.

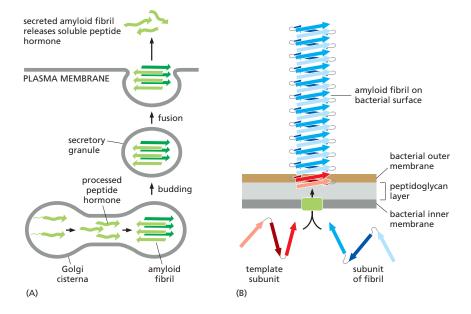

Figure 3–34 Two normal functions for amyloid fibrils. (A) In eukaryotic cells, protein cargo can be packed very densely in secretory vesicles and stored until signals cause a release of this cargo by exocytosis. For example, proteins and peptide hormones of the endocrine system, such as glucagon and calcitonin, are efficiently stored as short amyloid fibrils, which dissociate when they reach the cell exterior. (B) Bacteria produce amyloid fibrils on their surface by secreting their precursor proteins; these fibrils then create biofilms that link together, and help to protect, large numbers of individual bacteria.

Summary

A protein molecule's amino acid sequence determines its three-dimensional conformation. Large numbers of noncovalent attractions between different parts of the polypeptide chain stabilize its folded structure. For example, amino acids with hydrophobic side chains tend to cluster in the interior of the molecule, and local hydrogen-bond interactions between neighboring peptide bonds give rise to α helices and β sheets.

Regions of contiguous amino acid sequence fold into globular protein domains. These domains generally contain 40-350 amino acids, and they are the modular units from which larger proteins are constructed. Small proteins typically consist of only a single domain, while large proteins are formed from multiple domains linked together by various lengths of relatively disordered polypeptide chain. As organisms have evolved, the DNA sequences that encode these domains have duplicated, mutated, and been combined with other domains to construct large numbers of new proteins.

Proteins are brought together into larger structures by the same noncovalent attractions that determine protein folding. Proteins with binding sites for their own surface can assemble into dimers, closed rings, spherical shells, or helical polymers. The amyloid fibril is a long unbranched structure assembled through a repeating aggregate of β sheets.

Some mixtures of proteins and nucleic acids can assemble spontaneously into complex structures in a test tube. But not all structures in the cell are capable of spontaneous reassembly after they have been dissociated into their component parts, because many biological assembly processes involve assembly factors that have been removed from the final structure.

PROTEIN FUNCTION

We have seen that each type of protein consists of a precise sequence of amino acids that allows it to fold up into a particular three-dimensional shape, or conformation. These proteins can also have moving parts whose mechanical actions are coupled to chemical events. This coupling of chemistry and movement helps to give proteins the extraordinary capabilities that underlie the dynamic processes in living cells.

In this section, we explain how proteins bind to other selected molecules and how a protein's activity depends on such binding. We will use selected examples to demonstrate how their ability to bind to other molecules enables proteins to act as catalysts, signal receptors, switches, motors, or tiny pumps. These examples by no means exhaust the vast functional repertoire of proteins. You will encounter the specialized functions of many other proteins elsewhere in this book, based on similar principles.

All Proteins Bind to Other Molecules

A protein molecule's physical interaction with other molecules determines its biological properties. Thus, antibodies attach to viruses or bacteria to mark them for destruction, the enzyme hexokinase binds glucose and ATP so as to catalyze a reaction between them, actin molecules bind to each other to assemble into actin filaments, and so on. Indeed, all proteins stick, or *bind*, to other molecules. In some cases, this binding is very tight; in others it is weak and short-lived. But the binding always shows great *specificity*, in the sense that each protein molecule can usually bind just one or a few molecules out of the many thousands of different types it encounters. The substance that is bound by the protein—whether it is an ion, a small molecule, or a macromolecule such as another protein—is referred to as a **ligand** for that protein (from the Latin word *ligare*, meaning "to bind").

The ability of a protein to bind selectively and with high affinity to a ligand depends on the formation of a set of weak noncovalent bonds—hydrogen bonds, electrostatic attractions, and van der Waals attractions—plus favorable hydrophobic interactions (see Panel 2–3, pp. 98–99). Because each individual bond is

MBOC7_ptr_ch03_115-182.indd 140 02/12/21 2:17 PM

PROTEIN FUNCTION 141

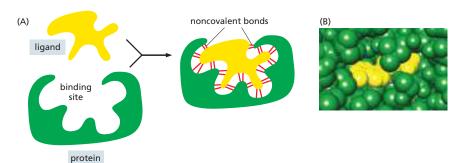

Figure 3–35 The selective binding of a protein to another molecule. Many weak bonds are needed to enable a protein to bind tightly to a second molecule, or ligand. A ligand must therefore fit precisely into a protein's binding site, like a hand into a glove, so that a large number of noncovalent bonds form between the protein and the ligand. (A) Schematic; (B) space-filling model. (PDB code: 1G6N.)

weak, effective binding occurs only when many of these bonds form simultaneously. Such binding is possible only if the surface contours of the ligand molecule fit very closely to the protein, matching it like a hand in a glove (Figure 3–35).

The region of a protein that associates with a ligand, known as the ligand's *binding site*, usually consists of a cavity in the protein surface formed by a particular arrangement of amino acids. These amino acids can belong to different portions of the polypeptide chain that are brought together when the protein folds (**Figure 3–36**). Separate regions of the protein surface generally provide binding sites for different ligands, allowing the protein's activity to be regulated, as we shall see later. And other parts of the protein act as a handle to position the protein in the cell—an example is the SH2 domain discussed previously, which often moves a protein containing it to particular intracellular sites in response to signals.

Although the atoms buried in the interior of the protein have no direct contact with the ligand, they form the framework that gives the surface its contours and its chemical and mechanical properties. Even small changes to the amino acids in the interior of a protein molecule can change its three-dimensional shape enough to destroy a binding site on the surface.

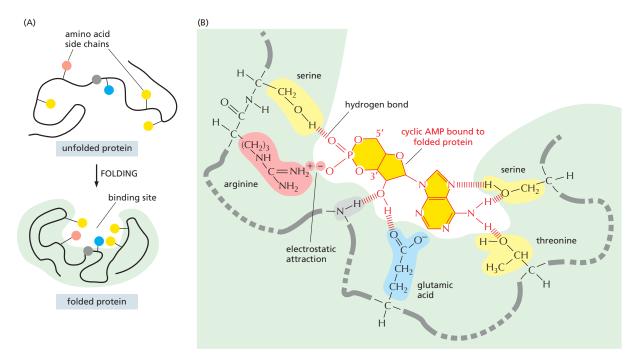

Figure 3–36 The binding site of a protein. (A) The folding of the polypeptide chain typically creates a crevice or cavity on the protein surface. This crevice contains a set of amino acid side chains disposed in such a way that they can form noncovalent bonds only with certain ligands. (B) A close-up of an actual binding site, showing the hydrogen bonds and electrostatic interactions formed between a protein and its ligand. In this example, a molecule of cyclic AMP is the bound ligand, shown in dark yellow.

MBOC7_ptr_ch03_115-182.indd 141 02/12/21 2:17 PM

The Surface Conformation of a Protein Determines Its Chemistry

The impressive chemical capabilities of proteins often require that the chemical groups on their surface interact in ways that enhance the chemical reactivity of one or more amino acid side chains. These interactions fall into two main categories.

First, the interaction of neighboring parts of the polypeptide chain may restrict the access of water molecules to that protein's ligand-binding sites. Because water molecules readily form hydrogen bonds that can compete with ligands for sites on the protein surface, a ligand will form tighter hydrogen bonds (and electrostatic interactions) with a protein if water molecules are kept away. It might be hard to imagine a mechanism that would exclude a molecule as small as water from a protein surface without affecting the access of the ligand itself. However, because of the strong tendency of water molecules to form water-water hydrogen bonds, water molecules exist in a large hydrogen-bonded network (see Panel 2–2, pp. 96–97). In effect, a protein can keep a ligand-binding site dry, increasing that site's reactivity, because it is energetically unfavorable for individual water molecules to break away from this network—as they must do to reach into a crevice on a protein's surface.

Second, the clustering of neighboring polar amino acid side chains can alter their reactivity. If protein folding brings together a number of negatively charged side chains against their mutual repulsion, for example, the affinity of the site for a positively charged ion is greatly increased. In addition, when amino acid side chains interact with one another through hydrogen bonds, normally unreactive groups (such as the $-\mathrm{CH}_2\mathrm{OH}$ on the serine shown in Figure 3–37) can become reactive, enabling them to be used to make or break selected covalent bonds.

The surface of each protein molecule therefore has a unique chemical reactivity that depends not only on which amino acid side chains are exposed, but also on their exact orientation relative to one another. For this reason, two slightly different conformations of the same protein molecule can differ greatly in their chemistry.

Sequence Comparisons Between Protein Family Members Highlight Crucial Ligand-binding Sites

As we have described previously, genome sequences allow us to group many of the domains found in proteins into families that show clear evidence of their evolution from a common ancestor. The three-dimensional structures of members of the same domain family are remarkably similar. For example, even when the amino acid sequence identity falls to 25%, the backbone atoms in a domain can follow a common protein fold within 0.2 nm (2 Å).

We can use a method called *evolutionary tracing* to identify those sites in a protein domain that are the most crucial to the domain's function. Those sites that bind to other molecules are the most likely to be kept unchanged as organisms

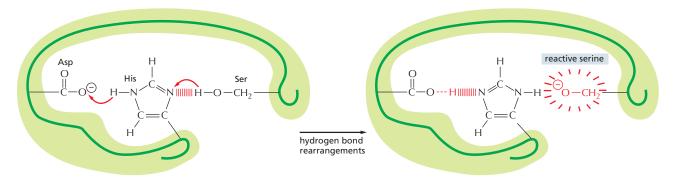

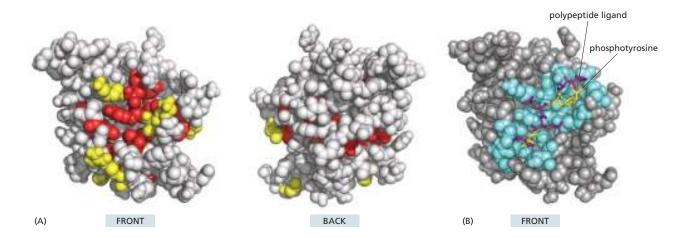

Figure 3–37 An unusually reactive amino acid at the active site of an enzyme. This example is the *catalytic triad* Asp-His-Ser found in chymotrypsin, elastase, and other serine proteases (see Figure 3–13). The aspartic acid side chain (Asp) induces the histidine (His) to remove the proton from a particular serine (Ser). This activates the serine and enables it to form a covalent bond with the enzyme's substrate, hydrolyzing a peptide bond. The many convolutions of the polypeptide chain are omitted here.

MBOC7_ptr_ch03_115-182.indd 142 02/12/21 2:17 PM

evolve. Thus, in this method, those amino acids that are the same, or nearly so, in all of the known protein family members are mapped onto a model of the three-dimensional structure of a single family member. When this is done, the most invariant positions often form one or more clusters on the protein surface, as illustrated in Figure 3–38A for the SH2 domain described previously (see Figure 3–9). These clusters generally correspond to ligand-binding sites.

The SH2 domain functions to link two proteins together. It binds the protein containing it to a second protein that contains a phosphorylated tyrosine side chain in a specific amino acid sequence context, as shown in Figure 3–38B. The amino acids located at the binding site for the phosphorylated polypeptide have been the slowest to change during the long evolutionary process that produced the large SH2 family of peptide recognition domains. Mutation is a random process; survival is not. Thus, natural selection (random mutation followed by nonrandom survival) produces the sequence conservation by preferentially eliminating organisms whose SH2 domains have become altered in a way that inactivates the SH2 binding site, destroying SH2 function.

Genome sequencing has revealed huge numbers of proteins whose functions are unknown. Once a three-dimensional structure has been determined for one member of a protein family, evolutionary tracing allows biologists to determine binding sites for the members of that family, and this provides a useful start in deciphering protein function.

Proteins Bind to Other Proteins Through Several Types of Interfaces

Proteins can bind to other proteins in multiple ways. In many cases, a portion of the surface of one protein contacts an extended loop of polypeptide chain (a *string*) on a second protein (**Figure 3–39A**). Such a surface-string interaction,

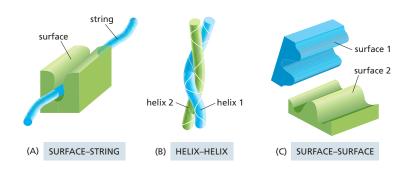

Figure 3-38 The evolutionary trace method applied to a protein domain. (A) Front and back views of a spacefilling model of the SH2 domain, with evolutionarily conserved amino acids on the protein surface colored vellow, and those more toward the protein interior colored red. (B) The structure of one specific SH2 domain with its bound polypeptide. Here, those amino acids located within 0.4 nm of the bound ligand are colored blue. The two key amino acids of the ligand are yellow, and the others are purple. Note the high degree of correspondence between A and B. (Adapted from O. Lichtarge et al., J. Mol. Biol. 257:342-358, 1996. PDB codes: 1SPR. 1SPS.)

Figure 3–39 Three ways in which two proteins can bind to each other. Only the interacting parts of the two proteins are shown. (A) A rigid surface on one protein can bind to an extended loop of polypeptide chain (a string) on a second protein. (B) Two α helices can bind together to form a coiled-coil. (C) Two complementary rigid surfaces often link two proteins together. Binding interactions can also involve the pairing of β strands (see, for example, Figure 3–19B).

MBOC7_ptr_ch03_115-182.indd 143 02/12/21 2:17 PM

144

for example, allows the SH2 domain to recognize a phosphorylated polypeptide loop on a second protein, as just described, and it also enables a protein kinase to recognize the proteins that it will phosphorylate (see below).

A second type of protein–protein interface forms when two α helices, one from each protein, pair together to form a coiled-coil (**Figure 3–39B**). This type of protein interface is found in several families of transcription regulatory proteins, as discussed in Chapter 7.

Another common way for proteins to interact is by the precise matching of one rigid surface with that of another (Figure 3–39C). Such interactions can be very tight, because a large number of weak bonds can form between two surfaces that match well. For the same reason, such surface-surface interactions can be extremely specific, enabling a protein to select just one partner from the many thousands of different proteins found in a cell.

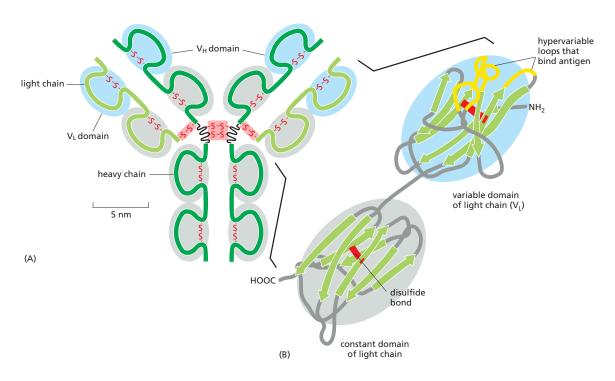

Antibody Binding Sites Are Especially Versatile

All proteins must bind to particular ligands to carry out their various functions, and the antibody family is notable for its capacity for tight, highly selective binding (see Chapter 24).

Antibodies, or immunoglobulins, are proteins produced by the immune system in response to foreign molecules, such as those on the surface of an invading microorganism. Each antibody binds tightly to a particular target molecule, thereby either inactivating the target molecule directly or marking it for destruction. An antibody recognizes its target (called an antigen) with remarkable specificity. Because there are potentially billions of different antigens that humans might encounter, we need to be able to produce billions of different antibodies.

Antibodies are Y-shaped molecules with two identical binding sites that are complementary to a small portion of the surface of the antigen molecule. A detailed examination of the antigen-binding sites of antibodies reveals that they are formed from several loops of polypeptide chain that protrude from the ends of a pair of closely juxtaposed protein domains (Figure 3–40). The genes that encode different antibodies generate an enormous diversity of antigen-binding sites by changing only the length and amino acid sequence of these loops, without altering the basic protein structure.

Figure 3-40 An antibody is Y-shaped and has two identical antigen-binding sites, one on each arm of the Y. (A) Schematic drawing of a typical antibody molecule. The protein is composed of four polypeptide chains (two identical heavy chains and two identical, smaller light chains), stabilized and held together by disulfide bonds (red). Each chain is made up of several similar domains, here shaded with blue, for the variable domains, or grav. for the constant domains. The antigenbinding site is formed where a heavy-chain variable domain (V_H) and a light-chain variable domain (V_I) come close together. These are the domains that differ most in their amino acid sequence in different antibodies-hence their name. (B) Ribbon drawing of a single light chain showing that the most variable parts of the polypeptide chain (orange) extend as loops at one end of the variable domain (VL) to form half of one antigen-binding site of the antibody molecule shown in A. Note that both the constant and variable domains are composed of a sandwich of two antiparallel β sheets connected by a disulfide bond (red). (See Movie 24.5.)

MBOC7_ptr_ch03_115-182.indd 144 02/12/21 2:17 PM

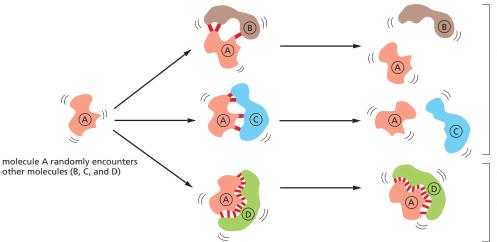

Loops of this kind are ideal for grasping other molecules. They allow a large number of chemical groups to surround a ligand so that the protein can link to it with many weak bonds. For this reason, loops often form the ligand-binding sites in proteins.

The Equilibrium Constant Measures Binding Strength

Molecules in the cell encounter each other very frequently because of their continual random thermal movements. Colliding molecules with poorly matching surfaces form few noncovalent bonds with one another, and the two molecules dissociate as rapidly as they come together. At the other extreme, when many noncovalent bonds form between two colliding molecules, the association can persist for a very long time (Figure 3–41). Such strong interactions occur in cells whenever a biological function requires that molecules remain associated; for example, when a group of RNA and protein molecules come together to make a subcellular structure such as a ribosome.

We can measure the strength with which any two molecules bind to each other. As an example, consider a population of identical antibody molecules that suddenly encounters a population of ligands diffusing in the fluid surrounding them. At frequent intervals, one of the ligand molecules will bump into the binding site of an antibody and form an antibody-ligand complex. The population of antibody-ligand complexes will therefore increase, but not without limit: over time, a second process, in which individual complexes break apart because of thermally induced motion, will become increasingly important. Eventually, any population of antibody molecules and ligands will reach a steady state, or **equilibrium**, in which the number of binding (association) events per second is precisely equal to the number of "unbinding" (dissociation) events (see Figure 2–30).

From the concentrations of the ligand, antibody, and antibody-ligand complex at equilibrium, we can calculate a convenient measure of the strength of binding—the **equilibrium constant** (*K*; Figure 3–42A). This constant was described in detail in Chapter 2, where its connection to free-energy differences was derived (see pp. 68–69). The equilibrium constant for a reaction in which two molecules (A and B) bind to each other to form a complex (AB) has units of liters/mole, and half of the binding sites will be occupied by ligand when that ligand's concentration (in moles/liter) reaches a value that is equal to 1/*K*. This equilibrium constant is larger the greater the binding strength, and it is a direct measure of the free-energy difference between the bound and free states (Figure 3–42B). Even a change of a few noncovalent bonds can have a striking effect on a binding interaction,

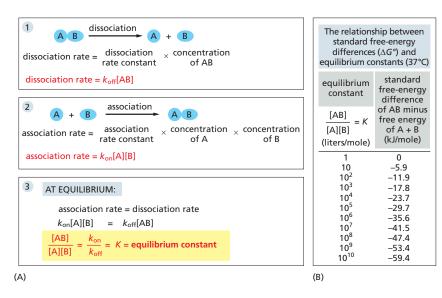

the surfaces of molecules A and B, and A and C, are a poor match and are capable of forming only a few weak bonds; thermal motion rapidly breaks them apart

the surfaces of molecules A and D match well and therefore can form enough weak bonds to withstand thermal jolting; they therefore stay bound to each other

Figure 3-41 How noncovalent bonds mediate interactions between macromolecules (see Movie 2.1).

MBOC7_ptr_ch03_115-182.indd 145 02/12/21 2:17 PM

as shown by the example in **Figure 3-43**. (Note that the equilibrium constant, as defined here, is the **association** or **affinity constant**, K_a ; the reciprocal of K_a is the **dissociation constant**, K_{d} , which is also widely used.)

We have used the case of an antibody binding to its ligand to illustrate the effect of binding strength on the equilibrium state, but the same principles apply to any molecule and its ligand. Many proteins are enzymes, which, as we now discuss, first bind to their ligands and then catalyze the breakage or formation of covalent bonds in these molecules.

Enzymes Are Powerful and Highly Specific Catalysts

Many proteins can perform their function simply by binding to another molecule. An actin molecule, for example, need only associate with other actin molecules to form a filament. There are other proteins, however, for which ligand binding is only a necessary first step in their function. This is the case for the large and very important class of proteins called **enzymes**. As described in Chapter 2, enzymes are remarkable molecules that cause the chemical transformations that make and break covalent bonds in cells. They bind to one or more ligands, called **substrates**, and convert them into one or more chemically modified *products*, doing this over and over again with amazing rapidity. Enzymes speed up reactions, often by a factor of a million or more, without themselves being changed; that is, they act as **catalysts** that permit cells to make or break covalent bonds in a controlled way. It is the catalysis of organized sets of chemical reactions by enzymes that creates and maintains the cell, making life possible.

We can group enzymes into functional classes that perform similar chemical reactions (Table 3–1). Each type of enzyme within such a class is highly specific, catalyzing only a single type of reaction. Thus, *hexokinase* adds a phosphate group to D-glucose but ignores its optical isomer L-glucose; the blood-clotting enzyme *thrombin* cuts one type of blood protein between a particular arginine and its adjacent glycine and nowhere else, and so on. As discussed in detail in Chapter 2, enzymes work in teams, with the product of one enzyme becoming the substrate for the next. The result is an elaborate network of metabolic pathways that provides the cell with energy and generates the many large and small molecules that the cell needs (see Figure 2–62).

Substrate Binding Is the First Step in Enzyme Catalysis

For a protein that catalyzes a chemical reaction (an enzyme), the binding of each substrate molecule to the protein is an essential prelude. In the simplest case, if we denote the enzyme by E, the substrate by S, and the product by P, the basic reaction

Figure 3-42 Relating standard free-energy difference (ΔG°) to the equilibrium constant (K). (A) The equilibrium between molecules A and B and the complex AB is maintained by a balance between the two opposing reactions shown in panels 1 and 2. Molecules A and B must collide if they are to react, and the association rate is therefore proportional to the product of their individual concentrations [A] \times [B]. (Square brackets indicate concentration.) As shown in panel 3, the ratio of the rate constants for the association and the dissociation reactions is equal to the equilibrium constant (K) for the reaction. (B) The equilibrium constant in panel 3 is that for the reaction $A + B \rightleftharpoons AB$, and the larger its value, the stronger the binding between A and B. Note that for every 5.91 kJ/mole decrease in standard free energy, the equilibrium constant increases by a factor of 10 at 37°C

The equilibrium constant here has units of liters/mole; for simple binding interactions it is also called the *affinity constant* or association constant, denoted K_a . The reciprocal of K_a is called the *dissociation constant*, K_d (in units of moles/liter).

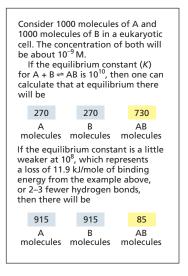

Figure 3–43 Small changes in the number of weak bonds can have drastic effects on a binding interaction. This example illustrates the dramatic effect of the presence or absence of a few weak noncovalent bonds in a biological context.

MBOC7_ptr_ch03_115-182.indd 146 02/12/21 2:17 PM

TABLE 3–1 Some Common Types of Enzymes		
Enzyme	Reaction catalyzed	
Hydrolases	General term for enzymes that catalyze a hydrolytic cleavage reaction; <i>nucleases</i> and <i>proteases</i> are more specific names for subclasses of these enzymes	
Nucleases	Break down nucleic acids by hydrolyzing bonds between nucleotides. <i>Endonucleases</i> and <i>exonucleases</i> cleave nucleic acids <i>within</i> and <i>from the ends of</i> the polynucleotide chains, respectively	
Proteases	Break down proteins by hydrolyzing bonds between amino acids	
Synthases	Synthesize molecules in anabolic reactions by condensing two smaller molecules together	
Ligases	Join together (ligate) two molecules in an energy-dependent process. DNA ligase, for example, joins two DNA molecules together end-to-end through phosphodiester bonds	
Isomerases	Catalyze the rearrangement of bonds within a single molecule	
Polymerases	Catalyze polymerization reactions such as the synthesis of DNA and RNA	
Kinases	Catalyze the addition of a phosphate group to a molecule. Protein kinases are an important group of kinases that attach phosphate groups to proteins	
Phosphatases	Catalyze the hydrolytic removal of a phosphate group from a molecule	
Oxido-reductases	General name for enzymes that catalyze reactions in which one molecule is oxidized while the other is reduced. Enzymes of this type are often more specifically named oxidases, reductases, or dehydrogenases	
ATPases	Hydrolyze ATP. Many proteins with a wide range of roles have an energy-harnessing ATPase activity as part of their function; for example, motor proteins such as <i>myosin</i> and membrane transport proteins such as the <i>sodium–potassium pump</i>	
GTPases	Hydrolyze GTP. A large family of GTP-binding proteins are GTPases with central roles in the regulation of cell processes	

Enzyme names typically end in "-ase," with the exception of some enzymes, such as pepsin, trypsin, thrombin, and lysozyme, that were discovered and named before the convention became generally accepted at the end of the nineteenth century. The common name of an enzyme usually indicates the substrate or product and the nature of the reaction catalyzed. For example, citrate synthase catalyzes the synthesis of citrate by a reaction between acetyl CoA and oxaloacetate.

path is $E+S\to ES\to EP\to E+P$. As illustrated in **Figure 3-44**, there is a limit to the amount of substrate that a single enzyme molecule can process in a given time. Although an increase in the concentration of substrate increases the rate at which product is formed, this rate eventually reaches a maximum value. At that point the enzyme molecule is saturated with substrate, and the rate of reaction (V_{max})

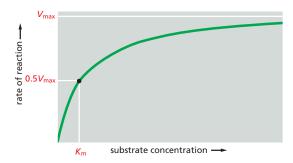

Figure 3–44 Enzyme kinetics. The rate of an enzyme reaction (V) increases as the substrate concentration increases until a maximum value (V_{max}) is reached. At this point all substrate-binding sites on the enzyme molecules are fully occupied, and the rate of reaction is limited by the rate of the catalytic process on the enzyme surface. For most enzymes, the concentration of substrate at which the reaction rate is half-maximal (K_{m}) is a measure of how tightly the substrate is bound, with a large value of K_{m} corresponding to weak binding (K_{m} approximates the dissociation constant, K_{d} , for substrate binding).

MBOC7_ptr_ch03_115-182.indd 147 02/12/21 2:17 PM

depends only on how rapidly the enzyme can process the substrate molecule. This maximum rate divided by the enzyme concentration is called the *turnover number*. Turnover numbers are often about 1000 substrate molecules processed per second per enzyme molecule, although turnover numbers between 1 and 10,000 are known.

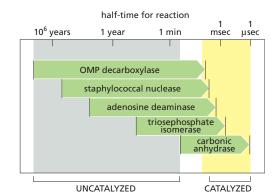

The other kinetic parameter frequently used to characterize an enzyme is its $K_{\rm m}$, the concentration of substrate that allows the reaction to proceed at one-half its maximum rate $(0.5V_{\rm max})$ (see Figure 3–44). A *low* $K_{\rm m}$ value means that the enzyme reaches its maximum catalytic rate at a *low concentration* of substrate and generally indicates that the enzyme binds to its substrate very tightly, whereas a *high* $K_{\rm m}$ value corresponds to weak binding. The methods used to characterize enzymes in this way are explained in Panel 3–2 (pp. 150–151).

Enzymes Speed Reactions by Selectively Stabilizing Transition States

Enzymes achieve extremely high rates of chemical reaction—rates that are far higher than for any synthetic catalysts. There are several reasons for this efficiency. First, when two molecules need to react, the enzyme greatly increases the local concentration of both of these substrate molecules at the catalytic site, holding them in the correct orientation for the reaction that is to follow. More important, however, some of the binding energy contributes directly to the catalysis. Substrate molecules must pass through a series of intermediate states of altered geometry and electron distribution before they form the ultimate products of the reaction. The free energy required to attain the most unstable intermediate state, called the transition state, is known as the activation energy for the reaction, and it is the major determinant of the reaction rate. Enzymes have a much higher affinity for the transition state of the substrate than they have for the stable form. Because this tight binding greatly lowers the energy of the transition state, the enzyme greatly accelerates a particular reaction by lowering the activation energy that is required (Figure 3-45; see also p. 63).

Enzymes Can Use Simultaneous Acid and Base Catalysis

Figure 3-46 compares the spontaneous reaction rates and the corresponding enzyme-catalyzed rates for five enzymes. Rate accelerations range from 10⁹ to 10²³. This is possible because enzymes not only bind tightly to a transition state, they also contain precisely positioned atoms that alter the electron distributions in the atoms that participate directly in the making and breaking of covalent bonds. Peptide bonds, for example, can be hydrolyzed in the absence of an enzyme by exposing a polypeptide to either a strong acid or a strong base. Enzymes are unique, however, in being able to use acid and base catalysis simultaneously, because the rigid framework of the protein constrains the acidic and

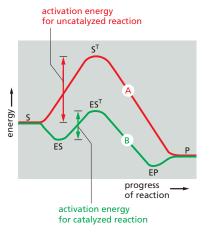

Figure 3–45 Enzymes accelerate chemical reactions by decreasing the activation energy. There is a single transition state in this example. However, often both the uncatalyzed reaction (A) and the enzyme-catalyzed reaction (B) go through a series of transition states. In that case, it is the transition state with the highest energy (S^T and ES^T) that determines the activation energy and limits the rate of the reaction. (S = substrate; P = product of the reaction; ES = enzyme-substrate complex; EP = enzyme-product complex.)

Figure 3–46 The rate accelerations caused by five different enzymes. (Adapted from A. Radzicka and R. Wolfenden, *Science* 267:90–93, 1995.)

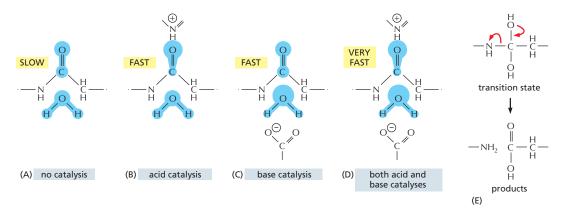

Figure 3–47 Simultaneous acid catalysis and base catalysis by an enzyme. (A) The start of the uncatalyzed reaction that hydrolyzes a peptide bond, with *blue* shading used to indicate electron distribution in the water and carbonyl bonds. (B) An acid likes to donate a proton (H⁺) to other atoms. By pairing with the carbonyl oxygen, an acid causes electrons to move away from the carbonyl carbon, making this atom much more attractive to the electronegative oxygen of an attacking water molecule. (C) A base likes to take up H⁺. By pairing with a hydrogen of the attacking water molecule, a base causes electrons to move toward the water oxygen, making it a better attacking group for the carbonyl carbon. (D) By having appropriately positioned atoms on its surface, an enzyme can perform both acid catalysis and base catalysis at the same time. (E) A tetrahedral intermediate is formed by the attack of the water oxygen atom on the carbonyl carbon atom, and this intermediate rapidly decays to hydrolysis products. The *red arrows* denote the electron shifts associated with product formation.

basic residues and prevents them from combining with each other, as they would do in solution (Figure 3-47).

The fit between an enzyme and its substrate needs to be precise. A small change introduced by genetic engineering in the active site of an enzyme can therefore have a profound effect. Replacing a glutamic acid with an aspartic acid in one enzyme, for example, shifts the position of the catalytic carboxylate ion by only 1 Å (about the radius of a hydrogen atom), yet this is enough to decrease the activity of the enzyme a thousandfold.

Lysozyme Illustrates How an Enzyme Works

To demonstrate how enzymes catalyze chemical reactions, we examine an enzyme that acts as a natural antibiotic in egg white, saliva, tears, and other secretions. **Lysozyme** catalyzes the cutting of polysaccharide chains in the cell walls of bacteria. The bacterial cell is under pressure from osmotic forces, and cutting even a small number of these chains causes the cell wall to rupture and the cell to burst. A relatively small and stable protein that can be easily isolated in large quantities, lysozyme was the first enzyme to have its structure worked out in atomic detail by x-ray crystallography (in the mid-1960s).

The reaction that lysozyme catalyzes is a hydrolysis: it adds a molecule of water to a single bond between two adjacent sugar groups in the polysaccharide chain, thereby causing the bond to break (see Figure 2–9). The reaction is energetically favorable because the free energy of the severed polysaccharide chain is lower than the free energy of the intact chain. However, there is an energy barrier for the reaction (its activation energy). In particular, a colliding water molecule can break a bond linking two sugars only if the polysaccharide molecule is distorted into a particular shape—the transition state—in which the atoms around the bond have an altered geometry and electron distribution. Because of this requirement, random collisions must supply a very large activation energy for the reaction to take place. In an aqueous solution at room temperature, the energy of collisions almost never exceeds the activation energy. The pure polysaccharide can therefore remain for years in water without being hydrolyzed to any detectable degree.

This situation changes drastically when the polysaccharide binds to lysozyme. The active site of lysozyme, because its substrate is a polymer, is a long groove that holds six linked sugars at the same time. As soon as the polysaccharide

WHY ANALYZE THE KINETICS OF ENZYMES?

Enzymes are the most selective and powerful catalysts known. An understanding of their detailed mechanisms provides a critical tool for the discovery of new drugs, for the large-scale industrial synthesis of useful chemicals, and for appreciating the chemistry of cells and organisms. A detailed study of the rates of the chemical reactions that are catalyzed by a purified enzyme—more specifically how these rates change with changes in conditions such as the concentrations of substrates, products, inhibitors, and regulatory ligands—allows

biochemists to figure out exactly how each enzyme works. For example, this is the way that the ATP-producing reactions of glycolysis, shown previously in Figure 2–47, were deciphered—allowing us to appreciate the rationale for this critical enzymatic pathway.

In this Panel, we introduce the important field of enzyme kinetics, which has been indispensable for deriving much of the detailed knowledge that we now have about cell chemistry.

STEADY-STATE ENZYME KINETICS

Many enzymes have only one substrate, which they bind and then process to produce products according to the scheme outlined in Figure 3–48A. In this case, the reaction is written as

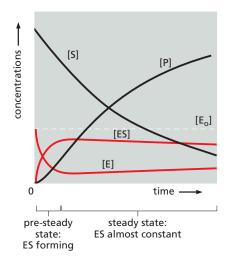

$$E + S \xrightarrow{k_1} ES \xrightarrow{k_{cat}} E + P$$

Here we have assumed that the reverse reaction, in which E + P recombine to form EP and then ES, occurs so rarely that we can ignore it. In this case, EP need not be represented, and we can express the rate of the reaction, known as its velocity, V, as

$$V = k_{cat}[ES]$$

where [ES] is the concentration of the enzyme–substrate complex, and $k_{\rm cat}$ is the turnover number, a rate constant that has a value equal to the number of substrate molecules processed per enzyme molecule each second.

But how does the value of [ES] relate to the concentrations that we know directly, which are the total concentration of the enzyme, [E_o], and the concentration of the substrate, [S]? When enzyme and substrate are first mixed, the concentration [ES] will rise rapidly from zero to a so-called steady-state level, as illustrated below.

At this steady state, [ES] is nearly constant, so that

rate of ES breakdown
$$k_{-1}[ES] + k_{cat}[ES] = rate of ES formation$$

$$k_{1}[E][S]$$

or, because the concentration of the free enzyme, [E], is equal to $[E_{\rm o}]$ – $[{\rm ES}]$,

[ES] =
$$\left(\frac{k_1}{k_{-1} + k_{cat}}\right)$$
[E][S] = $\left(\frac{k_1}{k_{-1} + k_{cat}}\right)$ $\left([E_0] - [ES]\right)$ [S]

Rearranging, and defining the constant $K_{\rm m}$ as

$$\frac{k_{-1} + k_{\text{cat}}}{k_1}$$

we get

$$[ES] = \frac{[E_o][S]}{K_m + [S]}$$

or, remembering that $V = k_{\rm cat}$ [ES], we obtain the famous Michaelis–Menten equation

$$V = \frac{k_{\text{cat}}[E_{\text{o}}][S]}{K_{\text{m}} + [S]}$$

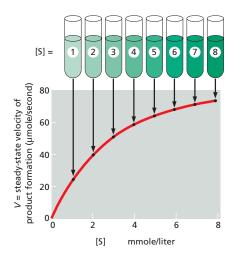

As [S] is increased to higher and higher levels, essentially all of the enzyme will be bound to substrate at steady state; at this point, a maximum rate of reaction, $V_{\rm max}$, will be reached where $V=V_{\rm max}=k_{\rm cat}[{\sf E}_{\rm o}]$. Thus, it is convenient to rewrite the Michaelis–Menten equation as

$$V = \frac{V_{\text{max}}[S]}{K_{\text{m}} + [S]}$$

MBOC7_ptr_ch03_115-182.indd 150 02/12/21 2:17 PM

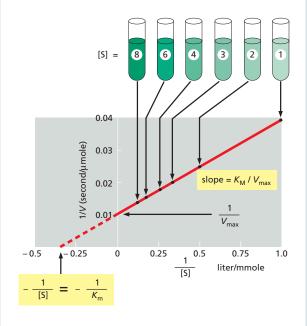

THE DOUBLE-RECIPROCAL PLOT

A typical plot of V versus [S] for an enzyme that follows Michaelis–Menten kinetics is shown below. From this plot, neither the value of $V_{\rm max}$ nor of $K_{\rm m}$ is immediately clear.

To obtain $V_{\rm max}$ and $K_{\rm m}$ from such data, a double-reciprocal plot is often used, in which the Michaelis–Menten equation has merely been rearranged, so that 1/V can be plotted versus 1/[S].

$$1/V = \left(\frac{K_{\rm m}}{V_{\rm max}}\right) \left(\frac{1}{[S]}\right) + 1/V_{\rm max}$$

THE SIGNIFICANCE OF $K_{\rm m}$, $k_{\rm cat}$, and $k_{\rm cat}/K_{\rm m}$

As described in the text, $K_{\rm m}$ is an approximate measure of substrate affinity for the enzyme: it is numerically equal to the concentration of [S] at $V=0.5V_{\rm max}$. In general, a lower value of $K_{\rm m}$ means tighter substrate binding. In fact, for those cases where $k_{\rm cat}$ is much smaller than k_{-1} , the $K_{\rm m}$ will be equal to $K_{\rm d}$, the dissociation constant for substrate binding to the enzyme ($K_{\rm d}=1/K_{\rm a}$).

We have seen that $k_{\rm cat}$ is the turnover number for the enzyme. At very low substrate concentrations, where [S] << $K_{\rm m}$, most of the enzyme is free. Thus we can think of [E] = [E $_{\rm o}$], so that the Michaelis–Menten equation can be simplified as $V = k_{\rm cat}/K_{\rm m}$ [E][S]. Thus, the ratio $k_{\rm cat}/K_{\rm m}$ is equivalent to the rate constant for the reaction between free enzyme and free substrate.

A comparison of $k_{\rm cat}/K_{\rm m}$ for the same enzyme with different substrates, or for two enzymes with their different substrates, is widely used as a measure of enzyme effectiveness.

For simplicity, in this Panel we have discussed enzymes that have only one substrate, such as the lysozyme enzyme described in the text (see p. 152). Most enzymes have two substrates, one of which is often an active carrier molecule—such as NADH or ATP.

A similar, but more complex, analysis is used to determine the kinetics of such enzymes—allowing the order of substrate binding and the presence of covalent intermediates along the pathway to be revealed.

SOME ENZYMES ARE DIFFUSION LIMITED

The values of $k_{\rm cat}$, $K_{\rm m}$, and $k_{\rm cat}/K_{\rm m}$ for some selected enzymes are given below:

enzyme	substrate	k _{cat} (sec ⁻¹)	K _m (M)	$k_{\rm cat}/K_{\rm m}$ (sec ⁻¹ M ⁻¹)
acetyl choline sterase	acetylcholine	1.4×10^{4}	9 × 10 ⁻⁵	1.6 × 10 ⁸
catalase	H ₂ O ₂	4×10^{7}	1	4×10^{7}
fumarase	fumarate	8×10^{2}	5 × 10 ⁻⁶	1.6 × 10 ⁸

Because an enzyme and its substrate must collide before they can react, $k_{\rm cat}/K_{\rm m}$ has a maximum possible value that is limited by collision rates. If every collision forms an enzyme–substrate complex, one can calculate from diffusion theory that $k_{\rm cat}/K_{\rm m}$ will be between 10^8 and 10^9 sec⁻¹ M⁻¹, in the case where all subsequent steps proceed immediately. Thus, it is claimed that enzymes like acetylcholinesterase and fumarase are "perfect enzymes," each enzyme having evolved to the point where nearly every collision with its substrate converts the substrate to a product.

MBOC7_ptr_ch03_115-182.indd 151 02/12/21 2:17 PM

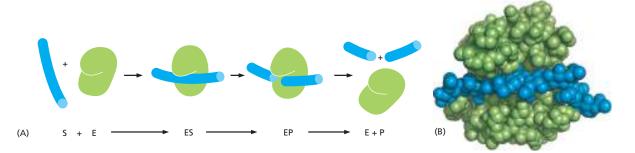

Figure 3–48 The overall reaction catalyzed by lysozyme. (A) The enzyme lysozyme (E) catalyzes the cutting of a polysaccharide chain, which is its substrate (S). The enzyme first binds to the chain to form an enzyme–substrate complex (ES) and then catalyzes the cleavage of a specific covalent bond in the backbone of the polysaccharide, forming an enzyme–product complex (EP) that rapidly dissociates. Release of the severed chain (the products P) leaves the enzyme free to act on another substrate molecule. (B) A space-filling model of the lysozyme molecule bound to a short length of polysaccharide chain before cleavage (Movie 3.8). (PDB code: 3AB6.)

binds to form an enzyme-substrate complex, the enzyme cuts the polysaccharide by adding a water molecule across one of its sugar-sugar bonds. The product chains are then quickly released, freeing the enzyme for further cycles of reaction (Figure 3–48).

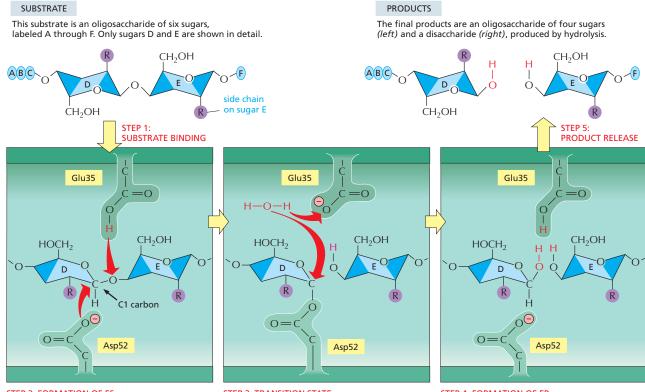

An impressive increase in hydrolysis rate is possible because conditions are created in the microenvironment of the lysozyme active site that greatly reduce the activation energy necessary for the hydrolysis to take place. In particular, lysozyme distorts one of the two sugars connected by the bond to be broken from its normal, most stable conformation. The bond to be broken is also held close to two amino acids with acidic side chains (a glutamic acid and an aspartic acid) that participate directly in the reaction. Figure 3–49 highlights the three central steps in this enzymatically catalyzed reaction, which occurs millions of times faster than uncatalyzed hydrolysis.

Other enzymes use similar mechanisms to lower activation energies and speed up the reactions they catalyze. In reactions involving two or more reactants, the active site also acts like a template, or mold, that brings the substrates together in the proper orientation for a reaction to occur between them (Figure 3–50A). As we saw for lysozyme, the active site of an enzyme contains precisely positioned atoms that speed up a reaction by using charged groups to alter the distribution of electrons in the substrates (Figure 3–50B). And as we have also seen, when a substrate binds to an enzyme, bonds in the substrate are often distorted, changing the substrate shape. These changes drive a substrate toward a particular transition state (Figure 3–50C). Finally, like lysozyme, many enzymes participate intimately in the reaction by transiently forming a covalent bond between the substrate and a side chain of the enzyme. Subsequent steps in the reaction restore the side chain to its original state, so that the enzyme remains unchanged after the reaction (see also Figure 2–47).

Tightly Bound Small Molecules Add Extra Functions to Proteins

Although we have emphasized the versatility of enzymes—and proteins in general—as chains of amino acids that perform remarkable functions, there are many instances in which the amino acids by themselves are not enough. Just as humans employ tools to enhance and extend the capabilities of their hands, enzymes and other proteins often use small nonprotein molecules to perform functions that would be difficult or impossible to do with amino acids alone. Thus, enzymes frequently have a small molecule or metal atom tightly associated with their active site that assists with their catalytic function. *Carboxypeptidase*, for example, an enzyme that cuts polypeptide chains, carries a tightly bound zinc ion in its active site. During the cleavage of a peptide bond by carboxypeptidase, the zinc ion forms a transient bond with one of the substrate atoms,

02/12/21 2:17 PM

STEP 2: FORMATION OF ES

In the enzyme-substrate complex (ES), the lysozyme forces sugar D into a strained conformation. The Glu35 in the active site is positioned to serve as an acid that attacks the adjacent sugar-sugar bond by donating a proton (H+) to sugar E: Asp52 is poised to attack the C1 carbon atom of sugar D.

STEP 3: TRANSITION STATE

The Asp52 has formed a covalent bond between the enzyme and the C1 carbon atom of sugar D. The Glu35 then polarizes a water molecule (red), so that its oxygen can readily attack the C1 carbon atom of sugar D and displace Asp52.

STEP 4: FORMATION OF EP

The water molecule splits: its –OH group attaches to sugar D and its remaining proton replaces the proton donated by Glu35 in step 2. This completes the hydrolysis and returns the enzyme to its initial state, forming the final enzymeproduct complex (EP).

Figure 3-49 Events at the active site of lysozyme. The top left and top right drawings show the free substrate and the free products, respectively. The other three drawings show the sequential events at the enzyme active site, where a sugar-sugar covalent bond is bent and then broken. Note the change in the conformation of sugar D in the enzyme-substrate complex compared with its conformation in the free substrate. This changed conformation favors the formation of the transition state shown in the middle panel, greatly lowering the activation energy that is required for the reaction. This reaction, and the structure of lysozyme bound to its product, are shown in Movie 3.8 and Movie 3.9. (Based on D.J. Vocadlo et al., Nature 412:835-838, 2001.)

thereby assisting the hydrolysis reaction. In other enzymes, a small organic molecule serves a similar purpose. Such organic molecules are often referred to as coenzymes. An example is biotin, which is found in enzymes that transfer a carboxylate group (-COO⁻) from one molecule to another (see Figure 2-40). Biotin participates in these reactions by forming a transient covalent bond to the -COO group to be transferred, being better suited to this function than any

TABLE 3–2 Many Vitamin Derivatives Are Critical Coenzymes for Human Cells				
Vitamin	Coenzyme	Enzyme-catalyzed reactions requiring these coenzymes		
Thiamine (vitamin B ₁)	Thiamine pyrophosphate	Activation and transfer of aldehydes		
Riboflavin (vitamin B ₂)	FADH	Oxidation-reduction		
Niacin	NADH, NADPH	Oxidation-reduction		
Pantothenic acid	Coenzyme A	Acyl group activation and transfer		
Pyridoxine	Pyridoxal phosphate	Amino acid activation; also glycogen phosphorylase		
Biotin	Biotin	CO ₂ activation and transfer		
Lipoic acid	Lipoamide	Acyl group activation; oxidation-reduction		
Folic acid	Tetrahydrofolate	Activation and transfer of single carbon groups		
Vitamin B ₁₂	Cobalamin coenzymes	Isomerization and methyl group transfers		

of the amino acids used to make proteins. Because it cannot be synthesized by humans, and must therefore be supplied in small quantities in our diet, biotin is a *vitamin*. Many other coenzymes are either vitamins or derivatives of vitamins (Table 3–2).

Other proteins also frequently require specific small-molecule adjuncts to function properly. Thus, the signal receptor protein *rhodopsin*, which is made by the photoreceptor cells in the retina, detects light by means of a small molecule, *retinal*, embedded in the protein (Figure 3–51A). Retinal, which is derived from vitamin A, changes its shape when it absorbs a photon of light, and this change causes the protein to trigger a cascade of enzymatic reactions that eventually lead to an electrical signal being carried to the brain.

Another example of a protein with a nonprotein portion is hemoglobin (see Figure 3–20). Each molecule of hemoglobin carries four *heme* groups, ringshaped molecules each with a single central iron atom (Figure 3–51B). Heme

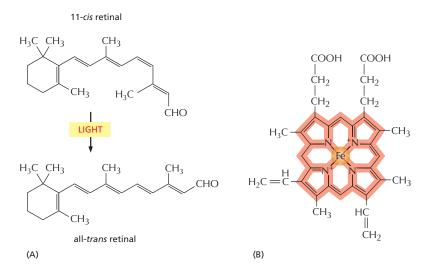

Figure 3–51 Retinal and heme. (A) The structure of retinal, the light-sensitive molecule attached to rhodopsin in the eye, showing its isomerization when it absorbs light. (B) The structure of a heme group. The carbon-containing heme ring is *red* and the iron atom at its center is *orange*. A heme group is tightly bound to each of the four polypeptide chains in hemoglobin, the oxygen-carrying protein whose structure is shown in Figure 3–20.

MBOC7_ptr_ch03_115-182.indd 154 02/12/21 2:17 PM

gives hemoglobin (and blood) its red color. By binding reversibly to oxygen gas through its iron atom, heme enables hemoglobin to pick up oxygen in the lungs and release it in the tissues.

Sometimes these small molecules are attached covalently and permanently to their protein, thereby becoming an integral part of the protein molecule itself. We shall see in Chapter 10 that proteins are often anchored to cell membranes through covalently attached lipid molecules. And membrane proteins exposed on the surface of the cell, as well as proteins secreted outside the cell, are often modified by the covalent addition of sugars and oligosaccharides.

The Cell Regulates the Catalytic Activities of Its Enzymes

A living cell contains thousands of enzymes, many of which operate at the same time and in the same small volume of the cytosol. By their catalytic action, these enzymes generate a complex web of metabolic pathways, each composed of chains of chemical reactions in which the product of one enzyme becomes the substrate of the next. In this maze of pathways, there are many branch points (nodes) where different enzymes compete for the same substrate. The system is complex (see Figure 2–62), and elaborate controls are required to regulate when and how rapidly each reaction occurs.

Regulation occurs at many levels. At one level, the cell controls how many molecules of each enzyme it makes by regulating the expression of the gene that encodes that enzyme (discussed in Chapter 7). The cell also controls enzymatic activities by confining sets of enzymes to particular subcellular compartments (discussed in Chapters 12 and 14) or by concentrating them on protein scaffolds (see pp. 170–173). As will be explained later in this chapter, enzymes are also covalently modified to control their activity. The rate of protein destruction by targeted proteolysis represents yet another important regulatory mechanism (see Figure 6–89). But the most general process that adjusts reaction rates operates through a direct, reversible change in the activity of an enzyme in response to the specific small molecules that it binds.

The most common type of control occurs when an enzyme binds a molecule that is not a substrate to a special regulatory site outside the active site, thereby altering the rate at which the enzyme converts its substrates to products. For example, in **feedback inhibition**, a product produced late in a reaction pathway inhibits an enzyme that acts earlier in the pathway. Thus, whenever large quantities of the final product begin to accumulate, this product binds to the enzyme and slows down its catalytic action, thereby limiting the further entry of substrates into that reaction pathway (**Figure 3–52**). Where pathways branch or intersect, there are usually multiple points of control by different final products, each of which works to regulate its own synthesis (**Figure 3–53**). Feedback inhibition can work almost instantaneously, and it is rapidly reversed when the level of the product falls.

Feedback inhibition is *negative regulation*: it prevents an enzyme from acting. Enzymes can also be subject to *positive regulation*, in which a regulatory molecule stimulates the enzyme's activity rather than shutting the enzyme down. Positive regulation occurs when a product in one branch of the metabolic network stimulates the activity of an enzyme in another pathway. As one example, the accumulation of ADP activates several enzymes involved in the oxidation of sugar molecules, thereby stimulating the cell to convert more ADP to ATP.

Allosteric Enzymes Have Two or More Binding Sites That Interact

A striking feature of both positive and negative feedback regulation is that the regulatory molecule often has a shape totally different from the shape of the substrate of the enzyme. This is why the effect on a protein is termed **allostery** (from the Greek words *allos*, meaning "other," and *stereos*, meaning "solid" or "three-dimensional"). As biologists learned more about feedback regulation,

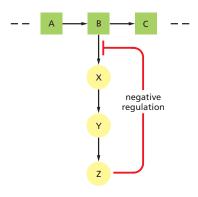

Figure 3–52 Feedback inhibition of a single biosynthetic pathway. The end product Z inhibits the first enzyme that is unique to its synthesis and thereby controls its own level in the cell. This is an example of neative regulation.

MBOC7_ptr_ch03_115-182.indd 155 02/12/21 2:17 PM

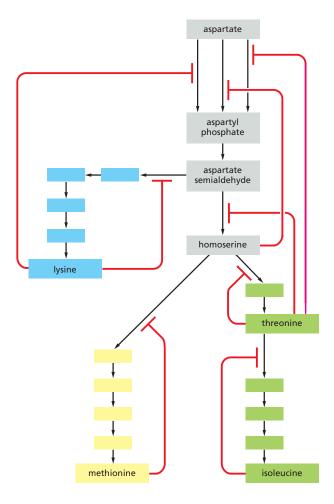

Figure 3–53 Multiple feedback inhibition. In this example, which shows the biosynthetic pathways for four different amino acids in bacteria, the *red lines* indicate positions at which products feed back to inhibit enzymes. Each amino acid controls the first enzyme specific to its own synthesis, thereby controlling its own levels and avoiding a wasteful or even dangerous buildup of intermediates. The products can also separately inhibit the initial set of reactions common to all the syntheses; in this case, three different enzymes catalyze the initial reaction, each inhibited by a different product.

they recognized that the enzymes involved must have at least two different binding sites on their surface—an **active site** that recognizes the substrates, and a **regulatory site** that recognizes a regulatory molecule. These two sites must somehow communicate, so that the catalytic events at the active site can be influenced by the binding of the regulatory molecule at its separate site on the protein's surface.

The interaction between separated sites on a protein molecule is now known to depend on a *conformational change* in the protein: binding at one of the sites causes a shift from one folded shape to a slightly different folded shape. During feedback inhibition, for example, the binding of an inhibitor at one site on the protein causes the protein to shift to a conformation that incapacitates its active site located elsewhere in the protein.

It is thought that most protein molecules are allosteric. They can adopt many slightly different conformations, and a shift from one to another caused by the binding of a ligand can alter their activity. This is true not only for enzymes but also for many other proteins, including receptors, structural proteins, and motor proteins. In all instances of allosteric regulation, each conformation of the protein has somewhat different surface contours, and the protein's binding sites for ligands are altered when the protein changes shape. Importantly, as we discuss next, each ligand will stabilize the conformation that it binds to most strongly, and thus—at high enough concentrations—will tend to "switch" the protein toward the conformation that has a high affinity for that ligand.

MBOC7_ptr_ch03_115-182.indd 156 02/12/21 2:17 PM

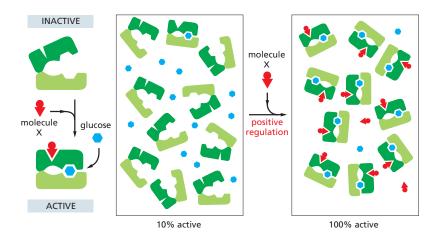

Figure 3–54 Positive regulation caused by conformational coupling between two separate binding sites. In this example, both glucose and molecule X bind best to the *closed* conformation of a protein with two domains. Because both glucose and molecule X drive the protein toward its closed conformation, each ligand helps the other to bind. Glucose and molecule X are therefore said to bind *cooperatively* to the protein.

Two Ligands Whose Binding Sites Are Coupled Must Reciprocally Affect Each Other's Binding

The effects of ligand binding on a protein follow from a fundamental chemical principle known as **linkage**. Suppose, for example, that a protein that binds glucose also binds another molecule, X, at a distant site on the protein's surface. If the binding site for X changes shape as part of the conformational change in the protein induced by glucose binding, the binding sites for X and for glucose are said to be *coupled*. Whenever two ligands prefer to bind to the *same* conformation of an allosteric protein, it follows from basic thermodynamic principles that each ligand must increase the affinity of the protein for the other. For example, if the shift of a protein to a conformation that binds glucose best also causes the binding site for X to fit X better, then the protein will bind glucose more tightly when X is present than when X is absent. In other words, X will positively regulate the protein's binding of glucose (**Figure 3–54**).

Conversely, linkage operates in a negative way if two ligands prefer to bind to *different* conformations of the same protein. In this case, the binding of the first ligand discourages the binding of the second ligand. Thus, if a shape change caused by glucose binding decreases the affinity of a protein for molecule X, the binding of X must also decrease the protein's affinity for glucose (**Figure 3–55**). The linkage relationship is quantitatively reciprocal, so that, for example, if glucose has a very large effect on the binding of X, X has a very large effect on the binding of glucose.

The relationships shown in Figures 3-54 and 3-55 apply to all proteins, and they underlie all of cell biology. The principle seems so obvious in retrospect

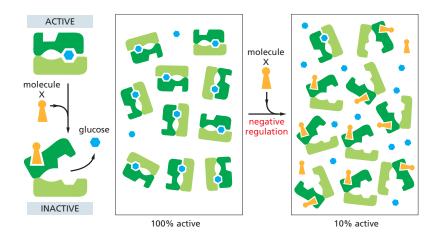

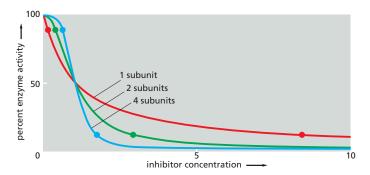

Figure 3–55 Negative regulation caused by conformational coupling between two separate binding sites. The scheme here resembles that in the previous figure, but here molecule X prefers the open conformation, while glucose prefers the closed conformation. Because glucose and molecule X drive the protein toward opposite conformations (closed and open, respectively), the presence of either ligand interferes with the binding of the other.

MBOC7_ptr_ch03_115-182.indd 157 02/12/21 2:17 PM

that we now take it for granted. But the discovery of linkage in studies of a few enzymes in the 1950s, followed by an extensive analysis of allosteric mechanisms in proteins in the early 1960s, had a revolutionary effect on our understanding of biology. Because molecule X in these examples binds at a site on the enzyme that is distinct from the site where catalysis occurs, it need not have any chemical relationship to the substrate that binds at the active site. Moreover, as we have just seen, for enzymes that are regulated in this way, molecule X can either turn the enzyme on (positive regulation) or turn it off (negative regulation). By such a mechanism, allosteric proteins serve as general switches that, in principle, can allow one molecule in a cell to affect the fate of any other.

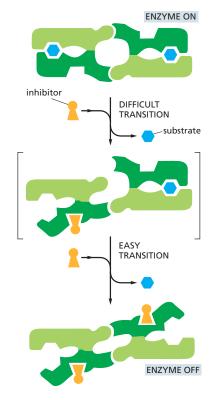

Symmetrical Protein Assemblies Produce Cooperative Allosteric Transitions

A single-subunit enzyme that is regulated by negative feedback can at most decrease from 90% to about 10% activity in response to a 100-fold increase in the concentration of an inhibitory ligand that it binds (Figure 3–56, red line). Responses of this type are apparently not sharp enough for optimal cell regulation, and most enzymes that are turned on or off by ligand binding consist of symmetrical assemblies of identical subunits. With this arrangement, the binding of a molecule of ligand to a single site on one subunit can promote an allosteric change in the entire assembly that helps the neighboring subunits bind the same ligand. As a result, a cooperative allosteric transition occurs (Figure 3–56, blue line), allowing a relatively small change in ligand concentration in the cell to switch the whole assembly from an almost fully active to an almost fully inactive conformation (or vice versa).

The principles involved in a cooperative "all-or-none" transition are the same for all proteins, whether or not they are enzymes. Thus, for example, they are critical for the efficient uptake and release of O_2 by hemoglobin in our blood. But they are perhaps easiest to visualize for an enzyme that forms a symmetrical dimer. In the example shown in Figure 3–57, the first molecule of an inhibitory ligand binds with great difficulty because its binding disrupts an energetically favorable interaction between the two identical monomers in the dimer. A second molecule of inhibitory ligand now binds more easily, however, because its binding restores

Figure 3–57 A cooperative allosteric transition in an enzyme composed of two identical subunits. This diagram illustrates how the conformation of one subunit can influence that of its neighbor. The binding of a single molecule of an inhibitory ligand (orange) to one subunit of the enzyme occurs with difficulty because it changes the conformation of this subunit and thereby disrupts the energetically favorable interactions in the symmetrical enzyme. Once this conformational change has occurred, however, the free energy gained by restoring the symmetrical pairing interaction between the two subunits makes it especially easy for the second subunit to bind the inhibitory ligand and undergo the same conformational change. Because the binding of the first molecule of ligand increases the affinity with which the other subunit binds the same ligand, the response of the enzyme to changes in the concentration of the ligand is much steeper than the response of an enzyme with only one subunit (see Figure 3–56 and Movie 3.10).

Figure 3–56 Enzyme activity versus the concentration of inhibitory ligand for single-subunit and multisubunit allosteric enzymes. For an enzyme with a single subunit (red line), a drop from 90% enzyme activity to 10% activity (indicated by the two dots on the curve) requires a 100-fold increase in the concentration of inhibitor. The enzyme activity is calculated from the simple equilibrium relationship K = [IP]/[I][P], where P is active protein, I is inhibitor, and IP is the inactive protein bound to inhibitor. An identical curve applies to any simple binding interaction between two molecules, A and B. In contrast, a multisubunit allosteric enzyme can respond in a switchlike manner to a change in ligand concentration: the steep response is caused by a cooperative binding of the ligand molecules, as explained in Figure 3-57. Here, the green line represents the idealized result expected for the cooperative binding of two inhibitory ligand molecules to an allosteric enzyme with two subunits, and the blue line shows the idealized response of an enzyme with four subunits. As indicated by the two dots on each of these curves, the more complex enzymes drop from 90% to 10% activity over a much narrower range of inhibitor concentration than does the enzyme composed of a single subunit.

MBOC7_ptr_ch03_115-182.indd 158 02/12/21 2:17 PM

the energetically favorable monomer–monomer contacts of a symmetrical dimer (this also completely inactivates the enzyme).

As an alternative to this *induced fit* model for a cooperative allosteric transition, we can view such a symmetrical enzyme as having only two possible conformations, corresponding to the "enzyme on" and "enzyme off" structures in Figure 3–57. In this view, ligand binding perturbs an all-or-none equilibrium between these two states, thereby changing the proportion of active molecules. Both models represent true and useful concepts.

Many Changes in Proteins Are Driven by Protein Phosphorylation

Proteins are regulated by more than the reversible binding of other molecules. A second method that eukaryotic cells use extensively to regulate a protein's function is the covalent addition of a smaller molecule to one or more of its amino acid side chains. The most common such regulatory modification in higher eukaryotes is the addition of a phosphate group. We shall therefore use *protein phosphorylation* to illustrate some of the general principles involved in the control of protein function through the covalent modification of amino acid side chains.

A phosphorylation event (by a kinase) can affect the protein that is modified in three important ways. First, because each phosphate group carries two negative charges, the enzyme-catalyzed addition of a phosphate group to a protein can cause a major conformational change in the protein by, for example, attracting a cluster of positively charged amino acid side chains. This can, in turn, affect the binding of ligands elsewhere on the protein surface, dramatically changing the protein's activity. When a second enzyme (called a phosphatase) removes the phosphate group, the protein returns to its original conformation and restores its initial activity.

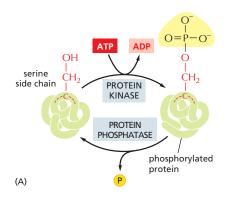

Second, an attached phosphate group can form part of a structure that the binding sites of other proteins recognize. As previously discussed, the SH2 domain binds to a short peptide sequence containing a phosphorylated tyrosine side chain (see Figure 3–38B). More than 10 other common domains provide binding sites for attaching their protein to phosphorylated peptides in other protein molecules, each recognizing a phosphorylated amino acid side chain in a different protein context. Third, the addition of a phosphate group can mask a binding site that otherwise holds two proteins together, and thereby disrupt protein–protein interactions. As a result of the last two effects, protein phosphorylation and dephosphorylation very often drive the regulated assembly and disassembly of protein complexes.

Reversible protein phosphorylation controls the activity, structure, and cellular localization of enzymes and many other types of proteins in eukaryotic cells. In fact, this regulation is so extensive that more than one-third of the 10,000 or so proteins in a typical mammalian cell are thought to be phosphorylated at any given time—many with more than one phosphate.

As might be expected, the addition and removal of phosphate groups from specific proteins often occur in response to signals that specify some change in a cell's state. For example, the complicated series of events that takes place as a eukaryotic cell divides is largely timed in this way (discussed in Chapter 17), and many of the signals mediating cell–cell interactions are relayed from the plasma membrane to the nucleus by a cascade of protein phosphorylation events (discussed in Chapter 15).

A Eukaryotic Cell Contains a Large Collection of Protein Kinases and Protein Phosphatases

Protein phosphorylation involves the enzyme-catalyzed transfer of the terminal phosphate group of an ATP molecule to the hydroxyl group on a serine, threonine, or tyrosine side chain of the protein (**Figure 3–58**). A **protein kinase** catalyzes this reaction, and the reaction is essentially unidirectional because of the large amount of free energy released when the phosphate-phosphate bond in

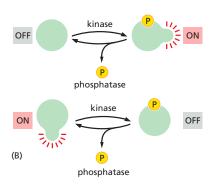

Figure 3-58 Protein phosphorylation. Many thousands of proteins in a typical eukaryotic cell are modified by the covalent addition of a phosphate group. (A) The general reaction transfers a phosphate group from ATP to an amino acid side chain of the target protein, catalyzed by a protein kinase. Removal of the phosphate group is catalyzed by a second enzyme, a protein phosphatase. In this example, the phosphate is added to a serine side chain: in other cases, the phosphate is instead linked to the -OH group of a threonine or a tyrosine in the protein. (B) The phosphorylation of a protein by a protein kinase can either increase or decrease the protein's activity. depending on the site of phosphorylation and the structure of the protein.

ATP is broken to produce ADP (discussed in Chapter 2). A **protein phosphatase** catalyzes the reverse reaction of phosphate removal, or *dephosphorylation*. Cells contain hundreds of different protein kinases, each responsible for phosphorylating a different protein or set of proteins. There are also many different protein phosphatases; some are highly specific and remove phosphate groups from only one or a few proteins, whereas others act on a broad range of proteins and are targeted to specific substrates by regulatory subunits. The state of phosphorylation of a protein at any moment, and thus its activity, depends on the relative activities of the protein kinases and phosphatases that modify it.

The protein kinases that phosphorylate proteins in eukaryotic cells belong to a very large family of enzymes that share a catalytic (kinase) sequence of about 290 amino acids. The various family members contain different amino acid sequences on either end of the kinase sequence (for example, see Figure 3–11) and often have short amino acid sequences inserted into loops within it. Some of these additional amino acid sequences enable each kinase to recognize the specific set of proteins it phosphorylates or to bind to structures that localize it in specific regions of the cell. Other parts of the protein regulate the activity of each kinase, so it can be turned on and off in response to different specific signals, as described below.

By comparing the number of amino acid sequence differences between the various members of a protein family, we can construct an "evolutionary tree" that is thought to reflect the pattern of gene duplication and divergence that gave rise to the family. Figure 3–59 shows an evolutionary tree for protein kinases. Kinases with related functions are often located on nearby branches of the tree: the protein kinases involved in cell signaling that phosphorylate tyrosine side chains, for example, are all clustered in the top left corner of the tree. The other kinases shown phosphorylate either a serine or a threonine side chain, and many are organized into clusters that seem to reflect their function—in transmembrane signal transduction, intracellular signal amplification, cell-cycle control, and so on.

As a result of the combined activities of protein kinases and protein phosphatases, the phosphate groups on proteins are continually turning over—being added and then rapidly removed. Such phosphorylation cycles may seem wasteful, but they are important in allowing the phosphorylated proteins to switch rapidly from one state to another. In fact, the more rapid this cycle is "turning," the faster a population of protein molecules can change its state of phosphorylation in response to a sudden change in its phosphorylation rate (see Figure 15–15).

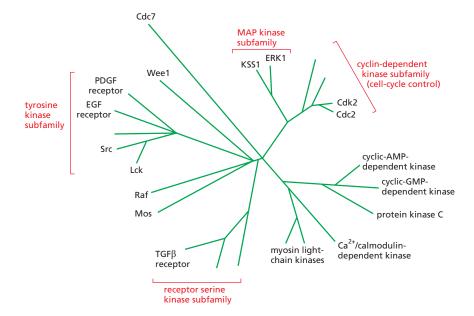

Figure 3–59 An evolutionary tree of selected protein kinases. A higher eukaryotic cell contains hundreds of such enzymes, and the human genome codes for more than 500. Note that only some of these, those discussed in this book, are shown.

MBOC7_ptr_ch03_115-182.indd 160 02/12/21 2:17 PM

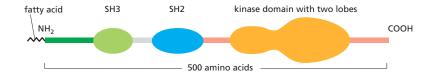

Figure 3–60 The domain structure of the Src family of protein kinases, mapped along the amino acid sequence. For the three-dimensional structure of Src, see Figure 3–11.

The energy required to drive this phosphorylation cycle is derived from the free energy of ATP hydrolysis, one molecule of which is consumed for each phosphorylation event.

The Regulation of the Src Protein Kinase Reveals How a Protein Can Function as a Microprocessor

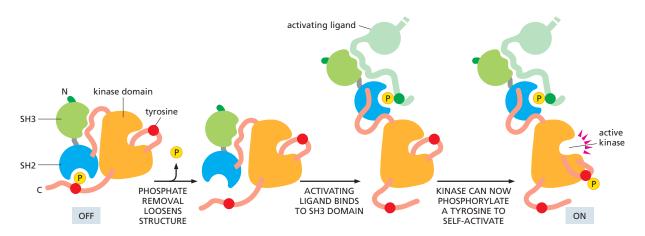

The hundreds of different protein kinases in a eukaryotic cell are organized into complex networks of signaling pathways that help to coordinate the cell's activities, drive the cell cycle, and relay signals into the cell from the cell's environment. Many of the extracellular signals involved need to be both integrated and amplified by the cell. Individual protein kinases (and other signaling proteins) serve as input-output devices, or "microprocessors," in the integration process. An important part of the input to these signal-processing proteins comes from the control that is exerted by phosphates added and removed from them by protein kinases and protein phosphatases, respectively.

The Src family of protein kinases (see Figure 3–11) exhibits such behavior. The Src protein (pronounced "sarc" and named for the type of tumor, a sarcoma, that its deregulation can cause) was the first tyrosine kinase to be discovered. It is now known to be part of a subfamily of nine very similar protein kinases, which are found only in multicellular animals. As indicated by the evolutionary tree in Figure 3–59, sequence comparisons suggest that tyrosine kinases as a group were a relatively late innovation that branched off from the serine/threonine kinases, with the Src subfamily being only one subgroup of the tyrosine kinases created in this way.

The Src protein and its relatives contain a short N-terminal region that becomes covalently linked to a strongly hydrophobic fatty acid, which anchors the kinase at the cytoplasmic face of the plasma membrane. Next along the linear sequence of amino acids come two peptide-binding domains, a Src homology 3 (SH3) domain and an SH2 domain, followed by the kinase catalytic domain (Figure 3–60). These kinases normally exist in an inactive conformation, in which a phosphorylated tyrosine near the C-terminus is bound to the SH2 domain, and the SH3 domain is bound to an internal peptide in a way that distorts the active site of the enzyme and helps to render it inactive.

As shown in **Figure 3–61**, turning the kinase on involves at least two specific inputs: removal of the C-terminal phosphate and the binding of the SH3 domain by a specific activating protein. In this way, the activation of the Src kinase signals

Figure 3–61 The activation of a Src-type protein kinase by two sequential events. As described in the text, the requirement for multiple upstream events to trigger these processes allows the kinase to serve as a signal integrator (Movie 3.11). (Adapted from S.C. Harrison, *Cell* 112: 737–740, 2003.)

MBOC7_ptr_ch03_115-182.indd 161 02/12/21 2:17 PM

the completion of a particular set of separate upstream events (Figure 3–62). Thus, the Src family of protein kinases serves as specific *signal integrators*, contributing to the web of information-processing events that enable the cell to compute useful responses to a complex set of different conditions.

Regulatory GTP-binding Proteins Are Switched On and Off by the Gain and Loss of a Phosphate Group

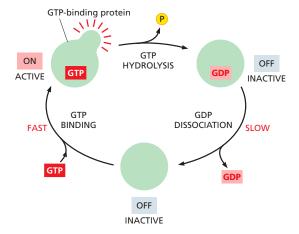

Eukaryotic cells have a second way to regulate protein activity by phosphate addition and removal. In this case, however, the phosphate is not enzymatically transferred from ATP to the protein. Instead, the phosphate is part of a guanine nucleotide—guanosine triphosphate (GTP)—that binds tightly to various types of GTP-binding proteins. These proteins, also called GTPases, bind to other proteins to regulate their activities. They serve as molecular switches: GTP-binding proteins are in their "on" conformation when GTP is bound, but they can hydrolyze this GTP to GDP—which releases a phosphate and flips the protein to its "off" conformation. As with protein phosphorylation, this process is reversible: the active conformation is regained by dissociation of the GDP, followed by the rapid binding of a fresh molecule of GTP (Figure 3–63).

Hundreds of different GTP-binding proteins function as such molecular switches in cells. They all contain variations of the same globular domain that undergoes a conformational change when its tightly bound GTP is hydrolyzed to GDP. The three-dimensional structure of a prototypical member of this family, the *monomeric GTPase* called **Ras** that plays important roles in cell signaling, is shown in **Figure 3–64**.

The crucial role that GTP-binding proteins play in intracellular signaling pathways is discussed in detail in Chapter 15.

Proteins Can Be Regulated by the Covalent Addition of Other Proteins

Cells contain a special family of small proteins whose members are covalently attached to many other proteins to determine the activity or fate of the second protein. In each case, the carboxyl end of the small protein becomes linked to the amino group of a lysine side chain of a target protein through an isopeptide bond. The first such protein discovered, and the most abundantly used, is **ubiquitin** (Figure 3–65A). Ubiquitin can be covalently attached to target proteins in a variety of ways, each of which has a different meaning for cells. The major form of ubiquitin addition produces *polyubiquitin* chains in which—once the first ubiquitin molecule is attached to the target—each subsequent ubiquitin molecule links to Lys48 of the previous ubiquitin, creating a chain of Lys48-linked ubiquitins that are attached to a single lysine side chain of the target protein. This form

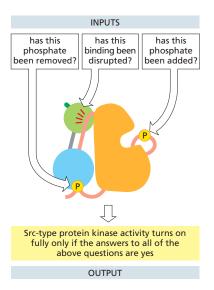

Figure 3–62 How a Src-type protein kinase acts as a signal-integrating device. A disruption of the inhibitory interaction illustrated for the SH3 domain (green) occurs when its binding to the indicated orange linker region is replaced with its higher-affinity binding to an activating ligand.

Figure 3-63 Many different GTP-binding proteins function as molecular switches. The activity of a GTP-binding protein (also called a GTPase) generally requires the presence of a tightly bound GTP molecule (switch "on"). Hydrolysis of this GTP molecule by the GTP-binding protein-at a rate that can be regulated-produces GDP and inorganic phosphate, and it causes the protein to convert to a different. usually inactive, conformation (switch "off"). Resetting the switch to "on" requires that the tightly bound GDP dissociate. This is a slow step, and the dissociation of GDP, which is followed by its rapid replacement by GTP, is controlled by cell signals (see Figure 15-8).

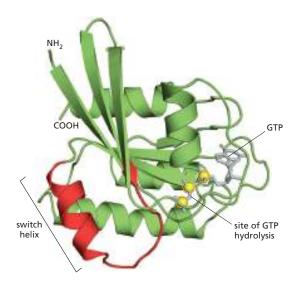

Figure 3–64 The structure of the Ras protein in its GTP-bound form. This monomeric GTPase illustrates the structure of a GTP-binding domain, which is present in a large family of GTP-binding proteins. The *red* regions change their conformation when the GTP molecule is hydrolyzed to GDP and inorganic phosphate by the protein; the GDP remains bound to the protein, while the inorganic phosphate is released. The special role of the *switch helix* in proteins related to Ras is explained in the text (see Figure 3–68 and Movie 15.7). (PDB code: 121P.)

of polyubiquitin directs the target protein to the interior of a proteasome, where it is digested to small peptides (see Figure 6–87). In other circumstances, only single molecules of ubiquitin are added to proteins. In addition, some target proteins are modified with a different type of polyubiquitin chain. These modifications have different functional consequences for the protein that is targeted (Figure 3–65B).

Related structures are created when a different member of the ubiquitin family, such as SUMO (small ubiquitin-related modifier), is covalently attached to a lysine side chain of target proteins. Not surprisingly, all such modifications are reversible. Cells contain sets of ubiquitylating and deubiquitylating (and sumoylating and desumoylating) enzymes that manipulate these covalent adducts, thereby playing roles analogous to the protein kinases and protein phosphatases that add and remove phosphates from protein side chains.

An Elaborate Ubiquitin-conjugating System Is Used to Mark Proteins

How do cells select target proteins for ubiquitin addition? As an initial step, the carboxyl end of ubiquitin needs to be activated. This activation is accomplished when a protein called a *ubiquitin-activating enzyme* (E1) uses ATP

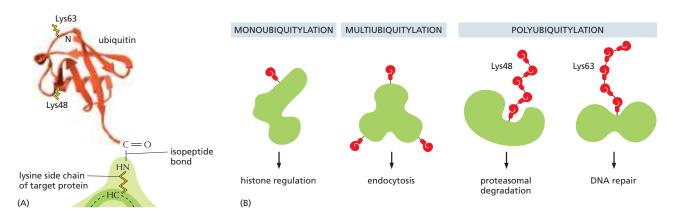

Figure 3–65 The marking of proteins by ubiquitin. (A) The three-dimensional structure of ubiquitin, a small protein of 76 amino acids. A family of special enzymes couples its carboxyl end to the amino group of a lysine side chain in a target protein molecule, forming an isopeptide bond. (B) Some modification patterns that have specific meanings to the cell. Note that the two types of polyubiquitylation differ in the way the ubiquitin molecules are linked together. Linkage through Lys48 signifies degradation by the proteasome (see Figure 6–87), whereas that through Lys63 has other meanings. Ubiquitin markings are "read" by proteins that specifically recognize each type of modification.

MBOC7_ptr_ch03_115-182.indd 163 02/12/21 2:17 PM

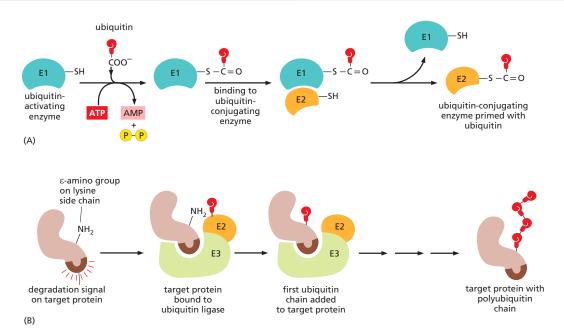

Figure 3–66 How ubiquitin is added to proteins. (A) Ubiquitin activations. The C-terminus of ubiquitin is initially activated by being linked via a high-energy thioester bond to a cysteine side chain on the E1 protein. This reaction requires ATP, and it proceeds via a covalent AMP-ubiquitin intermediate. The activated ubiquitin on E1, also known as the ubiquitin-activating enzyme, is then transferred to the cysteine on an E2 molecule. (B) The addition of a polyubiquitin chain to a target protein. In a mammalian cell, there are several hundred distinct E2–E3 complexes. The E2s are called ubiquitin-conjugating enzymes. The E3s are referred to as ubiquitin ligases. (Adapted from D.R. Knighton et al., Science 253:407–414, 1991.)

hydrolysis energy to attach ubiquitin to itself through a high-energy covalent bond (a thioester). E1 then passes this activated ubiquitin to one of a set of *ubiquitin-conjugating* (E2) enzymes, each of which acts in conjunction with a set of accessory (E3) proteins called **ubiquitin ligases** that select the target proteins to be modified. There are roughly 30 structurally similar but distinct E2 enzymes in mammals and hundreds of different E3 proteins that form complexes with specific E2 enzymes.

Figure 3–66 illustrates the process used to mark proteins for proteasomal degradation. [Similar mechanisms are used to attach ubiquitin (and SUMO) to other types of target proteins.] Here, the ubiquitin ligase binds to specific degradation signals, called *degrons*, in protein substrates, thereby helping E2 to form a *polyubiquitin* chain linked to a lysine of the substrate protein. This polyubiquitin chain on a target protein will then be recognized by a specific receptor in the proteasome, causing the target protein to be rapidly destroyed. Distinct ubiquitin ligases recognize different degradation signals, thereby targeting distinct subsets of intracellular proteins for destruction, often in response to specific signals (see Figure 6–89).

Protein Complexes with Interchangeable Parts Make Efficient Use of Genetic Information

Controlled protein degradation is critical for cells, and we will describe the structure and function of one of the families of E3 proteins that adds polyubiquitin chains to target proteins in order to illustrate a general principle: how the cell makes use of interchangeable parts to diversify its many protein complexes.

The *SCF ubiquitin ligase* is a C-shaped structure that is formed from five protein subunits, the largest of which serves as a scaffold on which the rest of the complex is built. The structure underlies a remarkable mechanism (Figure 3–67). At one end of the C is an E2 ubiquitin–conjugating enzyme. At the other end is a substrate-binding arm, a subunit known as an *F-box protein*. These two subunits are separated by a gap of about 5 nm. When this protein complex is activated, the

MBOC7_ptr_ch03_115-182.indd 164 02/12/21 2:17 PM

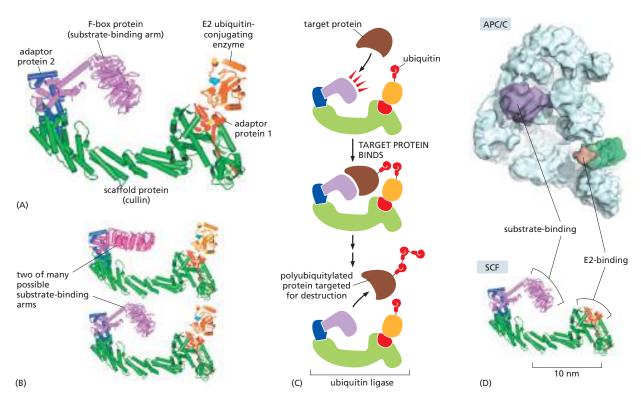

Figure 3–67 The structure and mode of action of a ubiquitin ligase. (A) The structure of the five-protein SCF ubiquitin ligase complex that includes an E2 ubiquitin-conjugating enzyme. Four proteins form the E3 portion. The protein denoted here as adaptor protein 1 is the Rbx1/Hrt1 protein, adaptor protein 2 is the Skp1 protein, and cullin is the Cul1 protein. One of the many different F-box proteins completes the complex. (B) Comparison of the same complex with two different substrate-binding arms, the F-box proteins Skp2 (top) and β-trCP1 (bottom), respectively. (C) The binding and ubiquitylation of a target protein by the SCF ubiquitin ligase. If, as indicated, a chain of ubiquitin molecules is added to the same lysine of the target protein, that protein is marked for rapid destruction by the proteasome. (D) Comparison of SCF (bottom) with a low-resolution electron microscopy structure of a ubiquitin ligase called the anaphase-promoting complex (APC/C; top) at the same scale. The APC/C is a large, 15-protein complex. As discussed in Chapter 17, its ubiquitylations control the late stages of mitosis. It is distantly related to SCF and contains a cullin subunit (green) that lies along the side of the complex at right, only partly visible in this view. E2 proteins are not shown here, but their binding sites are indicated in orange, along with substrate-binding sites in purple. (A and B, adapted from G. Wu et al., Mol. Cell 11:1445–1456, 2003. D, adapted from P. da Fonseca et al., Nature 470:274–278, 2011.)

F-box protein binds to a specific site on a target protein, positioning the protein in the gap so that some of its lysine side chains contact the ubiquitin-conjugating enzyme. The enzyme can then catalyze repeated additions of ubiquitin to these lysines (see Figure 3–67C), producing the polyubiquitin chains that mark its target proteins for destruction in a proteasome.

In this manner, specific proteins are targeted for rapid destruction in response to specific signals, thereby helping to drive the cell cycle (discussed in Chapter 17). The timing of the destruction often involves creating a specific pattern of phosphorylation on the target protein that is required for its recognition by the F-box subunit. It also requires the activation of an SCF-like ubiquitin ligase that carries the appropriate substrate-binding arm. Many of these arms (the F-box subunits) are interchangeable in the protein complex (see Figure 3–67B), and there are more than 70 human genes that encode them.

As emphasized previously, once a successful protein has evolved, its genetic information tends to be duplicated to produce a family of related proteins. Thus, for example, not only are there many F-box proteins—making possible the recognition of different sets of target proteins—but there is also a family of scaffolds (known as cullins) that give rise to a family of SCF-like ubiquitin ligases.

A protein machine like the SCF ubiquitin ligase, with its interchangeable parts, makes economical use of the genetic information in cells. It also creates

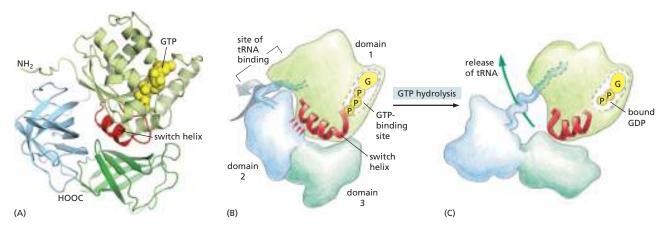

Figure 3–68 The large conformational change in EF-Tu caused by GTP hydrolysis. (A and B) The three-dimensional structure of EF-Tu with GTP bound. The domain at the top has a structure similar to the Ras protein, and its red α helix is the switch helix, which moves after GTP hydrolysis. (C) The change in the conformation of the switch helix in domain 1 allows domains 2 and 3 to rotate as a single unit by about 90 degrees toward the viewer, which releases the tRNA that was bound to this structure (see also Figure 3–69). (A, PDB code: 1EFT; B, courtesy of Mathias Sprinzl and Rolf Hilgenfeld.)

opportunities for "rapid" evolution, inasmuch as new functions can evolve for the entire complex simply by producing an alternative version of one of its subunits.

Ubiquitin ligases form a diverse family of protein complexes. Some of these complexes are far larger and more complicated than SCF, but their underlying enzymatic function remains the same (see Figure 3–67D).

A GTP-binding Protein Shows How Large Protein Movements Can Be Generated from Small Ones

Detailed structures obtained for one of the GTP-binding protein family members, the *EF-Tu protein*, provide a good example of how allosteric changes in protein conformations can produce large movements by amplifying a small, local conformational change. As will be discussed in Chapter 6, EF-Tu is an abundant molecule that serves as an elongation factor (hence the EF) in protein synthesis, loading each aminoacyl-tRNA molecule onto the ribosome. EF-Tu contains a Ras-like domain (see Figure 3–64), and the tRNA molecule forms a tight complex with its GTP-bound form. For the tRNA molecule to transfer its amino acid to the growing polypeptide chain requires that the GTP bound to EF-Tu be hydrolyzed, dissociating the EF-Tu from the tRNA. Because this GTP hydrolysis is triggered by a proper fit of the tRNA to the mRNA molecule on the ribosome, the EF-Tu serves to discriminate between correct and incorrect mRNA-tRNA pairings (see Figure 6–69).

By comparing the three-dimensional structure of EF-Tu in its GTP-bound and GDP-bound forms, we can see how the repositioning of the tRNA occurs. The dissociation of the inorganic phosphate group, which follows the reaction GTP \rightarrow GDP + phosphate, causes a shift of a few tenths of a nanometer at the GTP-binding site, just as it does in the Ras protein. This tiny movement, equivalent to a few times the diameter of a hydrogen atom, causes a conformational change to propagate along a crucial piece of α helix, called the *switch helix*, in the Ras-like domain of the protein. The switch helix seems to serve as a latch that adheres to a specific site in another domain of the molecule, holding the protein in a "shut" conformation. The conformational change triggered by GTP hydrolysis causes the switch helix to detach, allowing separate domains of the protein to swing apart, through a distance of about 4 nm (Figure 3–68). This releases the tRNA, allowing its attached amino acid to be used for protein synthesis (Figure 3–69).

Notice in this example how cells have exploited a simple chemical change that occurs on the surface of a small protein domain to create a movement 50 times

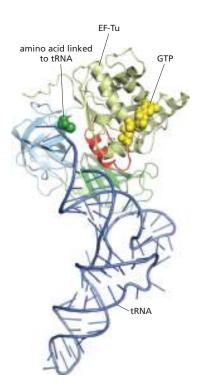

Figure 3–69 An aminoacyl tRNA molecule bound to EF-Tu. Note how the bound protein blocks the use of the tRNA-linked amino acid (dark green) for protein synthesis until GTP hydrolysis triggers the conformational changes shown in Figure 3–68C, dissociating the protein–tRNA complex. EF-Tu is a bacterial protein; however, a very similar protein exists in eukaryotes, where it is called EF-1 (Movie 3.12). (PDB code: 1B23.)

larger. Dramatic shape changes of this type also cause the very large movements that occur in motor proteins, as we discuss next.

Motor Proteins Produce Directional Movement in Cells

We have seen that conformational changes in proteins have a central role in enzyme regulation and cell signaling. We now discuss proteins whose major function is to move other molecules. These *motor proteins* generate the forces responsible for muscle contraction and the crawling and swimming of cells. Motor proteins also power smaller-scale intracellular movements: they help to move chromosomes to opposite ends of the cell during mitosis (discussed in Chapter 17), to move organelles along molecular tracks within the cell (discussed in Chapter 16), and to move enzymes along a DNA strand during the synthesis of a new DNA molecule (discussed in Chapter 5). All these fundamental processes depend on proteins with moving parts that operate as force-generating machines.

How do these machines work? It is a challenge for cells to use shape changes in proteins to generate persistent movements in a single direction. If, for example, a protein is required to walk along a long cytoskeletal filament, it can do this by undergoing a series of conformational changes, such as those shown in Figure 3–70. But with nothing to drive these changes in an orderly sequence, they are perfectly reversible, and the protein can only wander randomly back and forth along the thread. We can look at this situation in another way. Because the directional movement of a protein does work, the laws of thermodynamics (discussed in Chapter 2) demand that such movement use free energy from some other source (otherwise the protein could be used to make a perpetual motion machine). Therefore, without an input of energy, the protein molecule can only wander aimlessly.

How can the cell make such a series of conformational changes unidirectional? To force the entire cycle to proceed in one direction, it is enough to make any one of the changes in shape irreversible. Most proteins that are able to walk in one direction for long distances achieve this motion by coupling one of the conformational changes to the hydrolysis of an ATP molecule that is tightly bound to the protein. The mechanism is similar to the one discussed earlier that drives allosteric protein shape changes by GTP hydrolysis. Because ATP (or GTP) hydrolysis releases a great deal of free energy, it is very unlikely that the nucleotide-binding protein will undergo the reverse shape change needed for moving backward—as this would require that it also reverse the ATP hydrolysis by adding a phosphate molecule to ADP to form ATP.

In the model shown in Figure 3–71A, ATP binding shifts a motor protein from conformation 1 to conformation 2. The bound ATP is then hydrolyzed to produce ADP and inorganic phosphate, causing a change from conformation 2 to conformation 3. Finally, the release of the bound ADP and phosphate drives the protein back to conformation 1. Because the energy provided by ATP hydrolysis drives the transition $2 \to 3$, this series of conformational changes is effectively irreversible. Thus, the entire cycle goes in only one direction, causing the protein molecule to walk continuously to the right in this example.

Many motor proteins generate directional movement through the use of a similar unidirectional ratchet, including the muscle motor protein *myosin*, which walks along actin filaments (Figure 3–71B), and the *kinesin* proteins that walk along microtubules (both discussed in Chapter 16). These movements can be rapid: some of the motor proteins involved in DNA replication (the DNA helicases) propel themselves along a DNA strand at rates as high as 1000 nucleotides per second.

Proteins Often Form Large Complexes That Function as Protein Machines

Large proteins formed from many domains are able to perform more elaborate functions than small, single-domain proteins. But large protein assemblies formed from many protein molecules linked together by noncovalent bonds perform the most impressive tasks. Now that it is possible to reconstruct most biological

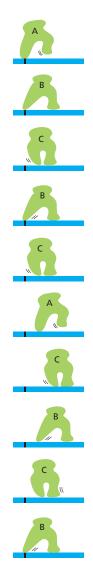

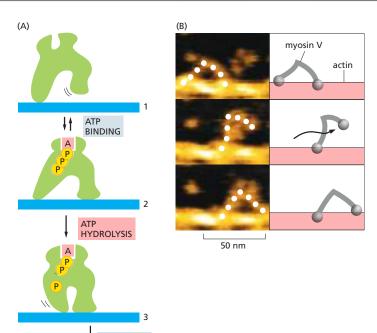

Figure 3–70 Changes in conformation can cause a protein to "walk" along a cytoskeletal filament, driven by its constant collisions with other molecules (thermal energy). This protein cycles between three different conformations (A, B, and C) as it moves along the filament. But, without an input of energy to drive its movement in a single direction, the protein can only wander randomly back and forth, ultimately getting nowhere.

INORGANIC PHOSPHATE RELEASE

direction of movement

ADP

Figure 3-71 How a protein can walk in one direction. (A) An allosteric motor protein driven by ATP hydrolysis. The transition between three different conformations includes a step driven by the hydrolysis of a tightly bound ATP molecule, creating a "unidirectional ratchet" that makes the entire cycle essentially irreversible. By repeated cycles, the protein therefore moves continuously to the right along the thread. (B) Direct visualization of a walking myosin motor protein by high-speed atomic force microscopy; the elapsed time between steps was less than 0.5 sec (see Movie 16.3). (B, adapted from N. Kodera et al., Nature 468:72-76, published 2010 by Macmillan Publishers Ltd. Reproduced with permission of SNCSC.)

processes in cell-free systems in the laboratory, it is clear that each of the central processes in a cell—such as DNA replication, protein synthesis, vesicle budding, or transmembrane signaling—is catalyzed by a highly coordinated, linked set of 10 or more proteins. In most such *protein machines*, energetically favorable reactions such as the hydrolysis of bound nucleoside triphosphates (ATP or GTP) drive an ordered series of conformational changes in one or more of the individual protein subunits, enabling the ensemble of proteins to move in a coordinated way. As a result, each enzyme can be moved directly into position as the machine catalyzes successive reactions in a series (**Figure 3-72**). This is what occurs, for example, in protein synthesis on a ribosome (an RNA-protein, or *macromolecular machine*, discussed in Chapter 6)—or in DNA replication, where a large multiprotein complex moves rapidly along the DNA (discussed in Chapter 5).

Cells have evolved protein machines for the same reason that humans have invented mechanical and electronic machines. For accomplishing almost any task, manipulations that are spatially and temporally coordinated through linked processes are much more efficient than the use of many separate tools.

The Disordered Regions in Proteins Are Critical for a Set of Different Functions

Scientists have discovered that proteins contain a surprisingly large amount of intrinsically disordered polypeptide chain. Thus, as previously mentioned, it is estimated that about a third of all eukaryotic proteins contain unstructured

MBOC7_ptr_ch03_115-182.indd 168 02/12/21 2:17 PM

Figure 3–72 Schematic example showing how protein machines can carry out complex functions. These machines are made of individual proteins that collaborate to perform a specific task (Movie 3.13). As in this example, the movement of these proteins is often coordinated by the hydrolysis of a bound nucleotide such as ATP or GTP. Directional allosteric conformational changes of proteins driven in this way often occur in a large protein assembly, thereby allowing directed movements within the complex to coordinate the activities of its individual molecules. (See also Movie 5.5.)

regions greater than 30 amino acids in length. Some of these regions are formed from only a limited subset of the 20 amino acids and are therefore designated as *low-complexity domains*. Because many unstructured regions have been conserved in a particular protein over long periods of evolutionary time, their presence must benefit the organisms that contain them. What do these disordered regions do?

Intrinsically disordered regions of proteins often form specific binding sites for other proteins that are of high specificity, as illustrated in Figure 3-73A. In addition, this type of binding interaction is easily controlled. Most protein phosphorylation sites are in intrinsically disordered regions, not in globular domains, and these regions are central to regulatory mechanisms. As one example, the eukaryotic RNA polymerase enzyme that produces mRNAs contains an unstructured C-terminal tail of 200 amino acids that is covalently modified as the RNA polymerase proceeds, thereby attracting specific other proteins to the transcription complex at different times (see Figure 6-23). Disordered regions tend to evolve rapidly, and the type of binding diagrammed in Figure 3-73B facilitates the fine-tuning and evolution of cell signaling networks (see Chapter 15).

A very different type of function is exemplified by *elastin*, an abundant protein in the extracellular matrix that is formed as a highly disordered polypeptide. Elastin's relatively loose and unstructured polypeptide chains are covalently cross-linked to produce an elastic meshwork that can be stretched like a rubber band, as illustrated in **Figure 3–74**. The elastic fibers that result enable skin and other tissues, such as arteries and lungs, to stretch and recoil without tearing.

Perhaps most uniquely, intrinsically disordered regions are widely used as tethers to concentrate reactants and thereby accelerate the reactions needed by a cell. For example, within large multienzyme complexes, unstructured regions of polypeptide chain can allow substrates to be carried sequentially between different active sites (Figure 3–75).

In their most general tethering role, unstructured regions allow large *scaffold proteins* with multiple binding sites to concentrate sets of interacting RNA and/or protein molecules at a particular site in a cell, as we discuss next.

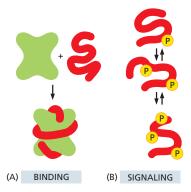

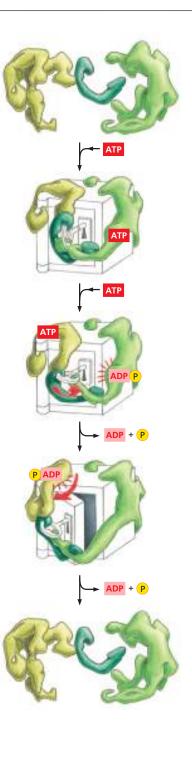

Figure 3–73 Intrinsically disordered protein sequences provide versatile binding sites. (A) Unstructured regions of polypeptide chain often form binding sites for other proteins. Although these binding events are of high specificity, they are often of low affinity because of the free-energy cost of folding the normally unfolded partner (and they are thus readily reversible). (B) Unstructured regions can be easily modified covalently to change their binding preferences, and they are therefore frequently involved in cell signaling processes. In this schematic, multiple sites of protein phosphorylation are indicated.

MBOC7_ptr_ch03_115-182.indd 169 02/12/21 2:17 PM

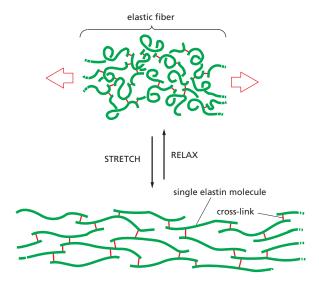

Figure 3–74 Intrinsically disordered protein chains are used to produce elastic structures. The polypeptide chains of the protein elastin are cross-linked together in the extracellular space to form rubberlike, elastic fibers. Each elastin molecule uncoils into a more extended conformation when the fiber is stretched, and it recoils spontaneously as soon as the stretching force is relaxed.

Scaffolds Bring Sets of Interacting Macromolecules Together and Concentrate Them in Selected Regions of a Cell

As scientists have learned more of the details of cell biology, they have recognized an increasing degree of sophistication in cell chemistry. We now know that protein machines play a predominant role and that all of their activities—like those of other proteins—are highly regulated. In addition, it has also become clear that

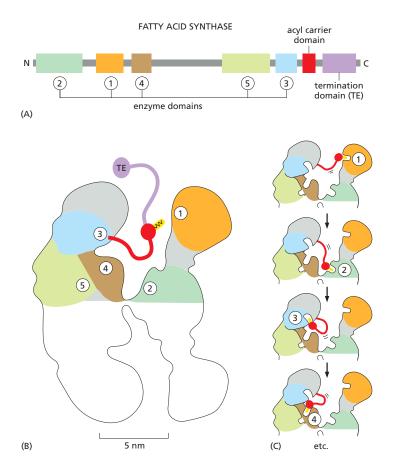

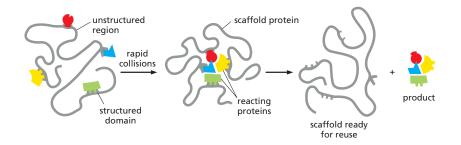

Figure 3-75 How unstructured regions of polypeptide chain can serve as tethers to allow reaction intermediates to be passed from one active site to another in a large multienzyme complex, the fatty acid synthase in mammals. (A) The locations of seven protein domains with different activities in this 270-kilodalton protein are shown. The numbers refer to the order in which each enzyme domain must function to complete each twocarbon addition step. After multiple cycles of two-carbon addition, the termination domain releases the final product once the desired length of fatty acid has been synthesized. (B) The structure of the dimeric enzyme, with the location of the five active sites in one monomer indicated. (C) How a flexible tether allows the substrate that remains linked to the acyl carrier domain (red) to be passed from one active site to another in each monomer. sequentially elongating and modifying the bound fatty acid intermediate (yellow). The five steps are repeated until the final length of fatty acid chain has been synthesized. (Only steps 1 through 4 are illustrated here.) (Adapted from T. Maier et al., Q. Rev. Biophys. 43:373-422, 2010.)

MBOC7_ptr_ch03_115-182.indd 170 02/12/21 2:17 PM

these machines are often localized to specific sites in the cell, being assembled and activated only where and when they are needed. As one example, when extracellular signaling molecules bind to receptor proteins in the plasma membrane, the activated receptors often recruit a set of other proteins to the inside surface of the plasma membrane to form a large protein complex that passes the signal on (illustrated and discussed in Chapter 15).

The mechanisms generally involve scaffold proteins that have binding sites for multiple other proteins and/or RNA molecules. Such scaffolds serve both to link together specific sets of interacting macromolecules and to position them at specific locations inside a cell. At one extreme are rigid scaffolds, such as the cullin in SCF ubiquitin ligase (see Figure 3-67). At the other extreme are large, flexible scaffold proteins that create special regions inside the cell that have a unique biochemistry. Networks of such large scaffolds often underlie regions of specialized plasma membrane. For example, the Discs-large protein (Dlg) of about 900 amino acids is concentrated in special regions beneath the plasma membrane in epithelial cells and at synapses. Dlg contains binding sites for at least seven other proteins interspersed with regions of more flexible polypeptide chain. An ancient protein, conserved in organisms as diverse as sponges, worms, flies, and humans, Dlg derives its name from the mutant phenotype of the organism in which it was first discovered. In a *Drosophila* embryo with a mutation in the *Dlg* gene, the imaginal disc cells fail to stop proliferating when they should, and they produce unusually large discs whose epithelial cells can form tumors.

Dlg and a large number of similar scaffold proteins are thought to function like the protein that is schematically illustrated in **Figure 3–76**. By binding a specific set of interacting proteins and/or RNA molecules, these scaffolds can enhance the rate of critical reactions, while also confining them to the particular region of the cell that contains the scaffold. For similar reasons, cells also make extensive use of *scaffold RNA molecules*, as discussed in Chapter 7.

Macromolecules Can Self-assemble to Form Biomolecular Condensates

The macromolecular assemblies and protein machines that we have discussed so far are defined by physical interactions that organize individual proteins and nucleic acids at defined positions relative to each other. Each copy of a macromolecular machine generally is built from the same parts and assembled into the same three-dimensional structure. For example, the bacterial ribosome responsible for synthesizing new proteins is built from 55 proteins and three RNA molecules arranged in an invariant complex (see Figure 6–65). Even in the case of protein complexes containing flexible scaffolds (see Figure 3–75), the macromolecular assembly has a characteristic (albeit flexible) conformation.

In contrast, **biomolecular condensates** are a different type of cellular structure built from proteins (and often RNA) held together by a large number of weak and constantly changing interactions among them. Each condensate is created by at least one scaffold macromolecule (a protein or RNA molecule) that is capable of making multiple independent interactions with either itself or with other macromolecules, which themselves often make multiple interactions. These types of macromolecules are said to be *multivalent*. Typically, each of the individual

Figure 3–76 How the proximity created by scaffold proteins can greatly speed reactions in a cell. In this example, long unstructured regions of polypeptide chain in a large scaffold protein connect a series of structured domains that bind a set of reacting proteins or RNA molecules. The unstructured regions serve as flexible tethers that greatly speed reaction rates by causing a rapid, random collision of all of the molecules that are bound to the scaffold. (For specific examples of protein tethering, see Figure 3–75 and Figure 16–14; for scaffold RNA molecules, see Figure 7–82.)

MBOC7_ptr_ch03_115-182.indd 171 02/12/21 2:17 PM

interactions among these multivalent proteins and RNAs is very weak, so it forms and breaks frequently. When any one interaction breaks, other interactions at different sites in that macromolecule prevent it from diffusing away and keep the macromolecule locally concentrated. By the time some of these other interactions break, new ones have already formed elsewhere. In this way, all of the proteins within a condensate continually interact with each other, even though the specific set of interactions changes from one moment to another.

Formation of a condensate serves to segregate and concentrate a subset of the cell's macromolecules into a separate compartment in the cell. In some cases, these macromolecules perform specialized biochemistry within the condensate—forming a biochemical "factory" that efficiently produces a specific product, as for the ribosomes that are produced by the nucleolus. In other cases, sequestration into a condensate can serve as a temporary storage depot for a set of macromolecules while blocking their activity, as for the stress granules that can form when a cell is perturbed.

The disordered, low-complexity domains of proteins are often found to mediate the fluctuating, weak binding interactions that form a condensate, frequently making a major contribution to their formation. In addition, other types of binding can also drive condensate formation (Figure 3–77A). The dynamic, fluctuating interactions within a condensate cause it to behave like a liquid: all of the participating molecules within it jostle around and rapidly exchange their relative positions; in addition, they often exchange rapidly with their equivalents outside the condensate (Figure 3–77B). Because the condensate remains intact and

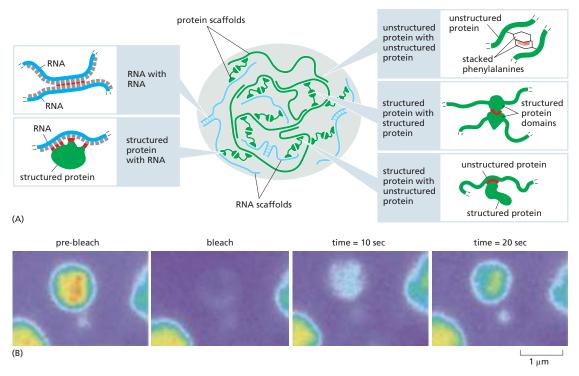

Figure 3–77 The multivalent interactions between scaffold macromolecules that drive the formation of biomolecular condensates. (A) Schematic diagram of a biomolecular condensate that contains both RNA and proteins; illustrated are some types of weak binding interactions frequently involved. Note that the low-complexity domains of scaffold proteins are often critical for forming these condensates, and that several different types of binding interactions are known to cause these unstructured regions to adhere to each other. In addition to the stacking of aromatic side chains (phenylalanine is shown), these include ionic attractions, cation–pi interactions, and the formation of kinked cross-beta structures that resemble amyloids. (B) A fluorescence recovery after photobleaching (FRAP) experiment reveals that the protein molecules inside a condensate are mobile. Here the multiple nucleoli in a mammalian cell have been fluorescently labeled by fusing GFP to the scaffold protein fibrillin, and this fibrillin in one of the nucleoli has been bleached with a flash from a focused laser beam. A rapid recovery of fluorescence demonstrates that the fibrillin in this condensate is continually exchanging with the fibrillin molecules in its surroundings. (B, from R.D. Phair and T. Misteli, *Nature* 404:604–609, 2000. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch03_115-182.indd 172 02/12/21 2:17 PM

Figure 3–78 Spherical, liquid-droplet-like nucleoli can be seen to fuse in the light microscope. In these experiments, the nucleoli are present inside a nucleus that has been dissected from *Xenopus* oocytes and placed under oil on a microscope slide. Here, three nucleoli are seen fusing to form a larger biomolecular condensate. A very similar process occurs after each round of division, when small nucleoli initially form on multiple chromosomes but then coalesce to form a single, large nucleolus (see Figure 6–47). (From C.P. Brangwynne et al., *Proc. Natl. Acad. Sci. USA* 108:4334–4339, 2011. With permission from National Academy of Sciences.)

distinct from the surrounding liquid, the process of condensate formation is commonly termed **liquid-liquid phase separation** or liquid-liquid demixing.

A characteristic feature of biomolecular condensates that reflects their dynamic nature is the readily reversible assembly and disassembly of many of these structures. Thus, for example, the nucleolus disappears during mitosis, and it reforms in early interphase by fusion of the initially separate droplets that form on different chromosomes at the start of each interphase (Figure 3–78). Likewise, the DNA repair, DNA replication, and DNA transcription factories in the nucleus appear only where and when each of these processes occurs (Figure 3–79; see also Figure 6–51C).

Classical Studies of Phase Separation Have Relevance for Biomolecular Condensates

A familiar phase-separation process is that between oil and water, which occurs in some salad dressings. A phase separation occurs whenever forming two phases instead of one minimizes the free energy of a mixture, and it requires overcoming the large unfavorable free-energy change caused by the entropic cost of demixing. Thus, in the oil and water example, there are many more ways of distributing the small oil molecules in between water molecules than there are ways of condensing the oil molecules all together. The completely mixed state is by far the most probable, and the act of demixing therefore involves a large unfavorable (negative) entropy change that produces a large unfavorable (positive) change in the ΔG for phase separation (remembering that $\Delta G = \Delta H - T\Delta S$). But because of an even larger, favorable ΔG derived from preventing the oil molecules from disrupting the hydrogen-bonded network of water molecules, the oil and water separate into distinct phases (see Panel 2–2, pp. 96–97).

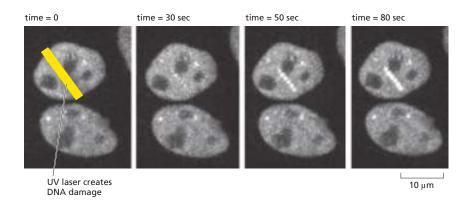

Figure 3–79 The formation of a biomolecular condensate in response to DNA damage. Here, a brief irradiation flash from a UV laser has been used to create a narrow line of DNA damage in the interphase nucleus of a mammalian cell. Because the FUS scaffold protein has been fluorescently labeled with GFP, the formation of the liquid-droplet-like DNA repair factories that this scaffold helps to generate can be followed in a living cell. (Adapted from Movie S1 in A. Patel et al., Cell 162:1066–1077, 2015. With permission from Elsevier.)

MBOC7_ptr_ch03_115-182.indd 173 02/12/21 2:17 PM

174 Chapter 3: Proteins

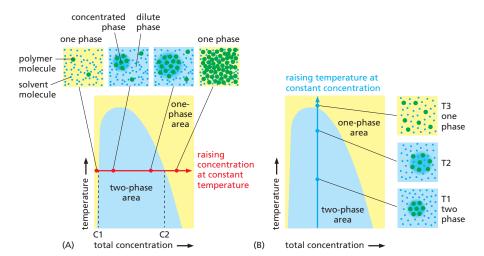

Figure 3-80 How phase diagrams are used to describe phase separations. (A) The effect of increasing the polymer concentration at constant temperature. At a low total concentration of a polymer (Ct), only a single dilute phase is observed. But as the polymer concentration is increased (red arrow), phase separation begins for Ct > C1, and a new concentrated phase now forms with the polymer at concentration C2 in equilibrium with a dilute phase at polymer concentration C1. As Ct is further increased, the phase with polymer concentration C2 increases in volume, while remaining in equilibrium with the polymer in the dilute phase at an unchanging concentration C1. Finally, for Ct > C2, there is only a single phase with concentration Ct. In the example illustrated, C2 is more than 10-fold greater than C1. (B) The effect of increasing temperature (T) at a constant total polymer concentration. As the temperature is raised in a solution that contains a phase-separated polymer from T1 to T2 (blue arrow), the concentration of polymer in its dilute phase (C1) increases and the concentration of polymer in its concentrated phase (C2) decreases. At a higher critical temperature C1 = C2, and the two phases become one. This occurs because the unfavorable entropy change for demixing (ΔS) makes an increasingly large, unfavorable contribution to the net free-energy change at higher temperatures (via the $-T\Delta S$ term in the equation for ΔG), eventually preventing any separation of phases.

For large polymers, which include proteins and nucleic acids, the entropic cost of demixing is considerably less than that for an equivalent mass of small molecules. This is because the monomeric subunits of a polymer are already greatly constrained in their possible arrangements through their covalent attachment to other subunits. As a result, a set of relatively weak attractions between the polymer molecules can often provide a large enough favorable free-energy change to drive phase separation—overcoming the unfavorable free-energy change of demixing.

Chemists have developed *phase diagrams* to describe what happens when chemically synthesized polymers phase-separate (**Figure 3-80**). As illustrated, when a threshold concentration of a polymer is reached, the solution separates into two distinct phases, one dilute and the other considerably more concentrated. The most important feature to notice is that, as more polymer is added at a fixed temperature (Figure 3–80A), its concentration in each phase remains the same. To accommodate the increased amount of polymer present, the volume of the concentrated phase increases and the volume of the dilute phase decreases. These and other features of phase separation are relevant when considering biomolecular condensates, even though the latter are generally composed of mixtures of more complex biological polymers (proteins and RNA molecules).

A Comparison of Three Important Types of Large Biological Assemblies

It has long been recognized that eukaryotic cells contain many membraneenclosed compartments central to cell biology. These take the form of organelles such as the nucleus, endoplasmic reticulum, Golgi apparatus, and lysosome. Each such organelle concentrates a particular set of enzymes and substrates, thereby

MBOC7_ptr_ch03_115-182.indd 174 02/12/21 2:17 PM

TABLE 3-3 Macromolecular Machines Compared to Biomolecular Condensates and Membrane-enclosed Compartments					
	Comparison of three types of large biochemical assemblies				
	Macromolecular machine	Biomolecular condensate	Membrane-enclosed compartment		
Properties	Fixed macromolecular composition, with a defined stoichiometry and spatial organization of constituents Formed from a specific set of protein molecules or from protein and RNA molecules Assembles spontaneously and can form <i>de novo</i> Nevertheless, in many cases assembly is regulated to occur at specific sites, as needed	Dynamic, often liquidlike or gellike organization, in which RNAs and low-complexity domains of proteins form specific, but transient, interactions Readily permeable to small molecules Larger than most macromolecular machines Macromolecule composition is selective, but stoichiometry is usually not fixed Can assemble de novo and be disassembled in response to changing conditions or cellular need	Creates a distinct chemical and protein environment that is maintained by active transport across the enclosing membrane Interior contains a variable stoichiometry of macromolecules in solution, as determined by the above transport processes Not permeable to most small molecules Formation usually requires a preexisting membrane-enclosed compartment of a special kind, different for each compartment		
Examples	SCF ubiquitin ligase DNA replication protein machine Ribosome	Nucleolus Centrosome Stress granule	Endoplasmic reticulum Mitochondrion Transport vesicle		
	Nuclear pore	Neuronal RNA transport granule	Lysosome		

creating a specialized biochemistry in its interior. Those compartments will be the subject of Chapter 12, where we will also discuss biomolecular condensates in more detail. In **Table 3–3**, we compare the properties of the protein machines and biomolecular condensates introduced in this chapter, both with each other and with membrane-enclosed compartments.

Many Proteins Are Controlled by Covalent Modifications That Direct Them to Specific Sites Inside the Cell

In this chapter, we have thus far described only a few ways in which proteins are post-translationally modified. A large number of other such modifications also occur, more than 200 distinct types being known. To give a sense of the variety, **Table 3–4** presents a few of the modifying groups with known regulatory roles.

TABLE 3-4 Some Molecules Covalently Attached to Proteins That Regulate Protein Function				
Modifying group	Some prominent functions			
Phosphate on Ser, Thr, or Tyr	Drives the assembly of a protein into larger complexes (see Figure 15-11)			
Methyl on Lys	Helps to create distinct regions in chromatin by forming either monomethyl, dimethyl, or trimethyl lysine in histones (see Figure 4–34)			
Acetyl on Lys	Helps to activate genes in chromatin by modifying histones (see Figure 4-34)			
Palmityl group on Cys	This fatty acid addition drives protein association with membranes (see Figure 10–18)			
N-Acetylglucosamine on Ser or Thr	Controls enzyme activity and gene expression in glucose homeostasis			
Ubiquitin on Lys	Monoubiquitin addition regulates the transport of membrane proteins in vesicles (see Figure 13–59)			
	A polyubiquitin chain targets a protein for degradation (see Figure 3-66)			
	(Ubiquitin is a 76-amino-acid polypeptide; there are at least 10 other ubiquitin-related proteins in mammalian cells.)			

MBOC7_ptr_ch03_115-182.indd 175 02/12/21 2:17 PM

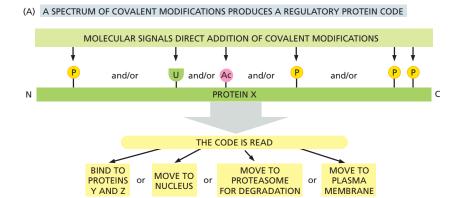

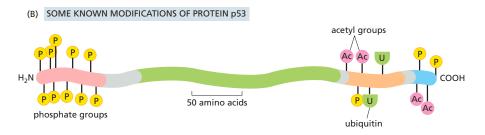

Figure 3–81 Multisite protein modification and its effects. (A) A protein that carries a post-translational addition to more than one of its amino acid side chains can be considered to carry a combinatorial regulatory code. Multisite modifications are added to (and removed from) a protein through signaling networks, and the resulting combinatorial regulatory code on the protein is read to alter its behavior in the cell. (B) The pattern of some covalent modifications to the protein p53.

Like the phosphate and ubiquitin additions described previously, these groups are added and then removed from proteins according to the needs of the cell.

A large number of proteins are modified on more than one amino acid side chain, with different regulatory events producing a different pattern of such modifications. A striking example is the protein p53, which plays a central part in controlling a cell's response to adverse circumstances (see Figure 17–60). Through one of four different types of molecular additions, this protein can be modified at 20 different sites. Because an enormous number of different combinations of these 20 modifications are possible, the protein's behavior can in principle be altered in a huge number of ways. Such modifications will often create a site on the modified protein that binds it to a scaffold protein in a specific region of the cell, thereby connecting it—via the scaffold—to the other proteins required for a reaction at that site. The effects can include moving the modified protein either into or out of a specific biomolecular condensate.

One can view each protein's set of covalent modifications as a *combinatorial regulatory code*. Specific modifying groups are added to or removed from a protein in response to signals, and the code then alters protein behavior—changing the activity or stability of the protein, its binding partners, and/or its specific location within the cell (Figure 3–81). As a result, the cell is able to respond rapidly and with great versatility to changes in its condition or environment.

A Complex Network of Protein Interactions Underlies Cell Function

There are many challenges facing cell biologists in this information-rich era when a huge number of complete genome sequences are known. One is the need to dissect each one of the thousands of protein machines that exist in an organism such as ourselves. To understand these remarkable protein complexes, each will need to be reconstituted from its purified protein parts, so that we can study its detailed mode of operation under controlled conditions in a test tube, free from all other cell components. This alone is a massive task. But we now know that each of these subcomponents of a cell also interacts with other sets of macromolecules, creating a large network of protein-protein and protein-nucleic acid interactions throughout the cell. To understand the cell, therefore, we will need to analyze most of these other interactions as well.

MBOC7_ptr_ch03_115-182.indd 176 02/12/21 2:17 PM

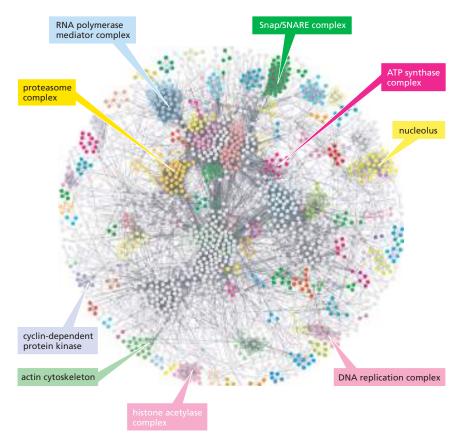

Figure 3–82 A network of protein-binding interactions in the cells of the fruit fly, *Drosophila*. Each line connecting a pair of dots (proteins) indicates a protein-protein interaction. Labels are used to denote a few of the highly interactive groups of proteins whose functions are described in this textbook. (From K.G. Guruharsha et al., *Cell* 147:690–703, 2011. With permission from Elsevier.)

We can begin to gain a sense of the nature of intracellular protein networks from a particularly well-studied example described in Chapter 16: the many dozens of proteins in the actin cytoskeleton that interact to control actin filament behavior (see Panel 16–3, p. 965). Biochemists and structural biologists are, in principle, able to purify all of these different actin-accessory proteins to study their effects on actin filaments individually and in combination, and to determine all of their protein-protein interactions and their atomic structures. But to truly understand the actin cytoskeleton will require that we also learn how to use this data to compute how any particular mixture of these components present in an individual cell creates that cell's observed set of three-dimensional networks of actin structures—a goal that currently seems out of reach.

Of course, understanding the cell will require much more than understanding actin. In recent years, as described in Chapter 8, robotics has been harnessed to a set of powerful technologies to produce enormous protein interaction maps (Figure 3-82). The data obtained suggest that each of the roughly 10,000 different proteins in a human cell interacts with 5-10 different partners, illustrating the challenges that face scientists working to understand the complexity of cell chemistry.

What does the future hold? Despite the enormous progress made in recent years, we cannot yet claim to understand even the simplest known cells, such as the small *Mycoplasma* bacterium formed from only about 500 gene products (see Figure 1–8). How then can we hope to understand a human? Clearly, a great deal of new biochemistry will be essential, in which each protein in a particular interacting set is purified so that its chemistry and interactions can be dissected in a test tube. But in addition, more powerful ways of analyzing networks will be needed using mathematical and computational tools not yet invented. Clearly, there are many wonderful challenges that remain for future generations of cell biologists.

MBOC7_ptr_ch03_115-182.indd 177 02/12/21 2:17 PM

Protein Structures Can Be Predicted and New Proteins Designed

Because the structures and functions of proteins are encoded in their amino acid sequences, in principle it is possible to predict the structures and functions of proteins directly from their amino acid sequences. We should also be able to create proteins with entirely new structures and functions by designing new amino acid sequences to produce these structures and functions, encoding them in synthetic genes. Success in the first endeavor would transform our ability to understand how the biology of an organism is encoded in the DNA sequence of its genome. Success in the second endeavor could lead to a new generation of designed proteins that address some of the twenty-first-century challenges confronting humanity.

There are major challenges in both of the above areas. A first challenge is the very large number of potential structures that are possible for any given amino acid sequence. Because, as we have seen, a protein folds to its lowest free-energy state, one needs to use physics to compute the energy of each protein conformation. But the number of possible conformations for even a relatively short protein of 100 amino acids is of the order 3^{100} , as each amino acid has on average 3 or more rotatable bonds. Success in predicting protein structure and in designing new proteins thus requires computational methods for very efficient searching through huge numbers of structures.

Progress has been made in recent years. For small proteins or for proteins from very large families to help constrain the problem, large-scale computer searches for the lowest energy state can often accurately predict protein structure starting from amino acid sequence. Recently developed deep learning approaches using artificial intelligence (AI) can produce even more accurate protein structure predictions. Conversely, many new protein structures and functions have been created from scratch by designing new sequences in which the lowest energy state has the desired structure and function (Figure 3–83).

While this progress suggests that the protein-folding problem is not intractable, huge challenges remain. Predicting function from structure is even more difficult: while in some cases function can be predicted from structure by analogy to other proteins with similar structures and already known functions, this can be problematic because even a few amino acid changes can considerably change function; for example, the identity of the substrate that an enzyme acts upon. On the design side, while it has been possible to design new proteins with new structures and binding

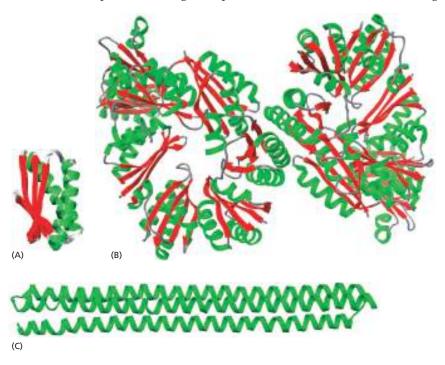

Figure 3-83 Some examples of designed proteins. The amino acid sequences of the three proteins illustrated were determined computationally, being selected so that each protein would adopt a specifically designed three-dimensional conformation in its lowest energy state. After each protein was produced in a bacterium using genetic engineering techniques, its actual structure was then determined and shown to be the same as that intended by the designer. (A) A small protein of 122 amino acids. (B) A protein that creates an octahedral shell formed from 24 identical subunits, only 8 of which are shown. (C) A protein that consists of an antiparallel three-helix bundle. (A, PDB code 2N76; B, PDB code 3VCD; C, PDB code 4TQL).

PROBLEMS 179

activities, it remains a big challenge to match the remarkable activities of natural enzymes and the sophisticated information integration and force generation of natural molecular machines.

Summary

The function of a protein largely depends on the detailed chemical properties of its surface. Enzymes are catalytic proteins that greatly accelerate the rates of covalent bond making and breaking. They do this by binding the high-energy transition state for a specific reaction path, lowering that reaction's activation energy. The rates of enzyme-catalyzed reactions are often so fast that they are limited only by diffusion.

Proteins can reversibly change their shape when ligands bind to their surface. The allosteric changes in protein conformation produced by one ligand affect the binding of a second ligand, and this linkage between two ligand-binding sites provides a crucial mechanism for regulating cell processes. Metabolic pathways, for example, are controlled by feedback regulation: some small molecules inhibit and other small molecules activate enzymes early in a pathway. Enzymes controlled in this way generally form symmetrical assemblies, allowing cooperative conformational changes to create a steep response to changes in the concentrations of the ligands that regulate them.

The expenditure of chemical energy can drive unidirectional changes in protein shape. By coupling allosteric shape changes to the hydrolysis of a tightly bound ATP molecule, for example, proteins can do useful work, such as generating a mechanical force or moving for long distances in a single direction. The three-dimensional structures of proteins have revealed how a small local change caused by nucleoside triphosphate hydrolysis is amplified to create major changes elsewhere in the protein. Highly efficient protein machines are formed by incorporating many different protein molecules into larger assemblies that coordinate the allosteric movements of the individual components. Machines of this type perform most of the important reactions in cells. They and other specific macromolecules can be brought together in large, liquid-like assemblies known as biomolecular condensates, which are created by weak, fluctuating interactions between multivalent protein and RNA scaffolds.

Proteins are subjected to many reversible, post-translational modifications, such as the covalent addition of a phosphate or an acetyl group to a specific amino acid side chain. The addition of these modifying groups is used to regulate the activity of a protein, changing its conformation, its binding to other proteins, and its location inside the cell. A typical protein in a cell will interact with more than five different partners. Understanding the large protein networks inside cells will require biochemistry, through which small sets of interacting proteins can be purified and their chemistry dissected in detail. In addition, new computational approaches will be required to make sense of the enormous complexity of these networks.

PROBLEMS

Which statements are true? Explain why or why not.

- 3–1 Each strand in a β sheet is a helix with two amino acids per turn.
- **3–2** Loops of polypeptide that protrude from the surface of a protein often form the binding sites for other molecules.
- **3–3** An enzyme reaches a maximum rate at high substrate concentration because it has a fixed number of active sites where substrate binds.
- **3–4** Higher concentrations of enzyme give rise to a higher turnover number for that enzyme.

- **3–5** Enzymes that undergo cooperative allosteric transitions invariably consist of symmetrical assemblies of multiple subunits.
- **3–6** Continual addition and removal of phosphates by protein kinases and protein phosphatases is wasteful of energy—because their combined action consumes ATP—but it is a necessary consequence of effective regulation by phosphorylation.

Discuss the following problems.

3–7 Titin, which has a mass of about 3×10^6 daltons, is the largest polypeptide yet described. Titin molecules

MBOC7_ptr_ch03_115-182.indd 179 02/12/21 2:17 PM

extend from muscle thick filaments to the Z disc; they are thought to act as springs to keep the thick filaments centered in the sarcomere. Titin is composed of a large number of repeated immunoglobulin (Ig) sequences of 89 amino acids, each of which is folded into a domain about 4 nm in length (Figure Q3-1A).

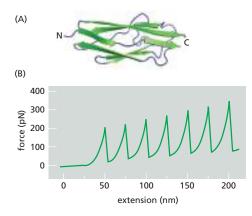

Figure Q3–1 Springlike behavior of titin (Problem 3–7). (A) The structure of an individual Ig domain. (B) Force in piconewtons versus extension in nanometers obtained by atomic force microscopy.

You suspect that the springlike behavior of titin is caused by the sequential unfolding (and refolding) of individual Ig domains. You test this hypothesis using an atomic force microscope, which allows you to pick up one end of a protein molecule and pull with an accurately measured force. For a fragment of titin containing seven repeats of the Ig domain, this experiment gives the sawtooth force-versus-extension curve shown in Figure Q3–1B. If the experiment is repeated in a solution of 8 M urea (a protein denaturant), the peaks disappear and the measured extension becomes much longer for a given force. If the experiment is repeated after the protein has been cross-linked by treatment with glutaraldehyde, once again the peaks disappear but the extension becomes much smaller for a given force.

- A. Are the data consistent with your hypothesis that titin's springlike behavior is due to the sequential unfolding of individual Ig domains? Explain your reasoning.
- **B.** Is the extension for each putative domain-unfolding event the magnitude you would expect? (In an extended polypeptide chain, amino acids are spaced at intervals of 0.34 nm.)
- **C.** Why does the force collapse so abruptly after each peak?
- 3–8 Consider the following statement. "To produce one molecule of each possible kind of polypeptide chain, 300 amino acids in length, would require more atoms than exist in the universe." Given the size of the universe, do you suppose this statement could possibly be correct? Because counting atoms is a tricky business, consider the problem from the standpoint of mass. The observable universe is estimated to contain 10^{80} protons plus neutrons, which have a total mass of about 1.7×10^{56} grams. Assuming that

the average mass of an amino acid is 110 daltons, what would be the total mass of one molecule of each possible kind of polypeptide chain 300 amino acids in length? Is this greater than the mass of the universe?

3–9 The so-called kelch motif consists of a four-stranded β sheet shaped like the blade of a propeller. It is usually found to be repeated four to seven times, forming a β propeller, or kelch repeat domain, in a multidomain protein. One such kelch repeat domain is shown in Figure Q3–2. Would you classify this domain as an *in-line* or *plug-in* type domain?

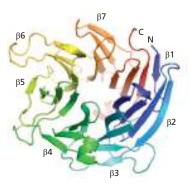

Figure Q3–2 The kelch repeat domain of galactose oxidase from *D. dendroides* (Problem 3–9). The seven individual blades of the β propeller are *color coded* and labeled. The N- and C-termini are indicated by N and C

3–10 In principle, dimers of identical proteins could be arranged either "head-to-tail" (same as "tail-to-head") or "head-to-head" (equivalent to "tail-to-tail"), as illustrated schematically in **Figure Q3–3**. Do you suppose that one type of dimer is significantly more common than the other? Why or why not?

Figure Q3-3 Head-to-head and tail-to-tail dimers (Problem 3-10).

- **3–11** An antibody binds to another protein with an equilibrium constant, K, of 5×10^9 M $^{-1}$. When it binds to a second, related protein, it forms three fewer hydrogen bonds, reducing its binding affinity by 11.9 kJ/mole. What is the K for its binding to the second protein? [Free-energy change is related to the equilibrium constant by the equation $\Delta G^{\circ} = -2.3$ $RT \log K$, where R is 8.3×10^{-3} kJ/(mole K) and T is 310 K.]
- **3–12** In bacteria, the protein SmpB binds to a special species of tRNA, tmRNA, to eliminate the incomplete proteins made from truncated mRNAs. If the binding of SmpB to tmRNA is plotted as fraction tmRNA bound versus SmpB concentration, one obtains a symmetrical S-shaped curve as shown in **Figure Q3–4**. This curve is a visual display of a very useful relationship between $K_{\rm d}$ and concentration, which has broad applicability. The general expression for fraction of ligand (L) bound to a protein (Pr) is derived from the equation for $K_{\rm d}$ ($K_{\rm d}$ = [Pr][L]/[Pr–L]) by substituting ([L]_{TOT} [L])

REFERENCES 181

for [Pr-L] and rearranging. Because the total concentration of ligand ($[L]_{TOT}$) is equal to the free ligand ([L]) plus bound ligand ([Pr-L]),

fraction bound = $[Pr-L]/[L]_{TOT} = [Pr]/([Pr] + K_d)$

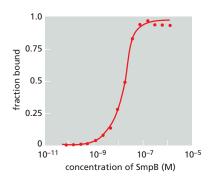

Figure Q3–4 Fraction of tmRNA bound versus SmpB concentration (Problem 3–12). (From A.W. Karzai, M.M. Susskind, and R.T. Sauer, *EMBO J* 18:3793–3799, 1999. With permission from European Molecular Biology Organization.)

For SmpB and tmRNA, the fraction bound = [SmpB-tmRNA]/ [tmRNA]_{TOT} = [SmpB]/([SmpB] + $K_{\rm d}$). Using this relationship, calculate the fraction of tmRNA bound for SmpB concentrations equal to $10^4~K_{\rm d}$, $10^3~K_{\rm d}$, $10^2~K_{\rm d}$, $10^1~K_{\rm d}$, $40^{-1}~K_{\rm d}$,

3–13 The enzyme hexokinase adds a phosphate to D-glucose but ignores its mirror image, L-glucose. Suppose that you were able to synthesize hexokinase entirely from D-amino acids, which are the mirror image of the normal L-amino acids.

A. Assuming that the "D" enzyme would fold to a stable conformation, what relationship would you expect it to have to the normal "L" enzyme?

B. Do you suppose the "D" enzyme would add a phosphate to L-glucose and ignore D-glucose?

3–14 Many enzymes obey simple Michaelis-Menten kinetics, which are summarized by the equation

$$rate = V_{\text{max}}[S]/([S] + K_{\text{m}})$$

where $V_{\text{max}} = \text{maximum velocity}$, [S] = concentration of substrate, and $K_{\text{m}} = \text{the Michaelis constant}$.

It is instructive to plug a few values of [S] into the equation to see how rate is affected. What are the rates for [S] equal to zero, equal to $K_{\rm m}$, and equal to infinite concentration?

3–15 Synthesis of the purine nucleotides AMP and GMP proceeds by a branched pathway starting with ribose 5-phosphate (R5P), as shown schematically in Figure Q3–5. Using the principles of feedback inhibition, propose a regulatory strategy for this pathway that ensures an adequate supply of both AMP and GMP and minimizes the buildup of the intermediates (*A–I*) when supplies of AMP and GMP are adequate.

Figure Q3–5 Schematic diagram of the metabolic pathway for synthesis of AMP and GMP from R5P (Problem 3–15).

3–16 How do you suppose that a molecule of hemoglobin is able to bind oxygen efficiently in the lungs and yet release it efficiently in the tissues?

3–17 Rous sarcoma virus (RSV) carries an oncogene called *Src*, which encodes a continually active protein tyrosine kinase that leads to unchecked cell proliferation. Normally, Src carries an attached fatty acid (myristoylate) group that allows it to bind to the cytoplasmic side of the plasma membrane. A mutant version of Src that does not allow attachment of myristoylate does not bind to the membrane. Infection of cells with RSV encoding either the normal or the mutant form of Src leads to the same high level of protein tyrosine kinase activity, but the mutant Src does not cause cell proliferation.

A. Assuming that the normal Src is all bound to the plasma membrane and that the mutant Src is distributed throughout the cytoplasm, calculate their relative concentrations in the neighborhood of the plasma membrane. For the purposes of this calculation, assume that the cell is a sphere with a radius (r) of 10 μ m and that the mutant Src is distributed throughout the cell, whereas the normal Src is confined to a 4-nm-thick layer immediately beneath the membrane. [For this problem, assume that the membrane has no thickness. The volume of a sphere is $(4/3)\pi r^3$.]

B. The target (X) for phosphorylation by Src resides in the membrane. Explain why the mutant Src does not cause cell proliferation.

BASIC GENETIC MECHANISMS

DNA, Chromosomes, and Genomes

CHAPTER

4

Life depends on the ability of cells to store, retrieve, and translate the genetic instructions required to make and maintain a living organism. This *hereditary information* is passed on from a cell to its daughter cells at cell division and from one generation of an organism to the next through the organism's reproductive cells. The instructions are stored in every living cell's genes, the information-containing units in its genome that determine the characteristics of a species as a whole and of the individuals within it.

As soon as genetics emerged as a science at the beginning of the twentieth century, scientists became intrigued by the nature of the hereditary information. They knew that it was copied and transmitted from cell to daughter cell millions of times to produce the many generations of a multicellular organism, and that it survives the process essentially unchanged. What form of molecule could be capable of such accurate and almost unlimited replication and also be able to exert precise control, directing multicellular development as well as the daily life of every cell? What kind of instructions does the hereditary information contain? And how can the enormous amount of information required for the development and maintenance of an organism fit within the tiny space of a cell?

The answers to some of these questions began to emerge in the 1940s. At this time researchers discovered, from studies in simple fungi, that genes consist largely of instructions for making proteins. Proteins are phenomenally versatile macromolecules that perform most cell functions. As we saw in Chapter 3, they serve as building blocks for cell structures and form the enzymes that catalyze most of the cell's chemical reactions. They also regulate gene expression (Chapter 7), and they enable cells to communicate with each other (Chapter 15) and to move (Chapter 16). The properties and functions of cells and organisms are determined to a great extent by the proteins that they are able to make, and these are determined by their genes.

Painstaking observations of cells and embryos in the late nineteenth century set the stage for experiments that led to the realization that the hereditary information is carried on *chromosomes*—threadlike structures in the nucleus of a eukaryotic cell that become visible by light microscopy as the cell begins to

Figure 4–1 Chromosomes in cells. (A) Two adjacent plant cells photographed through a light microscope. The DNA has been stained with a fluorescent dye (DAPI) that binds to it. The DNA is present in chromosomes, which become visible as distinct structures in the light microscope only when they become compact, sausage-shaped structures just before cell division. This can be easily seen in the cell on the *left*, where for clarity a single chromosome has been shaded *dark brown*. The cell on the *right* contains identical chromosomes, but they cannot be clearly distinguished at this phase in the cell's life cycle, because they are in a more extended conformation. (B) Schematic diagram of the outlines of the two cells along with their chromosomes. (A, courtesy of Peter Shaw.)

divide (Figure 4-1). Later, when biochemical analysis became possible, chromosomes were found to consist of deoxyribonucleic acid (DNA) and protein, with both being present in roughly the same amounts. For many decades, the DNA was thought to be merely a structural element. However, the other crucial advance made in the 1940s was the identification of DNA as the likely carrier of hereditary information. This breakthrough in our understanding of cells came from studies of inheritance in bacteria (Figure 4-2). But still, as the 1950s began, both how proteins could be specified by instructions in the DNA and how this information could be copied for transmission from cell to cell seemed completely mysterious. The puzzle was suddenly solved in 1953, when James Watson and Francis Crick derived the answers from their model for the structure of a DNA molecule. As outlined in Chapter 1, the determination of the double-helical structure of DNA immediately solved the problem of how the information in this molecule might be copied, or replicated. It also provided the first clues as to how a molecule of DNA might use the sequence of its subunits to encode the instructions for making proteins. Today, the fact that DNA is the genetic material is so fundamental to biological thought that it is difficult to appreciate the enormous intellectual gap that was filled by this sudden breakthrough discovery.

We begin this chapter by describing the structure of DNA. We see how, despite its chemical simplicity, the structure and chemical properties of DNA make it ideally suited as the raw material of genes. We then consider how the chromosomal proteins arrange and package this DNA. The packaging has to be done in an orderly fashion so that the chromosomes can be replicated and apportioned correctly between the two daughter cells at each cell division. And it must also allow access to chromosomal DNA, both for the enzymes that constantly repair DNA damage and for the specialized proteins that direct the expression of its many genes.

10 μm

Figure 4-2 The first experimental demonstration that DNA is the genetic material. These experiments, carried out in the 1920s (A) and 1940s (B), eventually showed that adding purified DNA to a bacterium changed the bacterium's properties and that this change was faithfully passed on to subsequent generations. Two closely related strains of the bacterium Streptococcus pneumoniae differ from each other in both the appearance of their colonies grown on an agar surface and their pathogenicity. One strain appears smooth (S) and causes death when injected into mice, and the other appears rough (R) and is nonlethal. (A) An initial experiment shows that some substance present in the S strain can change (or transform) the R strain into the S strain and that this change is inherited by subsequent generations of bacteria. (B) This later experiment, in which the R strain has been incubated with various types of biological molecules that were purified from the S strain, identifies the active substance as DNA.

MBOC7_ptr_ch04_183-252.indd 184 02/12/21 12:46 PM

In the past few decades, there has been a revolution in our ability to determine the exact order of subunits in a DNA molecule, as described in Chapter 8. As a result, we now know the sequence of the entire *human genome*—the 3.1 billion nucleotide pairs that provide the information for producing a human adult from a fertilized egg. We also have the DNA sequences for many thousands of other organisms. Detailed analyses of these sequences are providing exciting insights into the process of genome evolution, and it is with this subject that the chapter ends.

This is the first of four chapters that deal with basic genetic mechanisms—the ways in which the cell maintains, replicates, and expresses the hereditary information carried in its DNA. In the next chapter (Chapter 5), we shall discuss the mechanisms by which the cell accurately replicates and repairs DNA; we also describe how DNA sequences can be rearranged through the process of genetic recombination. Gene expression—the process through which the information encoded in DNA is interpreted by the cell to guide the synthesis of proteins—is the main topic of Chapter 6. In Chapter 7, we describe how this gene expression is controlled by the cell to ensure that each of the many thousands of proteins and RNA molecules encrypted in its DNA is manufactured at the proper time and place in the life of the cell.

THE STRUCTURE AND FUNCTION OF DNA

Biologists in the 1940s had difficulty in conceiving how DNA could be the genetic material. The molecule seemed too simple: a long polymer composed of only four types of nucleotide subunits, which resemble one another chemically. In the early 1950s, DNA was examined by x-ray diffraction analysis, a technique for determining the three-dimensional atomic structure of a molecule (discussed in Chapter 8). The x-ray diffraction results indicated that DNA was composed of two strands of the polymer wound into a helix. The observation that DNA was double-stranded provided one of the major clues that led to the Watson-Crick model for DNA structure that, as soon as it was proposed in 1953, made DNA's potential for replication and information storage immediately apparent.

A DNA Molecule Consists of Two Complementary Chains of Nucleotides

A deoxyribonucleic acid (DNA) molecule consists of two long polynucleotide chains composed of four types of nucleotide subunits. Each of these chains is known as a DNA strand. The two strands run antiparallel to each other, and hydrogen bonds between the base portions of the nucleotides hold the two strands together (Figure 4-3). As we saw in Chapter 2 (Panel 2-6, pp. 104-105), a nucleotide is composed of a five-carbon sugar to which a phosphate group and a nitrogen-containing base are attached. In the case of the nucleotides in DNA, the sugar is deoxyribose attached to a phosphate group (hence the name deoxyribonucleic acid), and the base may be either adenine (A), cytosine (C), guanine (G), or thymine (T). The nucleotides are covalently linked together in a chain through the sugars and phosphates, which thus form a "backbone" of alternating sugar-phosphate-sugar-phosphate (Figure 4-4). Because only the base differs in each of the four types of nucleotide subunit, each polynucleotide chain in DNA is analogous to a sugar-phosphate necklace (the backbone), from which hang four types of beads (the bases A, C, G, and T). These same symbols (A, C, G, and T) are commonly used to denote either the four bases or the four entire nucleotides; that is, the bases with their attached sugar and phosphate groups.

The way in which the nucleotides are linked together gives a DNA strand a chemical polarity. If we think of each sugar as a block with a protruding knob (the 5' phosphate) on one side and a hole (the 3' hydroxyl) on the other (see Figure 4–3), each completed chain, formed by interlocking knobs with holes, will have all of its subunits lined up in the same orientation. Moreover, the two ends of the chain will be easily distinguishable, as one has a hole (the 3' hydroxyl) and

MBOC7_ptr_ch04_183-252.indd 185 02/12/21 12:46 PM

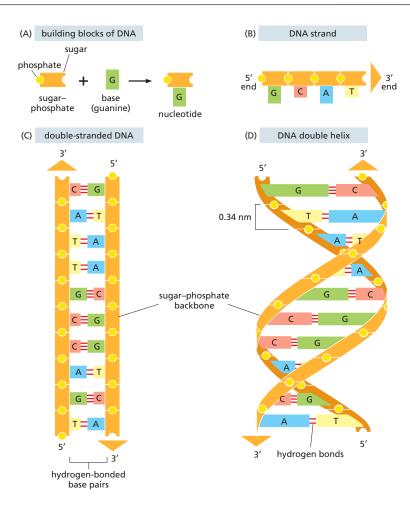

Figure 4-3 DNA and its four nucleotide building blocks. (A) Each nucleotide is composed of a sugar-phosphate covalently linked to a base-guanine (G) in this figure. (B) The nucleotides are covalently linked together into polynucleotide chains, with a sugar-phosphate backbone from which the bases-adenine, cytosine, guanine, and thymine (A, C, G, and T)-extend. (C) A DNA molecule is composed of two polynucleotide chains (complementary DNA strands) held together by hydrogen bonds between the paired bases-denoted here by either two (A-T) or three (G-C) red lines. The arrows on the DNA strands indicate the polarities of the two strands, which run antiparallel to each other (with opposite chemical polarities) in the DNA molecule. (D) Although the DNA molecule is shown straightened out in panel C, in reality it is wound into a double helix, as shown here. For details, see the figures that follow.

the other a knob (the 5' phosphate) at its terminus. This polarity of a DNA strand is indicated by referring to one end as the 3' end (pronounced "3 prime end") and the other as the 5' end (pronounced "5 prime end"), names derived from the orientation of the deoxyribose sugar (see Figure 4-4). With respect to DNA's information-carrying capacity, the chain of nucleotides in a DNA strand, being both directional and linear, can be read in much the same way as the letters on this page.

The three-dimensional structure of DNA—the DNA **double helix**—arises from the chemical and structural features of its two polynucleotide chains. Because the DNA strands are held together by hydrogen-bonding between the bases on the two different strands, all the bases are on the inside of the double helix, and the sugar-phosphate backbones are on the outside (see Figure 4–3). In each case, a bulkier two-ring base (a purine; see Panel 2–6, pp. 104–105) is paired with a single-ring base (a pyrimidine): A always pairs with T, and G with C (**Figure 4–5A**). This *complementary base-pairing* enables the **base pairs** to be packed in the energetically most favorable arrangement in the interior of the double helix. In this arrangement, each base pair is of similar width, thus holding the sugar-phosphate backbones a constant distance apart along the DNA molecule. To maximize the efficiency of base-pair packing, the two sugar-phosphate backbones wind around each other to form a right-handed double helix, with one complete turn every 10.4 base pairs (**Figure 4–5B** and **Figure 4–6**).

The members of each base pair can fit together within the double helix only if the two strands of the helix are **antiparallel**; that is, only if the polarity of one strand is oriented opposite to that of the other strand (see Figures 4–3 and 4–5). As a consequence of DNA's structure and base-pairing requirements, each strand of a

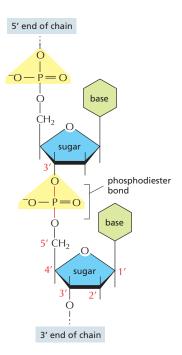

Figure 4–4 The nucleotide subunits within a DNA strand are held together by a phosphodiester bond. This bond connects one sugar to the next. The chemical differences in the ester linkages—between the 5' carbon of one sugar and the 3' carbon of the other—give rise to the polarity of the resulting DNA strand, as indicated. For simplicity, only two nucleotides are shown here.

MBOC7_ptr_ch04_183-252.indd 186 02/12/21 12:46 PM

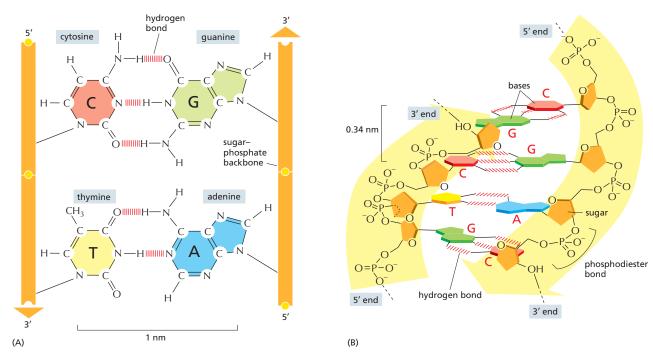

Figure 4–5 How the two strands of the DNA double helix are held together by hydrogen bonds between complementary base pairs.

(A) Schematic illustration showing how the shapes and chemical structures of the bases allow hydrogen bonds to form efficiently only between A and T and between G and C. As shown, two hydrogen bonds form between A and T, whereas three form between G and C. The bases can pair in this way only if the two polynucleotide chains that contain them are antiparallel; that is, oriented in opposite directions. (B) A short section of the double helix viewed from its side. Four base pairs are illustrated; note that they lie perpendicular to the axis of the helix, unlike those shown in the schematic of panel A. As shown in Figure 4–4, the nucleotides are linked together covalently by a phosphodiester bond that connects the 3'-hydroxyl (–OH) group of one sugar and the 5' phosphate (–PO₃) attached to the next (see Figure 4–4 to review how the carbon atoms in the sugar ring are numbered). This linkage gives each polynucleotide strand a chemical polarity; that is, its two ends are chemically different. The 3' end carries an unlinked –OH group attached to the 3' position on the sugar ring; the 5' end carries a free phosphate group attached to the 5' position on the sugar ring.

DNA molecule contains a sequence of nucleotides that is exactly **complementary** to the nucleotide sequence of its partner strand.

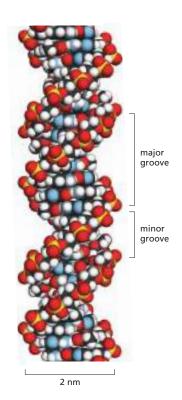

The Structure of DNA Provides a Mechanism for Heredity

The discovery of the structure of DNA immediately suggested answers to the two most fundamental questions about heredity. First, how could the information to specify an organism be carried in a chemical form? And second, how could this information be duplicated and copied from generation to generation?

The answer to the first question came from the realization that DNA is a linear polymer formed from four different kinds of monomers, strung out in a very long, defined sequence like the letters of a document written in an alphabetic script.

The answer to the second question came from the double-stranded nature of the structure: because each strand of DNA contains a sequence of nucleotides that is exactly complementary to the nucleotide sequence of its partner strand, each strand can act as a **template**, or mold, for the synthesis of a new complementary strand. In other words, if we designate the two DNA strands as S and S', strand S can serve as a template for making a new strand S', while strand S' can serve as a template for making a new strand S (**Figure 4–7**). Thus, the genetic

Figure 4–6 A space-filling model of the DNA double helix. The two strands wind around each other to form a right-handed helix (see Figure 3–23). Each turn of this helix contains 10.4 nucleotide pairs, and the center-to-center distance between adjacent nucleotide pairs is 0.34 nm. The coiling of the two strands around each other creates two grooves in the double helix: the wider groove is called the major groove, and the narrower groove is called the minor groove, as indicated. The colors of the atoms are N, blue; O, red; P, yellow; H, white; and C, black. (See Movie 4.1.)

MBOC7_ptr_ch04_183-252.indd 187 02/12/21 12:46 PM

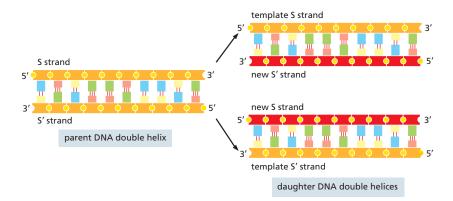

Figure 4–7 DNA as a template for its own duplication. Because the nucleotide A successfully pairs only with T, and G pairs with C, each strand of DNA can act as a template to specify the sequence of nucleotides in its complementary strand. In this way, double-helical DNA can be copied precisely, with each parent DNA helix producing two identical daughter DNA helices.

information in DNA can be accurately copied by the beautifully simple process in which strand S separates from strand S', and each separated strand then serves as a template for the production of a new complementary partner strand that is identical to its former partner.

The ability of each strand of a DNA molecule to act as a template for producing a complementary strand enables a cell to copy, or *replicate*, its genome before passing it on to its descendants. In Chapter 5, we shall describe the elegant machinery that the cell uses to perform this task.

Organisms differ from one another because their respective DNA molecules have different nucleotide sequences and, consequently, carry different biological messages. But how is the nucleotide alphabet used to make messages, and what do they spell out?

As discussed earlier, it was known well before the structure of DNA was determined that genes contain the instructions for producing proteins. If genes are made of DNA, the DNA must therefore somehow encode proteins. As discussed in Chapter 3, the properties of a protein, which are responsible for its biological function, are determined by its three-dimensional structure. This structure is determined in turn by the linear sequence of the amino acids of which it is composed. The linear sequence of nucleotides in a gene must therefore somehow spell out the linear sequence of amino acids in a protein. The exact correspondence between the four-letter nucleotide alphabet of DNA and the 20-letter amino acid alphabet of proteins—the *genetic code*—is not at all obvious from the DNA structure, and it took more than a decade after the discovery of the double helix before it was worked out. In Chapter 6, we will describe this code in detail in the course of elaborating the process of *gene expression*, through which a cell converts the nucleotide sequence of a gene first into the nucleotide sequence of an RNA molecule, and then into the amino acid sequence of a protein (Figure 4–8).

The complete store of information in an organism's DNA is called its **genome**, and it specifies all the RNA molecules and proteins that the organism will ever

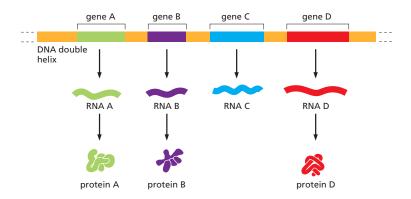

Figure 4–8 Most genes contain information to make proteins. As we discuss in Chapter 6, protein-coding genes each produce a set of RNA molecules (called mRNAs), which then direct the production of a specific protein molecule. Note that for a minority of genes, the final product is the RNA molecule itself, as shown here for gene C.

MBOC7_ptr_ch04_183-252.indd 188 02/12/21 12:47 PM

Figure 4–9 The nucleotide sequence of the human β -globin gene. By convention, a nucleotide sequence is written from its 5′ end to its 3′ end, and it should be read from left to right in successive lines down the page as though it were normal English text. This gene carries the information for the amino acid sequence of one of the two types of subunits of the hemoglobin molecule; a different gene, the α -globin gene, carries the information for the other. (Hemoglobin, the protein that carries oxygen in the blood, has four subunits, two of each type.) Only one of the two strands of the DNA double helix containing the β -globin gene is shown; the other strand has the exact complementary sequence.

The DNA sequences highlighted in *yellow* show the three regions of the gene that specify the amino acid sequence for the β -globin protein. We shall see in Chapter 6 how the cell splices these three sequences together at the RNA level to produce a messenger RNA molecule, and how this mRNA then guides the synthesis of a full-length β -globin protein.

synthesize. (The term "genome" is also used to describe the DNA that carries this information.) The amount of information contained in genomes is staggering. The nucleotide sequence of a very small human gene, written out in the four-letter nucleotide alphabet, occupies a quarter of a page of text (Figure 4–9), while the complete sequence of nucleotides in the human genome would fill more than a thousand books the size of this one. In addition to other critical information, the human genome contains roughly 20,000 protein-coding genes, which (through alternative splicing and other mechanisms described in Chapters 6 and 7) can give rise to a much greater number of distinct proteins.

In Eukaryotes, DNA Is Enclosed in a Cell Nucleus

As described in Chapter 1, nearly all the DNA in a eukaryotic cell is sequestered in a nucleus, which in many cells occupies about 10% of the total cell volume. This compartment is delimited by a *nuclear envelope* formed by two concentric lipid bilayer membranes (Figure 4–10). As illustrated, these two membranes are punctured at intervals by large nuclear pores, through which molecules move between the nucleus and the cytosol. The outer nuclear membrane is directly connected to the extensive system of intracellular membranes called the *endoplasmic reticulum*, which extend out from it into the cytoplasm. And the nuclear envelope is supported internally by a network of intermediate filaments called the *nuclear lamina*—a thin feltlike mesh just beneath the inner nuclear membrane (see Figure 4–10B).

The nuclear envelope allows the many proteins that act on DNA to be concentrated where they are needed in the cell, and, as we see in subsequent chapters, it also keeps nuclear and cytosolic proteins separate, a feature that is crucial for the proper functioning of eukaryotic cells.

Summary

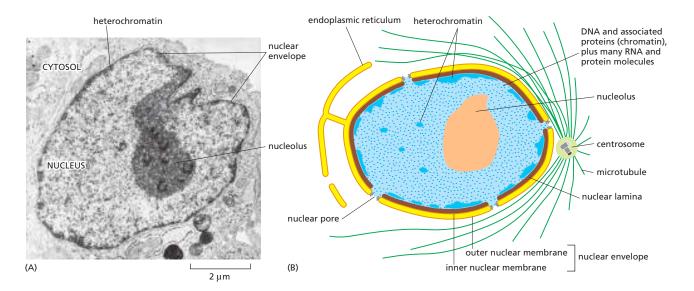

Genetic information is carried in the linear sequence of nucleotides in DNA. Each molecule of DNA is a double helix formed from two complementary antiparallel strands of nucleotides held together by hydrogen bonds between G-C and A-T base pairs. Duplication of the genetic information occurs by the use of one DNA strand as a template for the formation of a complementary strand. The genetic information stored in an organism's DNA sequence contains the instructions for all the RNA molecules and proteins that the organism will ever synthesize, and it is said to be that organism's genome. In eukaryotes, DNA is contained in the cell nucleus, a large membrane-bound compartment.

CHROMOSOMAL DNA AND ITS PACKAGING IN THE CHROMATIN FIBER

The most important function of DNA is to form genes, which are the information-carrying units that specify all the RNA molecules and proteins that make up an organism—including information about when, in what types of cells, and in what quantity each RNA molecule and protein is to be made. The nuclear DNA of eukaryotes is divided up into a set of chromosomes, each of which contains one

enormously long DNA molecule. In this section we see how genes are arranged on chromosomes. In addition, we describe three specialized DNA sequences that are required for a chromosome to be accurately duplicated as a separate entity and passed on from one generation to the next.

We also confront the serious challenge of DNA packaging. If the double helices of all 46 chromosomes in a human cell could be laid end to end, they would reach approximately 2 meters; yet the nucleus, which contains the DNA, is only about 6 μm in diameter. This is geometrically equivalent to packing 40 km (24 miles) of extremely fine thread into a tennis ball. The complex task of packaging DNA is accomplished by specialized proteins that bind to the DNA and fold it, generating a series of organized coils and loops that prevent the DNA from becoming an unmanageable tangle. Amazingly, although the DNA is very tightly compacted, it nevertheless remains accessible to the many enzymes in the cell that replicate it, repair it, and use its genes to produce RNA molecules and proteins.

Eukaryotic DNA Is Packaged into a Set of Chromosomes

Each **chromosome** in a eukaryotic cell consists of a single, enormously long linear DNA molecule along with the proteins that fold the fine DNA thread into a more compact structure. In addition to proteins involved in packaging, chromosomes are also associated with many other proteins (as well as numerous RNA molecules). These are required for the processes of gene expression, DNA replication, and DNA repair. The complex of DNA and tightly bound protein is called *chromatin* (from the Greek *chroma*, "color," because of its staining properties).

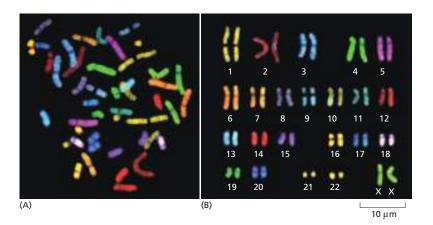

Bacteria lack a special nuclear compartment, and they generally carry their genes on a single DNA molecule, which is often circular (see Figure 1–38). This DNA is also associated with proteins that package and condense it, but they are different from the proteins that perform these functions in eukaryotes. Although the bacterial DNA with its attendant proteins is often called the bacterial "chromosome," it does not have the same structure as the eukaryotic chromosomes that will be our main focus.

With the exception of the gametes (eggs and sperm) and a few highly specialized cell types that cannot multiply and either lack DNA altogether (for example, red blood cells) or have replicated their DNA without completing cell division (for example, megakaryocytes), each human cell nucleus contains two copies of each chromosome, one inherited from the mother and one from the father. The maternal and paternal chromosomes of a pair are called **homologous chromosomes** (homologs). The only nonhomologous chromosome pairs are the sex chromosomes in males, where a *Y chromosome* is inherited from the father

Figure 4-10 A cross-sectional view of a typical cell nucleus. (A) Electron micrograph of a thin section through the nucleus of a human fibroblast. (B) Schematic drawing, showing that the nuclear envelope consists of two membranes, the outer one being continuous with the endoplasmic reticulum (ER) membrane (see also Figure 12-54). The space inside the endoplasmic reticulum (the ER lumen) is colored yellow; it is continuous with the space between the two nuclear membranes. The lipid bilayers of the inner and outer nuclear membranes are connected at each nuclear pore. A sheetlike network of filaments inside the nucleus forms the nuclear lamina (brown), providing mechanical support for the nuclear envelope (for details, see Chapter 12). Outside the nuclear envelope, a centrosome forms microtubules that help to organize the cytoplasm, as explained in Chapter 16. The dark-staining heterochromatin contains specially condensed regions of DNA that will be discussed later.

Prokaryotic cells (archaea and bacteria) have no nucleus. Lacking a nuclear envelope, their DNA is co-located with all other cell components in a single compartment, bounded by the cell's plasma membrane. (A, courtesy of E.G. Jordan and J. McGovern.)

MBOC7_ptr_ch04_183-252.indd 190 02/12/21 12:47 PM

and an *X chromosome* from the mother. Thus, each human cell contains a total of 46 chromosomes—22 pairs common to both males and females, plus two so-called sex chromosomes (X and Y in males, two X's in females). These human chromosomes can be readily distinguished by "painting" each one a different color using a technique that is based on *DNA hybridization* (Figure 4–11). In this method (see p. 505), short strands of nucleic acid tagged with fluorescent dyes serve as "probes" that pick out their complementary DNA sequence, lighting up the target chromosome at any site where they bind. Chromosome painting is most frequently done at the stage in the cell cycle called mitosis, when chromosomes are especially compacted and easy to visualize (discussed shortly).

Another more traditional way to distinguish one chromosome from another is to stain them with dyes that reveal a striking and reproducible pattern of bands along each mitotic chromosome (Figure 4–12). These banding patterns reflect variations in chromatin structure and/or base composition, although their basis is not well understood. Nevertheless, the pattern of these bands on each type of chromosome is unique, and it provided the initial means to identify and number each human chromosome reliably.

The display of the 46 human chromosomes at mitosis shown in Figure 4–11B is called the human **karyotype**. If parts of chromosomes are lost or are switched between chromosomes, these changes can be detected either by changes in the banding patterns or—with greater sensitivity—by changes in the pattern of chromosome painting (Figure 4–13). Cytogeneticists use these alterations to detect inherited chromosome abnormalities and to reveal the chromosome rearrangements that occur in cancer cells as they progress to malignancy (discussed in Chapter 20).

Chromosomes Contain Long Strings of Genes

Chromosomes carry genes—the functional units of heredity. A gene is often defined as a segment of DNA that contains the instructions for making a particular protein (or a set of closely related proteins), but this definition is too narrow. Genes that code for protein are indeed the majority, and most of the genes with clear-cut mutant phenotypes fall under this heading. In addition, however, there are many "RNA genes"—segments of DNA that generate a functionally significant RNA molecule, instead of a protein, as their final product. We shall say more about these RNA genes and their products later.

As might be expected, there can be a correlation between the complexity of an organism and the number of genes in its genome (see Table 1–2, p. 29). For example, some simple bacteria have only 500 genes, compared to about 25,000 for humans. Bacteria, archaea, and some single-celled eukaryotes, such as yeast, have concise genomes, consisting of little more than strings of closely packed genes. However, the genomes of multicellular plants and animals, as well as many other eukaryotes, contain, in addition to genes, a large quantity of interspersed DNA whose function

Figure 4-11 The complete set of human chromosomes. These chromosomes from a female, were isolated from a cell undergoing nuclear division (mitosis) and are therefore highly compacted. Each chromosome has been "painted" a different color to permit its unambiguous identification under the fluorescence microscope, using a technique called "spectral karyotyping." Chromosome painting can be performed by exposing the chromosomes to a large collection of DNA molecules (called DNA probes) whose sequences match known DNA sequences from the human genome. A set of sequences that matches a specific chromosome is coupled to a combination of fluorescent dyes. DNA molecules derived from chromosome 1 are labeled with one specific dye combination, those from chromosome 2 with another, and so on. Because the labeled DNA can form base pairs, or hybridize, only to the chromosome from which it was derived, each chromosome becomes labeled with a different combination of dyes. For such experiments, the chromosomes are subjected to treatments that separate the two strands of double-helical DNA in a way that permits base-pairing with the single-stranded, labeled DNA but keeps the overall chromosome structure relatively intact. (A) The chromosomes visualized as they originally spilled from the lysed cell. (B) The same chromosomes artificially lined up in their numerical order. This arrangement of the full chromosome set is called a karyotype. (Adapted from N. McNeil and T. Ried, Expert Rev. Mol. Med. 2:1-14, 2000. With permission from Cambridge University Press.)

MBOC7_ptr_ch04_183-252.indd 191 02/12/21 12:47 PM

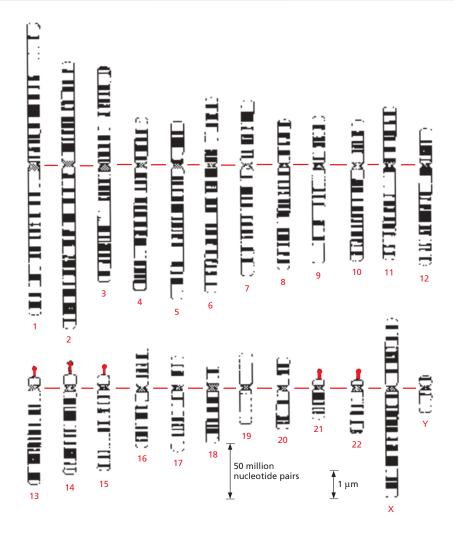

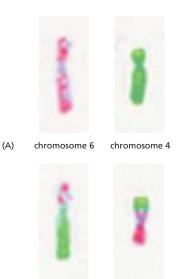

Figure 4-12 The banding patterns of human chromosomes. Chromosomes 1-22 are numbered in approximate order of size. A typical human cell contains two of each of these chromosomes. plus two sex chromosomes—two X chromosomes in a female, one X and one Y chromosome in a male. The chromosomes used to make these maps were stained at an early stage in mitosis, when the chromosomes are incompletely compacted. The horizontal red line represents the position of the centromere (see Figure 4-18), which appears as a constriction on mitotic chromosomes. The red knobs on chromosomes 13, 14, 15, 21, and 22 indicate the positions of genes that code for the large ribosomal RNAs and form the nucleolus (discussed in Chapter 6). These banding patterns are obtained by staining chromosomes with Giemsa stain, and they are observed under a light microscope. (Adapted from U. Francke, Cytogenet. Cell Genet. 31:24-32, 1981.)

is poorly understood. Some of this additional DNA is crucial for the proper control of gene expression, but this only partly explains why there is so much of it in multicellular organisms, whose genes need to be switched on and off according to complicated rules during development (discussed in Chapters 7 and 21).

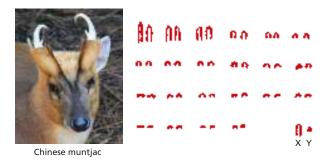

Differences in the amount of noncoding DNA, most of it interspersed between genes—far more than differences in numbers of genes—account for the astonishing variations in genome size that we see when we compare one species with another (see Figure 1–30). For example, the human genome is 200 times larger than that of the yeast *Saccharomyces cerevisiae*, but 30 times smaller than that of some plants and amphibians and 200 times smaller than that of a species of amoeba. Moreover, because of differences in the amount of noncoding DNA, the genomes of closely related organisms (bony fish, for example) can vary several hundredfold in their DNA content, even though they contain roughly the same number of genes. Whatever the excess DNA may do, it seems clear that it is not a great handicap for a eukaryotic cell to carry a large amount of it.

Figure 4–13 Aberrant human chromosomes. (A) Two normal human chromosomes, 4 and 6. (B) In an individual carrying a reciprocal *chromosomal translocation*, the DNA double helix in one chromosome has crossed over with the DNA double helix in the other chromosome because of an abnormal recombination event. The chromosome painting technique used on the chromosomes in each of the sets allows the identification of short pieces of chromosomes that have become translocated, a frequent event in cancer cells. (Courtesy of Zhenya Tang and the NIGMS Human Genetic Cell Repository at the Coriell Institute for Medical Research.)

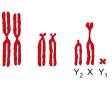

(B) reciprocal chromosomal translocation

MBOC7_ptr_ch04_183-252.indd 192 02/12/21 12:47 PM

How the genome is divided into chromosomes also differs from one eukaryotic species to the next. For example, while the cells of humans have 46 chromosomes, those of some small deer have only 6, while those of the common carp contain more than 100. Even closely related species with similar genome sizes can have very different numbers and sizes of chromosomes (Figure 4–14). Thus, there is no simple relationship between chromosome number, complexity of the organism, and total

relationship between chromosome number, complexity of the organism, and total genome size. Rather, the genomes and chromosomes of modern-day species have each been shaped by a unique history of seemingly random genetic events, acted on by poorly understood selection pressures over long evolutionary times.

The Nucleotide Sequence of the Human Genome Shows How Our Genes Are Arranged

With the determination of the full DNA sequence of the human genome, it became possible to see in detail how the genes are arranged along each of our chromosomes (Figure 4–15). Although many decades will pass before the information contained in the human genome sequence is fully analyzed, it has already stimulated an enormous number of new experiments that have had major effects on the content of every chapter in this book.

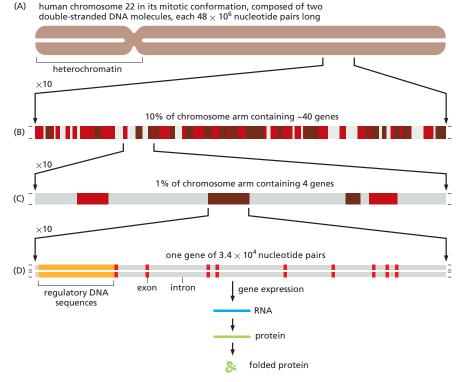

Figure 4–14 Two closely related species of deer with very different chromosome numbers. In the evolution of the Indian muntjac, initially separate chromosomes in an ancestor fused, without having a major effect on the animal. These two species contain a similar number of genes. (Chinese muntjac photo courtesy of Deborah Carreno, Natural Wonders Photography; Indian muntjac photo courtesy of Beatrice Bourgery.)

Figure 4-15 The organization of genes on a human chromosome, as determined from the initial sequencing of the human genome. (A) Chromosome 22, one of the smallest human chromosomes, contains 48×10^6 nucleotide pairs and makes up approximately 1.5% of the human genome. Most of the left arm of chromosome 22 consists of short repeated sequences of DNA that are packaged in a particularly compact form of chromatin (heterochromatin) discussed later in this chapter. (B) A tenfold expansion of a portion of chromosome 22 with about 40 genes indicated. Those in dark brown were known genes, and those in red were predicted genes. (C) An expanded portion of B showing four genes. (D) The intron-exon arrangement of a typical gene is shown after a further tenfold expansion. Each exon (red) codes for a portion of the protein. while the DNA sequence of the introns (gray) is relatively unimportant, as discussed in detail in Chapter 6. (Adapted from International Human Genome Sequencing Consortium, Nature 409:860-921, 2001.)

The human genome (3.1 imes 10 9 nucleotide pairs) is the totality of genetic information belonging to our species. Almost all of this genome is distributed over the 22 different autosomes and 2 sex chromosomes (see Figures 4-11 and 4-12) found within the nucleus. A minute fraction of the human genome (16,569 nucleotide pairs—in multiple copies per cell) is found in the mitochondria (introduced in Chapter 1 and discussed in detail in Chapter 14). The term "human genome sequence" refers to the complete nucleotide sequence of DNA in the 24 nuclear chromosomes and the mitochondria. Being diploid, a human somatic cell nucleus contains twice the haploid amount of DNA, or 6.2×10^9 nucleotide pairs, before duplicating its chromosomes in preparation for division.

MBOC7_ptr_ch04_183-252.indd 193 02/12/21 12:47 PM

TABLE 4–1 Some Vital Statistics for the Human Genome				
Human genome DNA length	3.1×10^9 nucleotide pairs*			
Number of genes coding for proteins	About 20,000 (19,116, plus hundreds of genes encoding proteins of 50 amino acids or less)**			
Largest gene coding for protein	2.5×10^6 nucleotide pairs			
Median size for protein-coding genes	26,000 nucleotide pairs			
Median size for messenger RNAs (including 5' and 3' untranslated regions)	2938 nucleotides			
Median size for amino-acid coding in messenger RNA sequences	1290 nucleotides			
Protein-coding gene features				
Median size of protein produced	430 amino acids			
Smallest number of exons per gene	1 (1068 of these unspliced genes)			
Largest number of exons per gene	363			
Median number of exons per gene	9.0			
Median exon size	131 nucleotide pairs			
Median intron size	1747 nucleotide pairs			
Number of noncoding RNA genes	About 5000, with 4849 annotated***			
Number of pseudogenes	More than 20,000****			
Percentage of protein-coding DNA sequence (in exons)	1%			
Percentage of DNA in other highly conserved sequences	3.5%			
Percentage of DNA transcribed (in protein-coding plus annotated noncoding RNA genes)	45%			
Percentage of DNA in high-copy-number repetitive elements	Approximately 50%			

^{*}The sequence of 2.85 billion nucleotides is known precisely (error rate of only about 1 in 100,000 nucleotides). The remaining DNA primarily consists of short sequences that are tandemly repeated many times over, with repeat numbers differing from one individual to the next. These highly repetitive blocks are difficult to sequence accurately.

Courtesy of Allison Piovesan, University of Bologna, Bologna, Italy.

The first striking feature of the human genome is how little of the DNA sequence (only about 1%) codes for proteins (Table 4–1 and Figure 4–16). It is also notable that nearly half of the chromosomal DNA is made up of mobile pieces of DNA that have gradually inserted themselves in the chromosomes over evolutionary time, multiplying like parasites in the genome and appearing as genome-wide repeat sequences (see Figure 4–63). We discuss these *transposable elements* in detail in later chapters.

A second notable feature of the human genome is the large average gene size—about 26,000 nucleotide pairs. As discussed earlier, a typical gene carries in

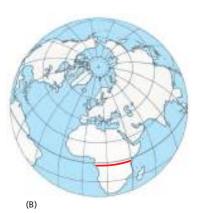

Figure 4–16 Scale of some human genome features. If drawn with a 1-mm space between each nucleotide pair (as in A), the human genome would extend 3100 km (nearly 2000 miles), far enough to stretch across the center of Africa, the site of our human origins (red line in B). At this scale, there would be, on average, a protein-coding gene every 160 meters. An average gene would extend for 26 meters, but the coding sequences in this gene would add up to only just over a meter.

MBOC7_ptr_ch04_183-252.indd 194 02/12/21 12:47 PM

^{**}RefSeq genes, with at least one reviewed/validated mRNA (A. Piovesan et al., *BMC Res. Notes* 12:315–319, 2019). For genes encoding tiny proteins, see T.F. Martinez et al., *Nat. Chem. Biol.* 16:458–468, 2020).

^{***}A considerable number of potential ncRNA genes are still uncharacterized and not annotated.
****A pseudogene is a DNA sequence closely resembling that of a functional gene but containing numerous mutations that prevent its proper expression or function; most are still uncharacterized and not annotated in databases.

its linear sequence of nucleotides the information for the linear sequence of the amino acids of a protein. Only about 1300 nucleotides are required to encode a protein of average size (about 430 amino acids in humans). Most of the remaining sequence in a gene consists of long stretches of noncoding DNA that interrupt the relatively short segments of DNA that code for protein. As will be discussed in detail in Chapter 6, the coding sequences are included in the **exons**; the intervening sequences in genes are noncoding and called **introns** (see Figure 4–15 and Table 4–1). The majority of human genes thus consist of a long string of alternating exons and introns, with most of the gene consisting of introns. In contrast, the majority of genes from organisms with concise genomes either lack introns (as in prokaryotes) or contain relatively short ones. This helps to account for the much smaller size of their genes, as well as for the much higher fraction of coding DNA in their chromosomes.

In addition to introns and exons, each gene is associated with *regulatory DNA sequences*, which are responsible for ensuring that the gene is turned on or off at the proper time, expressed at the appropriate level, and only in the proper type of cell. In humans, the regulatory sequences for a typical gene are spread out over hundreds of thousands of nucleotide pairs. As would be expected, these regulatory sequences are much more compact and less numerous in organisms with concise genomes. In Chapter 7 we discuss how regulatory DNA sequences work.

Detailed studies of genome sequences have surprised biologists with the discovery that, in addition to 20,000 protein-coding genes, the human genome contains thousands of genes that encode RNA molecules that do not produce proteins, but instead have a variety of other important functions. Although the roles of some of these non-coding RNA genes have been known for decades, many more remain mysterious, as will be discussed in Chapters 6 and 7.

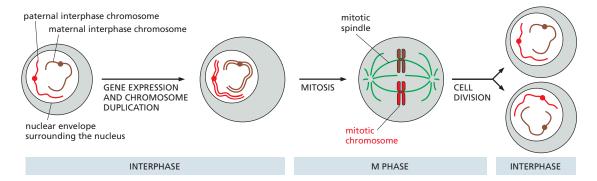

Last, but not least, the nucleotide sequence of the human genome has revealed that the archive of information needed to produce a human seems to be in an alarming state of chaos. As one commentator described our genome, "In some ways it may resemble your garage/bedroom/refrigerator/life: highly individualistic, but unkempt; little evidence of organization; much accumulated clutter (referred to by the uninitiated as 'junk'); virtually nothing ever discarded; and the few patently valuable items indiscriminately, apparently carelessly, scattered throughout." We shall discuss how this is thought to have come about in the final section of this chapter, which is titled "How Genomes Evolve."

Each DNA Molecule That Forms a Linear Chromosome Must Contain a Centromere, Two Telomeres, and Replication Origins

To form a functional chromosome, a DNA molecule must be able to do more than simply carry genes: it must be able to replicate, and the replicated copies must be separated and reliably partitioned into daughter cells at each cell division. This process occurs through an ordered series of stages, collectively known as the **cell cycle**, which provides for a temporal separation between the duplication of chromosomes and their segregation into two daughter cells. The eukaryotic cell cycle is briefly summarized in **Figure 4–17**, and it is discussed in detail in Chapter 17.

Figure 4–17 A simplified view of the eukaryotic cell cycle. During interphase, the cell is actively expressing its genes and is therefore synthesizing proteins. Also, during interphase and before cell division, the DNA is replicated, and each chromosome is duplicated to produce two closely paired sister DNA molecules (called sister chromatids). A cell with only one type of chromosome, present in maternal and paternal copies, is illustrated here.

Once DNA replication is complete, the cell can enter M phase, when mitosis occurs and the nucleus is divided into two daughter nuclei. During this stage, the chromosomes condense, the nuclear envelope breaks down, and the mitotic spindle forms from microtubules and other proteins. The condensed mitotic chromosomes are captured by the mitotic spindle, and one complete set of chromosomes is then pulled to each end of the cell by separating the members of each sister-chromatid pair. A nuclear envelope re-forms around each chromosome set, and in the final step of M phase, the cell divides to produce two daughter cells. Most of the time in the cell cycle is spent in interphase: M phase is brief in comparison. occupying only about an hour in many mammalian cells.

MBOC7_ptr_ch04_183-252.indd 195 02/12/21 12:47 PM

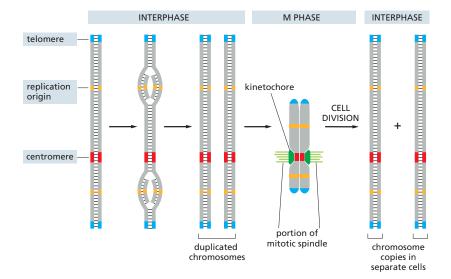

Briefly, during a long *interphase*, genes are expressed and chromosomes are replicated, with the two replicas remaining together as a pair of *sister chromatids*. Throughout this time the chromosomes are extended, and much of their chromatin exists as long threads in the nucleus so that individual chromosomes cannot be easily distinguished. It is only during a much briefer period of *mitosis* that each chromosome condenses so that its two sister chromatids can be separated and distributed to the two daughter nuclei. The highly condensed chromosomes in a dividing cell are known as *mitotic chromosomes* (**Figure 4-18**). This is the form in which chromosomes are most easily visualized; in fact, the images of chromosomes shown so far in the chapter are of chromosomes in mitosis.

Each chromosome operates as a distinct structural unit. For a faithful copy of a chromosome to be passed on to each daughter cell at division, it must have been completely replicated during interphase to produce two identical DNA molecules. In addition, these newly replicated, enormously long DNA copies must then be separated and partitioned correctly into the two daughter cells. These basic functions are controlled by three types of specialized sites on the DNA, each of which binds specific proteins that guide the machinery that replicates and segregates chromosomes (Figure 4–19).

Experiments in budding yeast, whose chromosomes are relatively small and easy to manipulate, have identified the minimal DNA sequence elements responsible for each of these functions. One type of nucleotide sequence acts as a DNA **replication origin**, the location at which duplication of the DNA begins. Eukaryotic chromosomes contain many origins of replication to ensure that the entire chromosome can be replicated rapidly, as discussed in detail in Chapter 5.

After DNA replication, the two sister chromatids that form each chromosome remain attached to one another and, as the cell cycle proceeds, they are condensed further to produce mitotic chromosomes. In budding yeasts, the presence of a second specialized DNA sequence, called a **centromere**, allows one copy of each duplicated and condensed chromosome to be pulled into each daughter cell when a cell divides. A protein complex called a *kinetochore* forms at the centromere and attaches the duplicated chromosomes to the mitotic spindle, in a manner that causes the two sister chromatids to be pulled apart (discussed in Chapter 17).

The third specialized DNA sequence forms **telomeres**, the ends of a chromosome. Telomeres contain repeated nucleotide sequences that enable the ends of chromosomes to be efficiently replicated. Telomeres also perform another function: the repeated telomere DNA sequences, together with the regions adjoining them, form structures that protect the end of the chromosome from

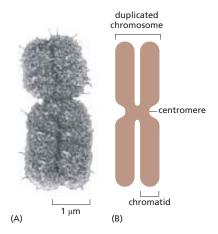

Figure 4–18 A mitotic chromosome. At the metaphase stage of M phase, each chromosome exists as a condensed duplicated chromosome, in which the two replicated chromosomes, called sister chromatids, are still linked together (see Figure 4–17). The constricted region indicates the position of the centromere. (A) Electron micrograph; (B) schematic drawing. (A, courtesy of Terry D. Allen.)

Figure 4-19 The three specialized sites on the DNA required to produce a eukaryotic chromosome that can be replicated and then segregated accurately at mitosis. Each chromosome has multiple origins of replication, one centromere, and two telomeres. Shown here is the sequence of events that a typical chromosome follows during the cell cycle. The DNA replicates during the portion of interphase known as S phase, beginning at the origins of replication and proceeding bidirectionally from the origins across the chromosome. In M phase, the centromere attaches the duplicated chromosomes to the mitotic spindle so that a copy of the entire genome is distributed to each daughter cell during mitosis: the special structure that attaches the centromere to the spindle is a protein complex called the kinetochore (dark green). The centromere also helps to hold the duplicated chromosomes together until they are ready to be moved apart. As explained in the text, the telomeres form special caps at each chromosome end.

MBOC7_ptr_ch04_183-252.indd 196 02/12/21 12:47 PM

being mistaken by the cell for a broken DNA molecule in need of repair. We discuss both this type of repair and the structure and function of telomeres in Chapter 5.

In budding yeast cells, the three types of sequences required to propagate a chromosome are relatively short (typically fewer than 1000 base pairs each) and therefore use only a tiny fraction of the information-carrying capacity of a chromosome. Although telomere sequences are fairly simple and short in all eukaryotes, the DNA sequences that form centromeres and replication origins in more complex organisms are much longer than their yeast counterparts. For example, experiments suggest that a human centromere can contain up to a million nucleotide pairs and that it may not require a stretch of DNA with a defined nucleotide sequence. Instead, as we shall discuss later in this chapter, a human centromere is thought to consist of a large, regularly repeating protein–nucleic acid structure that can be inherited when a chromosome replicates.

DNA Molecules Are Highly Condensed in Chromosomes

All eukaryotic organisms have special ways of packaging DNA into chromosomes. Thus, if the 48 million nucleotide pairs of DNA in human chromosome 22 could be laid out as one long double helix stretched out end to end, the molecule would extend for about 1.5 cm. But chromosome 22 measures only about 2 μm in length in mitosis (see Figure 4–11), representing an end-to-end compaction ratio of more than 7000-fold. This remarkable feat of compression is performed by proteins that successively coil and fold the DNA into higher levels of organization.

Although much less condensed than mitotic chromosomes, the DNA of human interphase chromosomes is still tightly packed. But interphase chromosomes have a dynamic structure. Specific regions of interphase chromosomes decondense to allow access to specific DNA sequences for gene expression, DNA repair, and replication—and then recondense when these processes are completed. The packaging of DNA in chromosomes is therefore accomplished in a way that allows rapid localized, on-demand access to the DNA. In the next sections, we discuss the specialized proteins that make this type of packaging possible.

Nucleosomes Are a Basic Unit of Eukaryotic Chromosome Structure

The proteins that bind to the DNA to form eukaryotic chromosomes are traditionally divided into two classes: the **histones** and the *non-histone chromosomal proteins*, each contributing about the same mass to a chromosome. The complex of both classes of protein with the nuclear DNA of eukaryotic cells is known as **chromatin** (Figure 4–20; Movie 4.2).

Histones are responsible for the first and most basic level of chromosome packing, a protein-DNA complex called the **nucleosome**. When interphase nuclei are broken open very gently and their contents examined under the electron microscope, most of the chromatin appears to be in the form of a fiber

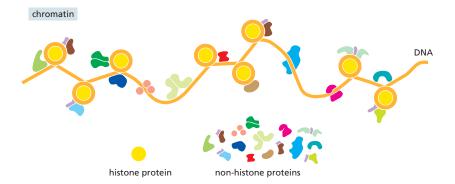

Figure 4–20 Chromatin. As illustrated, chromatin consists of DNA bound to both histone and non-histone proteins. The mass of histone protein present is about equal to the total mass of non-histone protein, but—as schematically indicated here—the latter class is composed of an enormous number of different species. In total, a chromosome is about one-third DNA and two-thirds protein by mass.

MBOC7_ptr_ch04_183-252.indd 197 02/12/21 12:47 PM

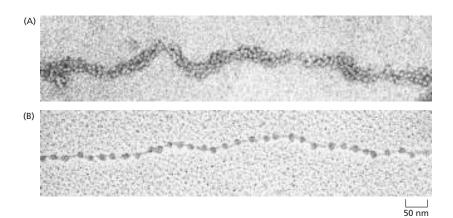

Figure 4–21 Nucleosomes as seen in the electron microscope. (A) Chromatin isolated directly from an interphase nucleus appears in the electron microscope as a thread of associated nucleosomes. (B) This electron micrograph shows a length of chromatin that has been experimentally decondensed after isolation to show the nucleosomes. (A, courtesy of Barbara Hamkalo; B, courtesy of Victoria Foe.)

(Figure 4-21A). If this chromatin is subjected to treatments that cause it to unfold partially, it can be seen under the electron microscope as a series of "beads on a string" (Figure 4-21B). The string is DNA, and each bead is a *nucleosome core particle* that consists of DNA wound around a histone core.

The nucleosome core particles can be isolated by digesting chromatin with particular enzymes (called nucleases) that cut DNA. After digestion for a short period, the exposed DNA between the nucleosome core particles, the *linker DNA*, is degraded. Each individual nucleosome core particle is found to consist of a complex of eight histone proteins—two molecules each of histones H2A, H2B, H3, and H4—and double-stranded DNA that is 147 nucleotide pairs long. This *histone octamer* forms a protein core around which the double-stranded DNA is wound (Figure 4–22).

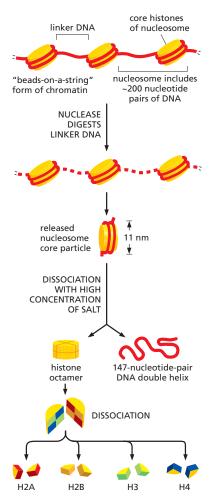

The region of linker DNA that separates each nucleosome core particle from the next can vary in length from a few nucleotide pairs up to about 80. (The term "nucleosome" technically refers to a nucleosome core particle plus one of its adjacent DNA linkers, but it is often used synonymously with "nucleosome core particle.") On average, therefore, nucleosomes repeat at intervals of about 200 nucleotide pairs. For example, a diploid human cell with 6.2×10^9 nucleotide pairs contains approximately 30 million nucleosomes. The formation of nucleosomes converts a DNA molecule into a chromatin thread that is about one-third of its initial length.

The Structure of the Nucleosome Core Particle Reveals How DNA Is Packaged

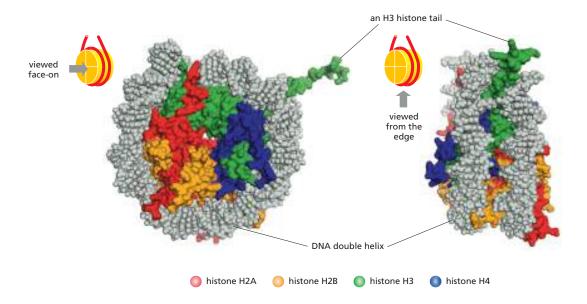

The high-resolution structure of a nucleosome core particle reveals a disc-shaped histone core around which the DNA is tightly wrapped in a left-handed coil of 1.7 turns (Figure 4–23). All four of the histones that make up the core of the nucleosome are relatively small proteins (102–135 amino acids), and they share a structural motif, known as the *histone fold*, formed from three α helices connected by two loops (Figure 4–24). In assembling a nucleosome, the histone folds first bind to each other to form H3–H4 and H2A–H2B dimers, and the H3–H4 dimers combine to form tetramers. An H3–H4 tetramer then further combines with two H2A–H2B dimers to form a compact *histone octamer*, the core around which the DNA is wound.

The interface between DNA and histone is extensive: 142 hydrogen bonds are formed between DNA and the histone core in each nucleosome. Nearly half

Figure 4–22 Structural organization of the nucleosome. A nucleosome contains a protein core made of eight histone molecules. In biochemical experiments, the nucleosome core particle can be released from isolated chromatin by digestion of the linker DNA with a nuclease, an enzyme that hydrolyzes the phosphodiester bonds that connect the nucleotides in DNA. (The nuclease can degrade the exposed linker DNA but cannot attack the DNA wound tightly around the nucleosome core.) After dissociation of the isolated nucleosome into its protein core and DNA, the length of the DNA that was wound around the core can be determined. This length of 147 nucleotide pairs is sufficient to wrap 1.7 times around the histone core.

MBOC7_ptr_ch04_183-252.indd 198 02/12/21 12:47 PM

of these bonds form between the amino acid backbone of the histones and the sugar-phosphate backbone of the DNA. Numerous hydrophobic interactions and salt linkages also hold DNA and protein together in the nucleosome. More than one-fifth of the amino acids in each of the core histones are either lysine or arginine (two amino acids with basic side chains), and their positive charges can effectively neutralize the negatively charged DNA backbone. These numerous interactions explain in part why DNA of virtually any sequence can be bound on a histone octamer core. The path of the DNA around the histone core is not smooth; rather, several kinks are seen in the DNA, as expected from the nonuniform surface of the core.

The bending of the DNA requires a substantial compression of the minor groove of the DNA helix. Certain dinucleotides in the minor groove are especially

Figure 4–23 The structure of a nucleosome core particle, as determined by x-ray diffraction analyses of crystals. Each histone is colored according to the scheme in Figure 4–22, with the DNA double helix in *light gray*. One H3 N-terminal tail (green) can be seen extending from the nucleosome core; the positions of the tails of the other histones could not be determined, due to their disorder. (Adapted from K. Luger et al., Nature 389:251–260, 1997.)

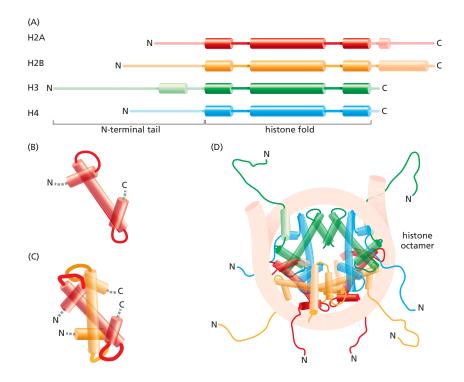

Figure 4–24 The overall structural organization of the core histones.

(A) Each of the core histones contains an N-terminal tail, which is subject to several forms of covalent modification, and a histone fold region, as indicated. (B) The structure of the histone fold, which is formed by all four of the core histones. (C) Histones H2A and H2B form a dimer through an interaction known as the "handshake." Histones H3 and H4 form a dimer through the same type of interaction. (D) The final histone octamer around which the DNA is wound. Note that all eight N-terminal tails of the histones protrude from the disc-shaped core structure. Their conformations are highly flexible, and they serve as binding sites for sets of other proteins.

MBOC7_ptr_ch04_183-252.indd 199 02/12/21 12:47 PM

easy to compress, and some nucleotide sequences bind the histone core more tightly than others (Figure 4-25). This probably explains some striking, but unusual, cases of very precise positioning of nucleosomes along a stretch of DNA. However, the sequence preference of nucleosomes must be weak enough to allow other factors to dominate, inasmuch as nucleosomes can occupy any one of a number of positions relative to the DNA sequence in most chromosomal regions.

In addition to its histone fold, each of the core histones has a largely unstructured N-terminal amino acid "tail," which extends out from the DNA-histone core (see Figure 4–24D). These histone tails are "hot spots" for different types of covalent modifications that control critical aspects of chromatin structure and function, as we shall discuss shortly.

As a reflection of their fundamental role in DNA function through controlling chromatin structure, the histones are among the most highly conserved eukary-otic proteins. For example, the amino acid sequence of histone H4 from a pea differs from that of a human at only two of the 102 positions. Although histones H2A and H2B have been somewhat less constrained in their evolution than histones H3 and H4, such a strong evolutionary conservation suggests that the functions of histones involve nearly all of their amino acids, so that a change in any position is deleterious to the cell.

In addition to this remarkable conservation, eukaryotic organisms also produce smaller amounts of specialized variant core histones that differ in amino acid sequence from the main ones. As discussed later, these variants, combined with the surprisingly large number of covalent modifications that can be added to the histones in nucleosomes, give rise to a variety of chromatin structures in cells.

Nucleosomes Have a Dynamic Structure and Are Frequently Subjected to Changes Catalyzed by ATP-dependent Chromatin-remodeling Complexes

For many years biologists thought that, once formed in a particular position on DNA, a nucleosome would remain fixed in place because of the very tight association between its core histones and DNA. If true, this would pose problems for genetic readout mechanisms, which require easy access to many specific DNA sequences. It would also hinder the rapid passage of the DNA transcription and replication machinery through chromatin. But kinetic experiments show that the DNA in an isolated nucleosome unwraps from each end at a rate of about four times per second, remaining exposed for 10–50 milliseconds before the partially unwrapped structure recloses. Thus, most of the DNA in an isolated nucleosome is in principle available for binding other proteins (see Figure 7–12).

Inside a cell, a further loosening of DNA-histone contacts is clearly required, because eukaryotic cells contain a variety of ATP-dependent *chromatin-remodeling complexes*. These abundant proteins include a subunit that hydrolyzes ATP (an ATPase evolutionarily related to the DNA helicases discussed in Chapter 5). This "motor subunit" binds both to the protein core of the nucleosome and to the double-stranded DNA that winds around it. By using the energy of ATP hydrolysis to move this DNA relative to the core, the remodeling complex changes the structure of a nucleosome temporarily, making the DNA less tightly bound to the histone core. Through repeated cycles of ATP hydrolysis that pull the DNA helix along the nucleosome core, a remodeling complex can catalyze *nucleosome sliding* (Figure 4–26). Because nucleosomes are frequently repositioned in this way, all of the DNA sequences in chromatin are potentially available for binding to other proteins in the cell.

In addition, some types of remodeling complexes are able to remove either all or part of the nucleosome core from a nucleosome—catalyzing either an exchange of its H2A-H2B histones or the complete removal of the octameric core from the DNA (Figure 4–27). As a result, a typical nucleosome is replaced on the DNA every 1 or 2 hours inside the cell.

Cells contain dozens of different ATP-dependent chromatin-remodeling complexes that are specialized for different roles, with roughly one complex present per five nucleosomes. Most are large protein complexes that can contain 10 or

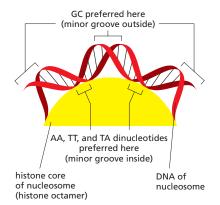

Figure 4–25 The bending of DNA in a nucleosome. The DNA helix makes 1.7 tight turns around the histone octamer. This diagram illustrates how the minor groove is compressed on the inside of the turn. Owing to structural features of the DNA molecule, the indicated dinucleotides are preferentially accommodated in such a narrow minor groove, which helps to explain why certain DNA sequences will bind more tightly than others to the nucleosome core.

Figure 4-27 Nucleosome removal and

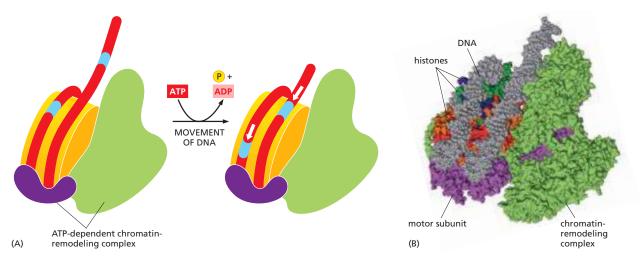

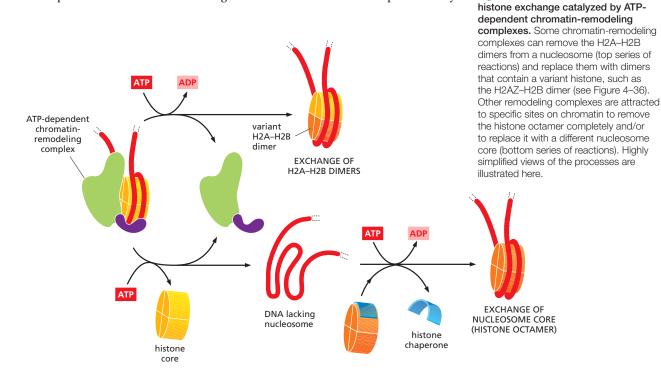

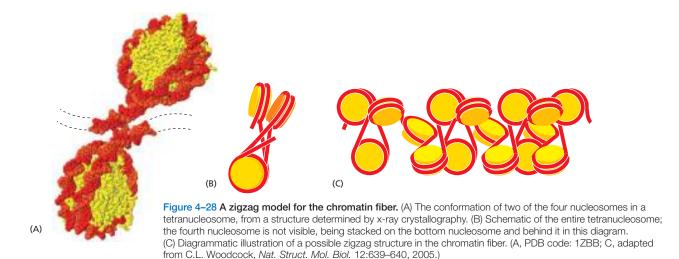

Figure 4–26 The nucleosome movements catalyzed by ATP-dependent chromatin-remodeling complexes. (A) Using the energy of ATP hydrolysis, a remodeling complex that catalyzes nucleosome sliding pulls on the DNA of its bound nucleosome and loosens its attachment to the histone octamer. Each cycle of ATP binding, ATP hydrolysis, and release of the ADP and phosphate products thereby moves the DNA in the direction of the arrows in this diagram. Because each cycle moves the DNA by one base pair, it requires many such cycles to produce the nucleosome sliding shown. (B) The structure of the yeast SWR1 chromatin-remodeling complex. This complex catalyzes an exchange of an H2A–H2B dimer for a dimer that contains an H2A histone variant. Its ATP-driven motor subunit is colored *purple*. (B, PDB code: 6GEJ.)

more subunits, some of which bind to specific modifications on histones. The activity of these complexes is controlled by the cell. As genes are turned on and off, chromatin-remodeling complexes are brought to specific regions of DNA where they act locally to influence chromatin structure (discussed in Chapter 7).

Although some DNA sequences bind more tightly than others to the nucleosome core (see Figure 4-25), the most important influence on nucleosome positioning appears to be the presence of other tightly bound proteins on the DNA. Some bound proteins favor the formation of a nucleosome adjacent to them. Others create obstacles that force the nucleosomes to move elsewhere. The exact positions of nucleosomes along a stretch of DNA therefore depend mainly

MBOC7_ptr_ch04_183-252.indd 201 02/12/21 12:47 PM

on the presence and nature of other proteins bound to the DNA. And due to the presence of ATP-dependent chromatin-remodeling complexes, the arrangement of nucleosomes on DNA can be highly dynamic, changing rapidly according to the needs of the cell.

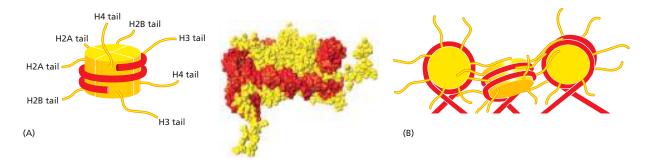

Attractions Between Nucleosomes Compact the Chromatin Fiber

Although enormously long strings of nucleosomes form on the chromosomal DNA, chromatin in a living cell probably rarely adopts the extended "beads-on-a-string" form. Instead, the nucleosomes are packed on top of one another, generating arrays in which the DNA is more highly condensed. Thus, when nuclei are very gently lysed onto an electron microscope grid, much of the chromatin is seen to be in the form of a fiber that is considerably wider than an individual nucleosome (see Figure 4–21A).

How nucleosomes are organized into condensed arrays is unclear. The structure of a tetranucleosome (a complex of four nucleosomes) obtained by x-ray crystallography and high-resolution electron microscopy of reconstituted chromatin has been used to support a zigzag model for the stacking of nucleosomes (Figure 4–28). But cryo-electron microscopy of carefully prepared nuclei suggests that most regions of chromatin are less regularly structured.

What causes nucleosomes to stack on each other? Nucleosome-to-nucleosome attractions that involve histone tails, most notably the H4 tail, constitute one important factor (Figure 4–29). In addition, an additional histone is often present in a 1-to-1 ratio with nucleosome cores, known as histone H1. This so-called *linker histone* is larger than the individual core histones, and it has been considerably less well conserved during evolution. A nucleosome can bind a single histone H1 molecule; this H1 molecule contacts both the DNA and the histone octamer and changes the path of the DNA as it exits from the nucleosome

Figure 4–29 A model for the role played by histone tails in the compaction of chromatin. (A) A schematic diagram shows the approximate exit points of the eight N-terminal histone tails, one from each histone protein, that extend from each nucleosome. The actual structure is shown to its *right*. In the high-resolution structure of the nucleosome, most of the histone tails are not visible, suggesting that they are relatively unstructured and highly flexible. (B) As indicated, the histone tails are thought to be involved in interactions between nucleosomes that help to hold them together. (A, PDB code: 1KX5.)

MBOC7_ptr_ch04_183-252.indd 202 02/12/21 12:47 PM

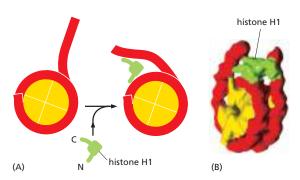

Figure 4–30 How the linker histone binds to the nucleosome. The position and structure of histone H1 are shown. H1 constrains the DNA where it exits from the nucleosome and thereby compacts chromatin. (A) Schematic, and (B) structure inferred for a single nucleosome from a structure determined by high-resolution electron microscopy of a reconstituted chromatin fiber. (B, adapted from F. Song et al., Science 344:376–380, 2014.)

(Figure 4–30). The change in the exit path of DNA is thought to help compact nucleosomal DNA. The presence of many other DNA-binding proteins, as well as proteins that bind directly to histones, is certain to add important additional features to any array of nucleosomes.

Summary

A gene is a nucleotide sequence in a DNA molecule that acts as a functional unit for the production of a protein, a structural RNA, or a catalytic or regulatory RNA molecule. In eukaryotes, protein-coding genes are usually composed of a string of alternating introns and exons associated with regulatory regions of DNA. A chromosome is formed from a single, enormously long DNA molecule that contains a linear array of many genes, bound to a large set of proteins. The human genome contains 3.1×10^9 DNA nucleotide pairs, divided between 22 different autosomes (present in two copies each) and 2 sex chromosomes. Only a small percentage of this DNA codes for proteins or functional RNA molecules. A chromosomal DNA molecule also contains three other types of important nucleotide sequences: replication origins and telomeres allow the DNA molecule to be efficiently replicated, while a centromere attaches the sister DNA molecules to the mitotic spindle, ensuring their accurate segregation to daughter cells during the M phase of the cell cycle.

The DNA in eukaryotes is tightly bound to an equal mass of histones, which form repeated arrays of DNA-protein particles called nucleosomes. The nucleosome is composed of an octameric core of histone proteins around which the DNA double helix is wrapped. Nucleosomes are spaced at intervals of about 200 nucleotide pairs, and they associate with neighboring nucleosomes to create a more compact chromatin fiber. Chromatin structure must be highly dynamic to allow access to the DNA. Some spontaneous DNA unwrapping and rewrapping occurs in the nucleosome itself; however, the general strategy for reversibly changing local chromatin structure in a cell features ATP-driven chromatin-remodeling complexes. Cells contain a large set of such complexes, which are targeted to specific regions of chromatin at appropriate times. The remodeling complexes allow nucleosome cores to be repositioned, reconstituted with different histones, or completely removed to expose the underlying DNA.

THE EFFECT OF CHROMATIN STRUCTURE ON DNA FUNCTION

Having described how DNA is packaged into nucleosomes to create a chromatin fiber, we next describe the mechanisms that create different chromatin structures in different regions of a cell's genome and how this affects DNA function in cells. Most strikingly, we shall see that some types of chromatin structure can be inherited; that is, the structure can be directly passed down from a cell to its descendants. Because this creates a cell memory that is not based on an inherited change in DNA sequence, it creates a form of **epigenetic inheritance**. The prefix *epi* is Greek for "on"; this is appropriate, because epigenetics represents a form of inheritance that is superimposed on the DNA-based genetic inheritance.

MBOC7_ptr_ch04_183-252.indd 203 02/12/21 12:47 PM

Chapter 7 explains the many different ways in which the expression of genes is regulated; there we will discuss epigenetic inheritance in detail and present several different mechanisms that can produce it. Here, we are concerned only with those epigenetic mechanisms based on chromatin structure. We shall emphasize some of the chemistry that makes this possible—the covalent modification of histones in nucleosomes. These modifications serve as recognition sites for protein domains that bind different non-histone protein complexes to different regions of chromatin. In total, these complexes are so abundant that, roughly speaking, chromatin consists of one-third DNA, one-third histones, and one-third non-histone proteins by mass (see Figure 4–20). The varieties of chromatin structures produced have critical effects not only on gene expression but also on many other DNA-dependent processes—playing an important role in the development, growth, and maintenance of all eukaryotic organisms, including ourselves.

Different Regions of the Human Genome Are Packaged Very Differently in Chromatin

Light-microscope studies in the 1930s distinguished two types of chromatin in the interphase nuclei of higher eukaryotic cells: a highly condensed form, called **heterochromatin**, and all the rest, called **euchromatin**, which is less condensed. Powerful new types of molecular analyses have now allowed scientists to classify these two chromatin types more precisely. Chromatin is now considered to be either "open and active" or "closed and inactive." As illustrated in **Figure 4–31**, roughly 80% of the human genome is in the closed form, half of which is compactly packaged in heterochromatin, with the other, less condensed half (part of the euchromatin) designated as "quiescent." Only about 20% of the genome is packaged in that portion of the euchromatin associated with the actively expressed genes that will be the focus of Chapters 6 and 7.

Heterochromatin Is Highly Condensed and Restricts Gene Expression

Heterochromatin represents an especially compact form of chromatin (see Figure 4–10), and we are finally beginning to understand its molecular properties. Some heterochromatin is concentrated in specialized chromosomal regions, most notably at the centromeres and telomeres introduced previously (see Figure 4–19). But heterochromatin is also present at many other locations along chromosomes—locations that can vary according to the developmental state of the cell.

The packaging of DNA in heterochromatin typically prevents gene expression. However, we know now that the term *heterochromatin* encompasses a number of

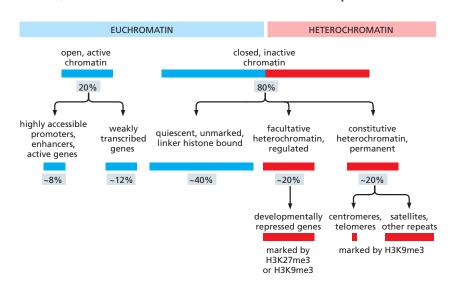

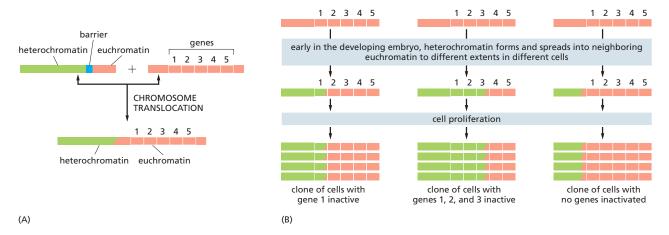

Figure 4-31 Some distinct ways that DNA is packaged in chromatin in a mammalian cell. Although all of these types of chromatin are based on long strings of nucleosomes, the nucleosomes are differently organized through association with different non-histone proteins. As we discuss shortly, these associations can depend on the particular ways that the histones in each nucleosome have been covalently "marked." For example, as indicated here, the histone H3 molecules in heterochromatin are marked either with trimethylated lysine 9 (H3K9me3) or with trimethylated lysine 27 (H3K27me3), depending on the particular structure that is formed (see Figure 4-40).

MBOC7_ptr_ch04_183-252.indd 204 02/12/21 12:47 PM

distinct modes of chromatin compaction that have different functions. There are two broad classes, distinguished as *constitutive heterochromatin* and *facultative heterochromatin* (see Figure 4–31). The constitutive class permanently condenses many regions of the genome (and hence its name), whereas the facultative class of heterochromatin can be regulated to control gene expression.

As described next, heterochromatin has the critical property of being able to self-propagate.

The Heterochromatic State Can Spread Along a Chromosome and Be Inherited from One Cell Generation to the Next

Through errors that can occur in chromosome rejoining when DNA double-strand breaks are repaired, a piece of chromosome that is normally euchromatic can be accidentally translocated into the neighborhood of heterochromatin. Remarkably, this often causes the *silencing*—inactivation—of normally active genes, a phenomenon referred to as a *position effect*. First recognized in the fruit fly *Drosophila*, such position effects have now been observed in many eukaryotes, including yeasts, plants, and humans. Position effects are caused by a spreading of the heterochromatic state into an originally euchromatic region, and detailed studies of this phenomenon have provided important clues to the mechanisms that create and maintain heterochromatin.

After the above type of chromosome breakage-and-rejoining event, the zone of silencing, where euchromatin is converted to a heterochromatic state, is found to spread for different distances in different cells of the early fly embryo. Remarkably, these differences then are perpetuated for the rest of the animal's life: in each cell, once the heterochromatic condition is established on a piece of chromatin, it tends to be stably inherited by all of that cell's progeny (Figure 4–32). This remarkable phenomenon, called *position effect variegation*, was first recognized as a mottled loss of red pigment in the fly eye (Figure 4–33).

These observations, taken together, point to a fundamental feature of heterochromatin formation: heterochromatin begets more heterochromatin. This

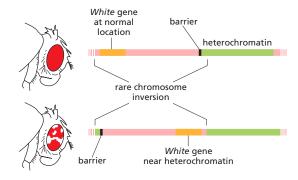

Figure 4–32 The cause of position effect variegation in *Drosophila*.

(A) Heterochromatin (green) is normally prevented from spreading into adjacent regions of euchromatin (red) by barrier DNA sequences, which we shall discuss shortly. In flies that inherit certain chromosomal rearrangements, however, this barrier is no longer present. (B) During the early development of such flies, heterochromatin can spread into neighboring chromosomal DNA, proceeding for different distances in different cells. This spreading soon stops, but the established pattern of heterochromatin is subsequently inherited, so that large clones of progeny cells are produced that have the same neighboring genes condensed into heterochromatin and thereby inactivated (hence the "variegated" appearance of some of these flies; see Figure 4-33).

Figure 4-33 The discovery of position effects on gene expression. The White gene in the fruit fly Drosophila controls eye pigment production and is named after the mutation that first identified it. Wild-type flies with a normal White gene (White+) have normal pigment production, which gives them red eyes, but if the White gene is mutated and inactivated, the mutant flies (White-) make no pigment and have white eyes. In flies in which a normal White gene has been moved near a region of heterochromatin, the eyes are mottled, with both red and white patches. The white patches represent cell lineages in which the White gene has been silenced by the effects of the heterochromatin. In contrast, the red patches represent cell lineages in which the White gene is expressed. Early in development, when the heterochromatin is first formed, it spreads into neighboring euchromatin to different extents in different embryonic cells (see Figure 4-32). The presence of large patches of red and white cells reveals that the state of transcriptional activity, as determined by the packaging of this gene into chromatin in those ancestor cells, is inherited by all daughter cells.

MBOC7_ptr_ch04_183-252.indd 205 02/12/21 12:47 PM

(A) LYSINE ACETYLATION AND METHYLATION ARE COMPETING REACTIONS

Figure 4–34 Some prominent types of covalent amino acid side-chain modifications found on nucleosomal histones. (A) Three different levels of lysine methylation are shown; each can be recognized by a different binding protein, and thus each can have a different significance for the cell. Note that acetylation removes the plus charge on lysine, and that, perhaps most important, an acetylated lysine cannot be methylated, and vice versa. (B) Serine phosphorylation adds a negative charge to a histone. Modifications of histones not shown here include the mono- or dimethylation of an arginine, the phosphorylation of a threonine, the addition of ADP-ribose to a glutamic acid, and the addition of a ubiquityl, sumoyl, or biotin group to a lysine.

positive feedback can operate both in space, causing the heterochromatic state to spread along the chromosome, and in time, across cell generations, propagating the heterochromatic state of the parent cell to its daughters. The challenge is to explain the molecular mechanisms that underlie this remarkable behavior.

As a first step, one can carry out a search for the molecules that are involved. This has been done by means of *genetic screens*, in which large numbers of mutants are generated, after which one picks out those that show an abnormality of the process in question. Extensive genetic screens in *Drosophila*, fungi, and mice have identified more than 100 genes whose products either enhance or suppress the spread of heterochromatin and its stable inheritance—in other words, genes that serve as either *enhancers* or *suppressors* of position effect variegation. Many of these genes turn out to code for non-histone chromosomal proteins that interact with histones and are involved in modifying or maintaining chromatin structure. These include genes that encode some of the enzymes that add or remove covalent modifications to histone side chains, as we discuss next.

The Core Histones Are Covalently Modified at Many Different Sites

The amino acid side chains of the four histones in the nucleosome core are subjected to a remarkable variety of covalent modifications, including the acetylation of lysines, the mono-, di-, and trimethylation of lysines, and the phosphorylation of serines (Figure 4–34). A large number of these side-chain modifications occur on the eight relatively unstructured N-terminal "histone tails" that protrude from the nucleosome (Figure 4–35). However, there are also more than 20 specific side-chain modifications on the nucleosome's globular core.

All of the above types of modifications are reversible, with one enzyme serving to create a particular type of modification and a different enzyme serving to remove it. These enzymes are highly specific. Thus, for example, acetyl groups are added to specific lysines by a set of different histone acetyl transferases (HATs) and removed by a set of histone deacetylase complexes (HDACs). Likewise, methyl groups are added to lysine side chains by a set of different histone methyl transferases and removed by a set of histone demethylases. Each enzyme is recruited to specific sites on the chromatin at defined times in each cell's life history. The initial recruitment can depend on transcription regulatory proteins (sometimes

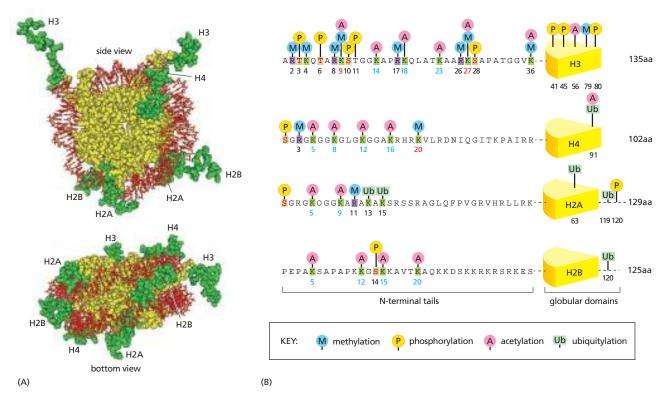

Figure 4–35 The covalent modification of core histones. (A) The structure of the nucleosome highlighting the location of the first 30 or so amino acids in each of its eight N-terminal histone tails (green). These tails are unstructured and highly mobile, and thus will change their conformation depending on other bound proteins. (B) Some well-documented modifications of the four histone core proteins are indicated. Notably, although only a single symbol is used here for methylation (M), each lysine (K) or arginine (R) can be methylated in several different ways. Thus, for example, mono-, di-, or trimethyl lysine groups can have very different effects. Note also that some positions (for example, lysine 9 of H3) can be modified either by methylation or by acetylation, but not both. Most of the modifications shown add a relatively small molecule onto a histone; the exception is ubiquitin, a 76-amino-acid protein also used for other cell processes (see Figure 3–65). Note that while most of the modifications occur in unstructured regions, including on short tails at the C-terminus of histone H2A and histone H2B, there are also important modifications in structured histone folds. (A, PDB code: 1KX5; B, based on D. Allis et al., Epigenetics, 2nd ed., Overview and concepts. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, 2015.)

called "transcription factors"). As we shall explain in Chapter 7, these proteins recognize and bind to specific DNA sequences in the chromosomes. They are produced at different times and places in the life of an organism, thereby determining where and when the chromatin-modifying enzymes will act. In this way, the DNA sequence ultimately determines how histones are modified. But as we shall discuss shortly, the covalent modifications on nucleosomes in heterochromatin can persist long after the transcription regulatory proteins that first induced them have disappeared, thereby providing the cell with a memory of its developmental history. Most remarkably, as in the related phenomenon of position effect variegation discussed earlier, this "heterochromatin memory" can be transmitted from one cell generation to the next.

Very different patterns of covalent modification are found on different groups of nucleosomes, depending both on their exact position in the genome and on the history of the cell. The modifications of the histones are carefully controlled, and they can have important consequences. The acetylation of lysines on the N-terminal tails loosens chromatin structure, in part because adding an acetyl group to lysine removes its positive charge. However, the most profound effects of the histone modifications lie in their ability to recruit specific other proteins to the modified stretch of chromatin. For example, as we discuss shortly, the trimethylation of one specific lysine on the histone H3 tail attracts the protein HP1 and promotes the establishment and spread of one type of heterochromatin,

MBOC7_ptr_ch04_183-252.indd 207 02/12/21 12:47 PM

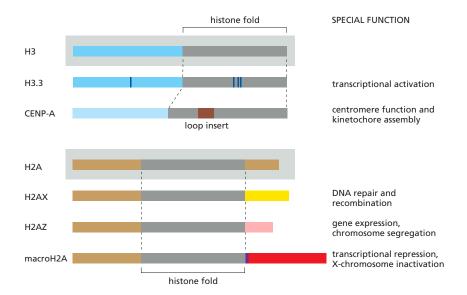

Figure 4-36 The structure of some histone variants compared with the major histone that they replace in a histone octamer. The histone variants are inserted into nucleosomes at specific sites on chromosomes by ATP-dependent chromatin-remodeling complexes (see Figure 4-26). The CENP-A (centromere protein-A) variant of histone H3 is discussed later in this chapter (see Figure 4-42); other variants are discussed in Chapter 7. The sequences in each variant that are colored differently (compared to the major histone above it) denote regions with an amino acid sequence different from this major histone. (Adapted from K. Sarma and D. Reinberg, Nat. Rev. Mol. Cell Biol. 6:139-149, 2005.)

while the trimethylation of a different lysine attracts a different protein to form a second heterochromatin type (see Figure 4–40). In this way and many others, the recruited proteins act with the modified histones to determine how and when genes will be expressed, as well as other critical chromosome functions.

Chromatin Acquires Additional Variety Through the Site-specific Insertion of a Small Set of Histone Variants

In addition to the four highly conserved standard core histones, eukaryotes also contain a few variant histones that can also assemble into nucleosomes. These histones are present in much smaller amounts than the major histones, and they have been less well conserved over long evolutionary times. Variants are known for each of the core histones with the exception of H4; some examples are shown in Figure 4–36.

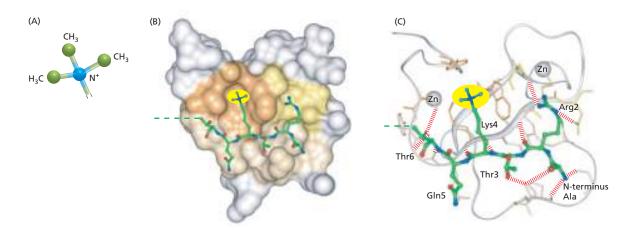

The major histones are synthesized primarily during the S phase of the cell cycle and assembled into nucleosomes on the daughter DNA helices just behind the replication fork (see Figure 5–32). In contrast, most histone variants are synthesized throughout interphase. They are often inserted into already-formed chromatin. This requires a histone-exchange process catalyzed by a special ATP-dependent chromatin-remodeling complex that binds both the variant histone and the nucleosome containing the histone to be exchanged (see Figure 4–27). These remodeling complexes contain subunits that cause them to bind to specific sites on chromatin. As a result, each histone variant is inserted into chromatin in a highly selective manner.

Covalent Modifications and Histone Variants Can Act in Concert to Control Chromosome Functions

The number of possible distinct markings on an individual nucleosome is in principle enormous, and this potential for diversity becomes still greater when one considers the nucleosomes that contain histone variants. The histone modifications are known to occur in coordinated sets, and more than 15 such sets can be identified in mammalian cells. However, it is not yet clear how many different types of chromatin are functionally important.

Some combinations are known to have a specific meaning for the cell in the sense that they determine how and when the DNA packaged in the nucleosomes is to be accessed or manipulated—a fact that led to the idea of a "histone code." For example, one type of marking signals that a stretch of chromatin has been newly replicated, another signals that the DNA in that chromatin has been

MBOC7_ptr_ch04_183-252.indd 208 02/12/21 12:47 PM

damaged and needs repair, while others signal when and how gene expression should take place. Various regulatory proteins contain small domains that bind to specific marks, recognizing, for example, a trimethylated lysine at a specific position in one of the histones (Figure 4–37; see also Figure 9–52). These domains are often linked together as modules in a large protein complex, such as in an ATP-dependent chromatin remodeler, allowing that complex to recognize a specific *combination* of histone modifications. These so-called *reader protein complexes* (Figure 4–38) allow particular combinations of markings on chromatin to attract a set of additional proteins, so as to execute an appropriate biological function at the right time.

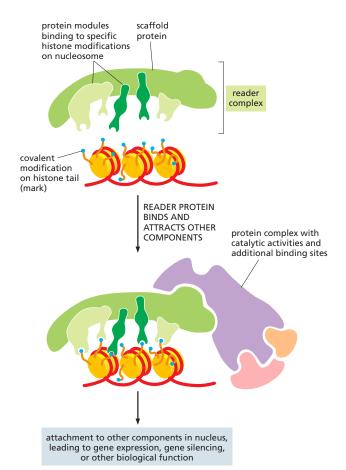

Figure 4-37 How a mark on a

nucleosome is read. The figure shows the structure of a protein module (called an ING PHD domain) that specifically recognizes histone H3 trimethylated on lysine 4. (A) A trimethyl group. (B) Space-filling model of an ING PHD domain bound to a histone tail (green, with the trimethyl group highlighted in yellow). (C) A ribbon model showing how the N-terminal six amino acids in the H3 tail are recognized. The hatched red lines represent hydrogen bonds. This is one of a family of PHD domains that recognize methylated lysines on histones; different members of the family bind tightly to lysines located at different positions, and they can discriminate between a mono-, di-, and trimethylated lysine. In a similar way, other small protein modules recognize specific histone side chains that have been marked with acetyl groups, phosphate groups, and so on. (Adapted from P.V. Peña et al., Nature 442:100-103, published 2006 by Nature Publishing Group. Reproduced with permission of SNCSC.)

Figure 4–38 Schematic diagram showing how a particular combination of histone modifications can be recognized by a reader protein complex.

A large protein complex that contains a series of protein modules, each of which recognizes a specific histone mark, is schematically illustrated (green). This reader complex will bind tightly only to a region of chromatin that contains several of the different histone marks that it recognizes. Therefore, only a specific combination of marks will cause the complex to bind to chromatin and attract the additional protein complexes (purple) needed to catalyze a biological function.

MBOC7_ptr_ch04_183-252.indd 209 02/12/21 12:47 PM

TABLE 4–2 Some Effects of Histone Modifications			
Histone modification	Association with chromatin type	Gene expression	Abundance (%)
H4K4me3	Highly accessible, open chromatin	ON	1
H3K9ac	Highly accessible, open chromatin	ON	1
H3K9me3	Heterochromatin (either constitutive or facultative)	OFF	25
H3K27me3	Facultative heterochromatin	OFF	13

In general, sets of modifications act in combination, but only a small number of their meanings are clear. For how the two different kinds of heterochromatin listed here form, see Figure 4–40.

Each of the marks on nucleosomes is denoted as follows: listed first is an abbreviation for the particular histone involved, written as H3, H4, H2A, or H2B. The marked amino acid side chain then follows, using its one-letter abbreviation followed by its distance from that histone's amino-terminus—thus, for example, H3K9 or H4K4 (see Figure 4–35). Listed last is the type of modification on that amino acid side chain, as in H3K9ac (acetylated), H3K9me2 (dimethylated), or H3K9me3 (trimethylated).

All of the covalent additions to histones are dynamic, being constantly removed and added at rates that depend both on their chromosomal locations and on specific states of the cell. Because the histone tails extend outward from the nucleosome core and are likely to be accessible even when chromatin is condensed, they would seem to provide an especially suitable format for creating marks that can be readily altered as a cell's needs change. Although much remains to be learned about the meaning of the different histone modifications, a few well-studied examples of the information that can be encoded in histone modifications are listed in Table 4–2.

A Complex of Reader and Writer Proteins Can Spread Specific Chromatin Modifications Along a Chromosome

The phenomenon of position effect variegation described previously requires that some modified forms of chromatin have the ability to spread for substantial distances along a chromosomal DNA molecule (see Figure 4–32). How is this possible?

The enzymes that add or remove modifications to histones in nucleosomes are part of multisubunit complexes. They can initially be brought to a particular region of chromatin by one of the sequence-specific DNA-binding proteins (transcription regulators) discussed in Chapters 6 and 7 (for a specific example, see Figure 7–23). But after a modifying enzyme "writes" its mark on one or a few neighboring nucleosomes, events that resemble a chain reaction can ensue. In such a case, the *writer enzyme* works in concert with a *reader protein* located in the same protein complex. The reader protein contains a module that recognizes the mark and binds tightly to the newly modified nucleosome (see Figure 4–37), allosterically activating an attached writer enzyme and positioning it near an adjacent nucleosome. Through many such read–write cycles, the reader protein can carry the writer enzyme along the DNA—spreading the mark in a hand-overhand manner along the chromosome (Figure 4–39A; Movie 4.2).

As important examples, there are two major classes of heterochromatin in mammalian cells, one centered on the trimethylation of H3K9 and the other on the trimethylation of H3K27 (see Figure 4-31). The H3K27me3 class

MBOC7_ptr_ch04_183-252.indd 210 02/12/21 12:47 PM

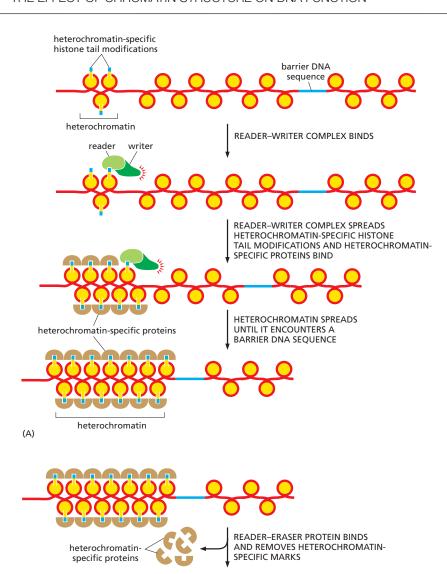

Figure 4–39 How the recruitment of reader–writer and reader–eraser complexes can spread chromatin changes along a chromosome.

(A) The writer is an enzyme that creates a particular modification on one of the four nucleosomal histones. After a writer enzyme modifies a few nucleosomes following its recruitment to a specific site on a chromosome-for example, by a transcription regulatory protein—the writer collaborates with a reader protein to spread its mark from nucleosome to nucleosome by means of the indicated reader-writer complex. For this mechanism to work, the reader must recognize the same histone modification mark that the writer produces, and its binding to that mark should activate the writer. In this schematic example, a spreading wave of chromatin condensation is thereby induced, forming heterochromatin. (B) A reader-eraser complex (not shown) reverses the chromatin change illustrated in A. As described in the text, additional proteins are involved in these two types of spreading events, including ATP-dependent chromatin-remodeling complexes.

of heterochromatin is generated by the extensively studied *polycomb repressive complex (PRC)*. Because this class is highly regulated, it is designated as facultative heterochromatin. The H3K9me3 class of heterochromatin plays an important structural role in forming the centromere (to be described shortly) and in silencing a variety of "selfish DNA" elements (see p. 465). It was once thought to remain unchanged in all cells of a multicellular organism ("constitutive heterochromatin"). However, recent data reveal that some of its forms are reversible, and that it can be used to regulate gene expression. For example, it is used to tightly repress genes that are active early in embryonic development, once they are no longer needed (see Chapter 7).

(B)

The H3K9me3 class of heterochromatin also serves to block the frequent genetic recombination that would otherwise occur between the highly repeated DNA sequences in genomes. Roughly speaking, 40% of the human genome is packaged into heterochromatin, with the ratio of the H3K9me3 class to the H3K27me3 class of heterochromatin being about 2:1 (see Figure 4–31).

MBOC7_ptr_ch04_183-252.indd 211 02/12/21 12:47 PM

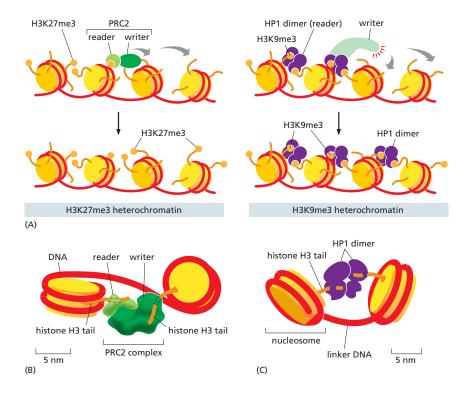

Figure 4–40 outlines what is known about the two different processes that spread and maintain these abundant heterochromatin forms.

A related type of process is used to remove specific histone modifications from a region of the DNA. In this case, an *eraser enzyme*, such as a histone demethylase or a histone deacetylase, is recruited to the complex, producing a read–erase cycle that spreads along a chromosome (Figure 4–39B).

In reality, the process is more complicated than the schemes just described. Both readers and writers are part of a protein complex that may contain multiple readers and writers, as well as erasers, and require multiple marks on the nucleosome to spread. Moreover, many of these reader-writer complexes also contain an ATP-dependent chromatin-remodeling protein (see Figure 4–27), with the reader, writer, and remodeling proteins working in concert to alter long stretches of chromatin as the reader moves progressively along the nucleosome-packaged DNA. Some idea of the complexity can be derived from the results of genetic screens for genes that either enhance or suppress the spreading and stability of heterochromatin, as manifest for example in effects on position effect variegation in *Drosophila* (see Figure 4–33). As pointed out previously, more than 100 such genes are known, and many of them are likely to code for subunits in one or more reader-writer-remodeling protein complexes. However, nearly all of the details remain to be deciphered by future research.

Barrier DNA-Protein Complexes Block the Spread of Reader-Writer Complexes and Thereby Separate Neighboring Chromatin Domains

The above mechanisms for spreading chromatin structures raise a potential problem. Inasmuch as each chromosome contains one continuous, very long DNA molecule, what prevents a cacophony of confusing cross-talk between adjacent chromatin domains of different structure and function? Early studies of position effect variegation had suggested an answer: certain DNA sequences mark the boundaries of chromatin domains and separate one such domain from another (see Figure 4–32). Several such *barrier DNA sequences* have now

Figure 4–40 Some of the proteins required for the formation of two classes of heterochromatin in mammalian cells. (A) Schematic diagrams that compare the reader–writer complexes for two classes of heterochromatin: one that catalyzes the spread of H3K27me3 marks along chromatin and the other that catalyzes the spread of H3K9me3 marks.

(B) The H3K27me3 class of heterochromatin is produced by the polycomb repressive complex (PRC). This complex, first discovered in Drosophila, is composed of a PRC1 protein complex, which creates the initial mark, plus a PRC2 complex that spreads it. Shown here is the three-dimensional structure of a PRC2 reader-writer complex bridging two adjacent nucleosomes. (C) The reader for the H3K9me3 class of heterochromatin, the HP1 protein, is present in very large amounts compared to its writer enzyme. In addition to binding the writer it exists as a dimer whose two H3K9me3 binding sites enable it to bridge two adjacent nucleosomes as shown, thereby helping to package the marked nucleosomes (see also panel A, above). (B, based on S. Poepsel et al., Nat. Struct. Mol. Biol. 25:154-162, 2018; C, based on S. Machida et al., Mol. Cell 69:385-397,

MBOC7_ptr_ch04_183-252.indd 212 02/12/21 12:47 PM

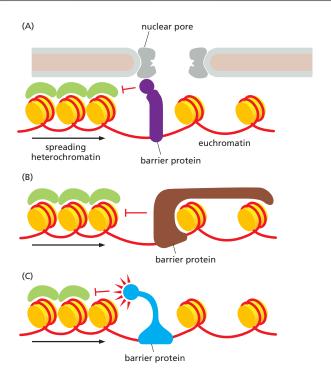

Figure 4-41 Some mechanisms of barrier action. These models are derived from experimental analyses of barrier action, and a combination of several of them may function at any one site. (A) The tethering of a region of chromatin to a large fixed site, such as the nuclear pore complex illustrated here, can form a barrier that stops the spread of heterochromatin. (B) The tight binding of barrier proteins to a group of nucleosomes can make this chromatin resistant to heterochromatin spreading. (C) By recruiting a group of highly active histone-modifying enzymes, barriers can erase the histone marks that are required for heterochromatin to spread. For example, a potent acetylation of lysine 9 on histone H3 will compete with lysine 9 methylation, thereby preventing the binding of the HP1 protein needed to form a major form of heterochromatin. (Based on A.G. West and P. Fraser, Hum. Mol. Genet. 14:R101-R111, 2005.)

been identified and characterized through the use of genetic engineering techniques that allow specific DNA segments to be deleted from or inserted into chromosomes.

Analysis of one type of barrier sequence reveals that it contains a cluster of binding sites for histone acetylase enzymes. The acetylation of a lysine side chain is incompatible with the methylation of the same side chain, and specific lysine methylations are required to spread heterochromatin (see Figure 4-40). Histone acetylases are therefore logical candidates for the formation of the barriers that stop heterochromatin spreading, as are the histone-demethylating enzymes that erase the marks on histones specific to heterochromatin. Other types of barrier mechanisms are also known (Figure 4-41).

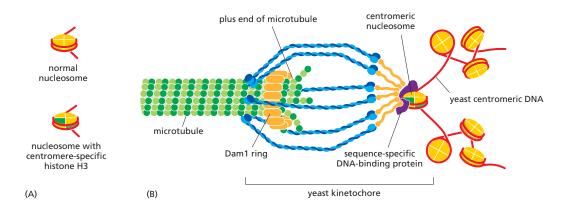

Centromeres Have a Special, Inherited Chromatin Structure

There is a specialized chromatin structure at the centromere, the region of each chromosome required for its orderly attachment to the mitotic spindle. In many complex organisms, including humans, each centromere is embedded in a stretch of special *centromeric chromatin* that persists throughout interphase, even though the centromere-mediated attachment to the spindle and movement of DNA occur only during mitosis. This chromatin contains a centromere-specific variant H3 histone, known as CENP-A (centromere protein-A; see Figure 4–36), plus additional proteins that pack the nucleosomes into particularly dense arrangements and form the kinetochore, the structure required for mitotic spindle attachment (see Figure 4–19).

In the yeast *Saccharomyces cerevisiae*, a specific DNA sequence of approximately 125 nucleotide pairs is sufficient to serve as a centromere. Despite its small size, more than a dozen different proteins assemble on this DNA sequence; the proteins include the CENP-A histone H3 variant that, along with the three other core histones, forms a centromere-specific nucleosome. The additional proteins at the yeast centromere form a kinetochore, which links this nucleosome to a single microtubule from the yeast mitotic spindle (Figure 4–42).

The centromeres in more complex organisms are considerably larger than those in budding yeasts. For example, human centromeres extend over several million nucleotide pairs, and, while they contain multiple copies of CENP-A and bind

MBOC7_ptr_ch04_183-252.indd 213 02/12/21 12:47 PM

about 20 microtubules, they do not seem to contain a centromere-specific DNA sequence. These centromeres largely consist of short, repeated DNA sequences, known as *alpha satellite DNA*. But the same repeat sequences are also found at other (non-centromeric) positions on chromosomes, indicating that they are not sufficient to direct centromere formation. And most striking, in some unusual cases, new human centromeres (called neocentromeres) have been observed to form spontaneously on fragmented chromosomes at positions that were originally euchromatic and lack alpha satellite DNA altogether (Figure 4–43).

It seems that centromeres in complex organisms are defined by an assembly of proteins rather than by a specific DNA sequence. Essential for this assembly is a set of CENP-A nucleosomes. And once a special region of centromeric chromatin forms, this assembly is thereafter faithfully inherited when a chromosome replicates, despite the fact that no special DNA sequence need be involved.

The inactivation of some centromeres and the genesis of others *de novo* occur as organisms evolve. Different species, even when quite closely related, often have different numbers of chromosomes (see Figure 4–14 for an extreme example). And, as we discuss later, detailed genome comparisons show that many changes in chromosomes have arisen through chromosome breakage-and-rejoining events; these create novel chromosomes, some of which must initially have contained abnormal numbers of centromeres—either more than one or

Figure 4-42 The structure of a simple centromere. (A) In the yeast Saccharomyces cerevisiae, a special centromeric DNA sequence assembles a single nucleosome in which two copies of an H3 variant histone (called CENP-A in most organisms) replace the normal H3. (B) How amino acid sequences unique to this variant histone (see Figure 4-36) help to assemble additional proteins, some of which form a kinetochore. The yeast kinetochore is unusual in capturing only a single microtubule; humans have much larger centromeres and form kinetochores that can capture 20 or more microtubules. The kinetochore is discussed in detail in Chapter 17.

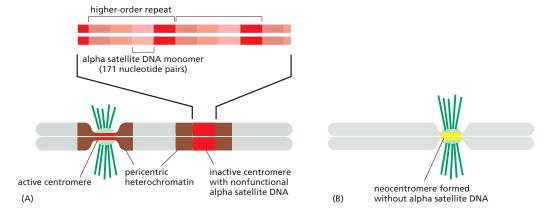

Figure 4–43 Evidence for the plasticity of human centromere formation. (A) A series of A-T-rich alpha satellite DNA sequences is repeated many thousands of times at each human centromere (red) and is surrounded by pericentric heterochromatin (brown). The pericentric heterochromatin standard (brown). The pericentric heterochromatin contains H3K9me3, along with HP1 protein, and it is an example of "classical" constitutive heterochromatin (see Figure 4–31). As indicated, some human chromosomes contain two blocks of alpha satellite DNA, each of which presumably functioned as a centromere in its original chromosome. (B) In a small fraction (1/2000) of human births, extra chromosomes are observed in cells of the offspring. Some of these extra chromosomes, which have formed from a breakage event, contain alpha satellite DNA sequences that have been co-opted to form new centromeres (neocentromeres); other neocentromeres lack alpha satellite DNA altogether and have arisen from what was originally euchromatic DNA.

MBOC7_ptr_ch04_183-252.indd 214 02/12/21 12:47 PM

none at all. Yet stable inheritance requires that each chromosome should contain one centromere, and one only. It seems that surplus centromeres must have been inactivated and/or new centromeres created, so as to allow the rearranged chromosome sets to be stably maintained.

Some Forms of Chromatin Can Be Directly Inherited

The changes in centromere activity just discussed, once established, need to be perpetuated through subsequent cell generations. What could be the mechanism of this type of epigenetic inheritance?

It has been proposed that *de novo* centromere formation requires an initial seeding event, which is followed by the formation of a specialized DNA-protein structure that contains nucleosomes formed with the CENP-A variant of histone H3. In humans, this seeding event happens more readily on arrays of alpha satellite DNA than on other DNA sequences. The entire centromere then forms as an all-or-none entity, suggesting that the creation of centromeric chromatin is a highly cooperative process, spreading out from an initial seed. And once established, this special form of chromatin is passed on to each daughter cell when a cell divides.

Both the spreading and the inheritance of centromeric chromatin mimic the phenomenon of position effect variegation that we discussed earlier (see Figure 4–32). The spreading of a particular chromatin structure can be explained by the action of reader–writer complexes (see Figure 4–39A). But how can we explain the inheritance of centromeric chromatin from one cell generation to the next?

Notably, experiments have revealed that the H3–H4 tetramers from each nucleosome on the parent DNA helix are directly inherited by both of the sister DNA helices at a replication fork, being equally partitioned between them. This is quickly followed by the addition of two H2A–H2B dimers to complete each "half-old" nucleosome, and by the deposition of the new histone octamers needed to restore the normal complement of nucleosomes (see Figure 5–32). Therefore, once a set of CENP-A-containing nucleosomes has been assembled on a stretch of DNA, it is easy to understand how a new centromere could be generated in the same place on both daughter chromosomes after each round of cell division. One need only assume that the presence of the CENP-A histone in an inherited nucleosome selectively recruits more CENP-A histone to its newly formed neighbors.

An analogous scheme is thought to explain the observation that both the H3K9me3 and H3K29me3 forms of heterochromatin, once formed, are directly inherited after each round of chromosome replication. In those cases, the H3–H4 tetramers that contain a particular modified histone will be passed to each daughter DNA helix, followed by the rapid addition of H2A–H2B to re-form specifically marked nucleosomes. The action of reader–writer complexes can then spread the identical marks to the new neighboring nucleosomes—either H3K9me3 or H3K27me3 (see Figure 4–40). Thus, the activities of reader–writer complexes can explain not only the spreading of specific forms of chromatin along a chromosome, but also the propagation of heterochromatin across cell generations—from parent cell to daughter cell (Figure 4–44).

In vertebrates, but not in flies, this inheritance of heterochromatin is often reinforced by a second process that silences the same genes. As described in Chapter 7, this process is based on a DNA methylation system that generates an inherited pattern of methylated C nucleotides (see Figures 7–47 and 7–48).

The Abnormal Perturbations of Heterochromatin That Arise During Tumor Progression Contribute to Many Cancers

As described in Chapter 20, cancer arises from a series of accidental changes in a cell's control systems, each of which is inherited and accumulates progressively in a clone of daughter cells. Many of these sequential changes are the result of mutations that alter the sequence of the DNA encoding an important regulatory protein, such as a protein kinase involved in cell signaling. Other

MBOC7_ptr_ch04_183-252.indd 215 02/12/21 12:47 PM

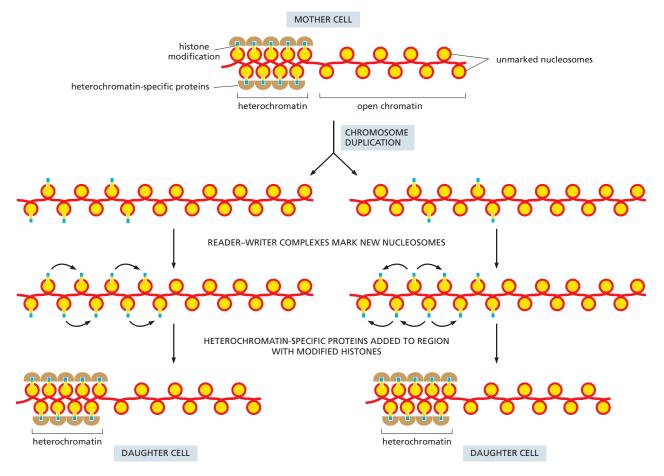

Figure 4–44 The propagation of heterochromatin across generations. After DNA replication, all of the old H3–H4 molecules in the parent chromatin will be passed directly to the daughter DNA helices, half to each daughter (see Figure 5–32). This causes the specially marked nucleosomes in heterochromatin to be inherited, as indicated. Reader–writer complexes can then add the same pattern of histone modification to their new, unmarked nucleosome neighbors, as previously illustrated in Figure 4–40. As the original pattern of histone marks is reestablished, binding sites are created for the heterochromatin-specific non-histone proteins that assemble to reproduce the parent chromatin structure. This type of process is thought to occur for both H3K9me3 and H3K27me3 classes of heterochromatin, as well as for the chromatin at centromeres; it is thought not to occur for the open structure of chromatin at active genes.

mutations that are known to drive tumor progression alter chromatin structure, for example by affecting the readers, writers, or erasers of histone marks—or by altering a chromatin-remodeling complex. Because changes in chromatin can alter gene expression, as we explore further in Chapter 7, this finding is not surprising.

Much more surprising is the discovery that a change in a single amino acid in a histone can cause cancer. As very abundant proteins, each histone is encoded by multiple copies of its histone gene. As a result, any mutation that changes a histone should alter less than 10% of the molecules, meaning that any effect observed must be dominant—overriding the presence of a large excess of the normal histone. Such *oncohistone* mutations appear to be present in about 4% of all tumors, and for a few special cancers they are a predominant cancer driver. In particular, a mutation that changes the lysine at position 27 of histone H3 to a methionine (denoted as H3K27M) is almost universally present in a lethal type of pediatric brain tumor (diffuse intrinsic pontine glioma; DIPG), while also being occasionally found in acute myeloid leukemias and melanomas in adults. This mutation has been shown to exert its dominant effect by binding abnormally

MBOC7_ptr_ch04_183-252.indd 216 02/12/21 12:47 PM

tightly to the PCR2 protein complex, thereby altering the overall pattern and level of H3K27me3 modifications across the human genome (see Figure 4–40), a finding that illustrates the important role that heterochromatin plays in controlling genes.

Summary

In the chromosomes of eukaryotes, DNA is assembled into long strings of nucleosomes, but a variety of different chromatin structures is possible. This variety is based on a large set of reversible covalent modifications of the four histones in the nucleosome core. The modifications include the mono-, di-, and trimethylation of many different lysine side chains, an important reaction that is incompatible with the acetylation that can occur on the same lysines. Specific combinations of the modifications mark many nucleosomes, governing their interactions with other proteins. These marks are read when protein modules that are part of a larger protein complex bind to the modified nucleosomes in a region of chromatin. These reader proteins then attract additional proteins that perform various functions.

Some reader protein complexes contain a histone-modifying enzyme, such as a histone lysine methylase, that "writes" the same mark that the reader recognizes. A reader-writer-remodeling complex of this type can spread a specific form of chromatin along a chromosome. In particular, large regions of condensed heterochromatin are thought to be formed in this way. Heterochromatin is commonly found around centromeres and near telomeres, but it is also present at many other positions in chromosomes. The tight packaging of DNA into heterochromatin usually silences the genes within it.

The phenomenon of position effect variegation provides strong evidence for the inheritance of condensed states of chromatin from one cell generation to the next. A similar mechanism appears to be responsible for maintaining the specialized chromatin at centromeres. More generally, the ability to propagate specific chromatin structures across cell generations makes possible an epigenetic cell memory process that plays a role in maintaining the set of different cell states required by complex multicellular organisms.

THE GLOBAL STRUCTURE OF CHROMOSOMES

Having discussed the DNA and protein molecules from which the chromatin fiber is made, we now turn to the organization of the chromosome on a more global scale and the way in which its various domains are arranged in space. Packaged into nucleosomes, a typical human chromosome would be able to span the nucleus thousands of times. Thus, a higher level of folding is required, even in interphase chromosomes. As we shall see, this higher-order packaging involves the folding of each chromosome into a series of large loops through a process catalyzed by ring-shaped SMC (structural maintenance of chromosomes) protein complexes.

We begin this section by describing some unusual chromosomes that can be easily visualized. Exceptional though they are, these special cases reveal features that are relevant for all eukaryotic chromosomes. Next, we describe how the interphase chromosomes are arranged in the mammalian cell nucleus. Finally, we discuss the mechanisms that cause a special compaction of chromosomes during their passage from interphase to mitosis.

Chromosomes Are Folded into Large Loops of Chromatin

An early insight into the structure of the chromosomes in interphase cells came from studies of the stiff and enormously extended chromosomes in growing amphibian oocytes (immature eggs). These very unusual **lampbrush chromosomes** (the largest chromosomes known), paired in preparation for meiosis, are clearly visible in the light microscope, where they are seen to contain a

MBOC7_ptr_ch04_183-252.indd 217 02/12/21 12:47 PM

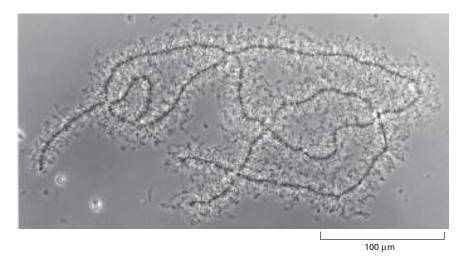

Figure 4-45 A light micrograph of lampbrush chromosomes in an amphibian oocyte. Early in oocyte differentiation, each chromosome replicates to begin meiosis, and the homologous replicated chromosomes pair to form this highly extended structure. Each lampbrush chromosome consists of two aligned sets of paired sister chromatids, with large chromatin loops as a prominent feature. The chromosome set contains thousands of loops, each containing a particular DNA sequence that remains extended in the same manner as the oocyte grows, producing huge amounts of RNA for storage in the oocyte. The lampbrush chromosome stage persists for months or years, while the oocyte builds up a supply of materials required for its ultimate development into a new individual. These chromosomes were first described in 1878. (Courtesy of Joseph G. Gall.)

series of large chromatin loops emanating from a linear chromosomal axis (Figure 4-45).

Figure 4–46 summarizes lampbrush chromosome structure. Each chromosome is formed by a very long DNA helix packed into chromatin, and it is joined to a sister DNA helix, called a *sister chromatid*. Most of the DNA is located near the junction of the two chromatids, and it is highly condensed and transcriptionally inert; this DNA serves to organize each chromatid along a linear chromosome axis. In contrast, the highly transcribed regions of the DNA extend from the axis as large loops, which range in length from tens of thousands to hundreds of thousands of nucleotide pairs.

Meiotic chromosomes are found to adopt the lampbrush chromosome state in the growing oocytes of all vertebrates, except for mammals. However, if incubated in amphibian oocyte cytoplasm, human sperm chromosomes will form lampbrush chromosomes. This reveals that chromosomes are highly dynamic structures that can restructure in different environments.

Polytene Chromosomes Are Uniquely Useful for Visualizing Chromatin Structures

Further early insight into the structure of interphase chromosomes came from a second unusual type of cell—the *polytene cells* of flies, such as the fruit fly *Drosophila*. Some special cells, in many organisms, grow abnormally large through

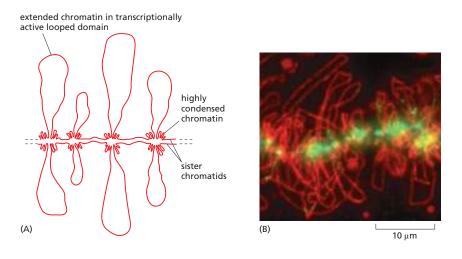

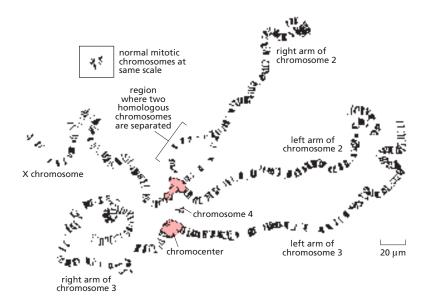

Figure 4-46 The structure of lampbrush chromosomes. (A) Model for a small portion of one pair of sister chromatids. Two identical DNA double helices are aligned side by side, packaged into different types of chromatin (see Figure 4-45). (B) Merged light micrographs of the lampbrush chromosomes in an axolotl (a type of salamander), stained for transcriptionally active (RNA polymerase, red) and inactive (DNA containing 5-methyl C, green) chromatin regions. The loops are stiff and extended because they are being unusually highly transcribed, with RNA polymerases spaced only about 100 nucleotide pairs apart. Most of the rest of the DNA in each chromosome (the great majority) remains condensed and is located close to the chromatid axis. (B. from G.T. Morgan et al., Chromosome Res. 20:925-942, 2012. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch04_183-252.indd 218 02/12/21 12:47 PM

multiple cycles of DNA synthesis without cell division. Such cells, containing increased numbers of standard chromosomes, are said to be *polyploid*. In the salivary glands of fly larvae, this process is taken to an extreme degree, creating huge cells that contain hundreds or thousands of copies of the genome. Moreover, in this case, all the copies of each chromosome are aligned side by side in exact register, like drinking straws in a box, to create giant **polytene chromosomes**. These chromosomes allow features to be detected that are thought to be shared with ordinary interphase chromosomes but are normally hard to see.

When polytene chromosomes from a fly's salivary glands are viewed in the light microscope, distinct alternating dark *bands* and light *interbands* are visible (Figure 4-47), each formed from a thousand identical DNA sequences arranged side by side in register. About 95% of the DNA in polytene chromosomes is in bands, and 5% is in interbands. A very thin band can contain 3000 nucleotide pairs, while a thick band may contain 200,000 nucleotide pairs in each of its chromatin strands. The chromatin in each band appears dark because the DNA is more condensed than the DNA in interbands; it may also contain a higher concentration of proteins (Figure 4-48).

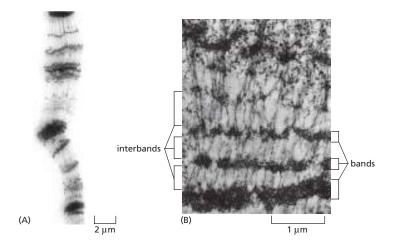

Figure 4-47 The entire set of polytene chromosomes in one Drosophila salivary cell. In this drawing of a light micrograph, the giant chromosomes have been spread out for viewing by squashing them against a microscope slide. Drosophila has four chromosomes, and there are four different chromosome pairs present. But each chromosome is tightly paired with its homolog (so that each pair appears as a single structure), which is not true in most nuclei (except in meiosis). Each chromosome has undergone multiple rounds of replication, and the homologs and all their duplicates have remained in exact register with each other, resulting in huge chromatin cables many DNA strands thick

The four polytene chromosomes are normally linked together by heterochromatic regions near their centromeres that aggregate to create a single large chromocenter (pink region). In this preparation, however, the chromocenter has been split into two halves by the squashing procedure used. (Adapted from T.S. Painter, J. Hered. 25:465–476, 1934. With permission from Oxford University Press.)

Figure 4-48 Micrographs of polytene chromosomes from Drosophila salivary glands. (A) Light micrograph of a portion of a chromosome. The DNA has been stained with a fluorescent dve. but a reverse image is presented here that renders the DNA black rather than white; the bands are clearly seen to be regions of increased DNA concentration. This chromosome has been processed by a high-pressure treatment so as to show its distinct pattern of bands and interbands more clearly. (B) An electron micrograph of a small section of a Drosophila polytene chromosome seen in thin section. Bands of very different thickness can be readily distinguished, separated by interbands, which contain less condensed chromatin. (A, adapted from D.V. Novikov et al., Nat. Methods 4:483-485, published 2007 by Nature Publishing Group. Reproduced with permission of SNCSC; B, courtesy of Veikko Sorsa.)

MBOC7_ptr_ch04_183-252.indd 219 02/12/21 12:47 PM

There are approximately 3700 bands and 3700 interbands in the complete set of *Drosophila* polytene chromosomes, a number that should be compared to the 14,000 genes in this fruit fly (see Table 1–2, p. 29). The bands can be recognized by their different thicknesses and spacings, and each one has been given a number to generate a chromosome "map" that has been indexed to the finished genome sequence of *Drosophila*.

The *Drosophila* polytene chromosomes provide a good starting point for examining how chromatin is organized on a large scale. In the previous section, we saw that there can be many forms of chromatin, each of which contains nucleosomes with a different combination of modified histones. Specific sets of non-histone proteins assemble on these nucleosomes to affect biological function in different ways. Recruitment of some of these non-histone proteins can spread for long distances along the DNA, imparting a similar chromatin structure to broad tracts of the genome (see Figure 4–39A). At low resolution, the interphase chromosome can therefore be considered as a mosaic of chromatin structures, each containing particular nucleosome modifications associated with a particular set of non-histone proteins.

Polytene chromosomes allow us to see details of this mosaic of domains in the light microscope and to observe some of the changes associated with gene expression. For example, by staining *Drosophila* polytene chromosomes with antibodies and using ChIP (chromatin immunoprecipitation) analysis (see Chapter 8), the locations of specific histone modifications and non-histone proteins in chromatin can be mapped across the entire *Drosophila* DNA sequence. These results suggest that three types of repressive chromatin predominate in this organism, along with two types of chromatin on actively transcribed genes, and that each type is associated with a different complex of non-histone proteins. In addition to these five major chromatin types, other more minor forms of chromatin appear to be present, each of which may be differently regulated and have distinct roles in the cell. Much remains to be learned about the molecular structures that underlie these findings.

Chromosome Loops Decondense When the Genes Within Them Are Expressed

When an organism containing polytene chromosomes progresses from one developmental stage to another, distinctive *chromosome puffs* arise and old puffs recede in its polytene chromosomes as new genes become expressed and old ones are turned off (**Figure 4-49**). From inspection of each puff when it is relatively small and the banding pattern is still discernible, it seems that most puffs arise from the decondensation of a single chromosome band.

The individual chromatin fibers that make up a puff can be visualized with an electron microscope. In favorable cases, loops are seen. When genes in the loop are not expressed, the loop assumes a thickened, condensed structure, but when gene expression is occurring, the loop becomes more extended—resembling the loops seen in lampbrush chromosomes. This again demonstrates that chromosome structures are dynamic, as we had concluded from lampbrush experiments.

Mammalian Interphase Chromosomes Occupy Discrete Territories in the Nucleus, with Their Heterochromatin and Euchromatin Distributed Differently

Light microscopy after chromosome painting reveals that each of the 46 interphase chromosomes in a human cell occupies its own discrete territory within the nucleus; that is, the chromosomes are not extensively entangled with one another (Figure 4–50). However, pictures such as these present only an average view of the DNA in each chromosome. By staining a heterochromatic region of a chromosome, one finds that it is often closely associated with the nuclear envelope,

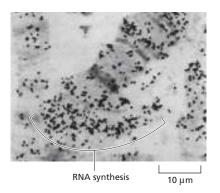

Figure 4-49 RNA synthesis in polytene chromosome puffs. An autoradiograph of a single puff in a polytene chromosome from the salivary glands of the freshwater midge Chironomus tentans, the fly in which polytene chromosomes were first discovered in 1881. As outlined in Chapter 1 and described in detail in Chapter 6. the first step in gene expression is the synthesis of an RNA molecule using the DNA as a template. The decondensed portion of the chromosome is undergoing RNA synthesis and has become labeled with ³H-uridine, an RNA precursor molecule that is incorporated into growing RNA chains. The black dots are produced where the radioactivity emitted interacts with an overlying photographic emulsion. (From J.J. Bonner and M.L. Pardue, Cell 12:227-234, 1977. With permission from Elsevier.)

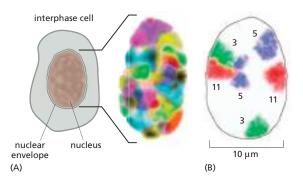

Figure 4–50 Simultaneous visualization of the chromosome territories for all of the human chromosomes in a single interphase nucleus. Here, the DNA probes for a specific chromosome are labeled so as to fluoresce at specific wavelengths, and a different combination of dyes is used to label the probes for each chromosome so that each chromosome fluoresces differently. This "chromosome painting" technique allows DNA–DNA hybridization to be used to detect each chromosome, as in Figure 4–11. Three-dimensional reconstructions were then produced. (A) Viewed in a fluorescence microscope, the nucleus is seen to be filled with a patchwork of discrete colors. (B) To highlight their distinct locations, three sets of chromosomes are singled out: chromosomes 3, 5, and 11. Note that pairs of homologous chromosomes, such as the two copies of chromosome 3, are not generally located in the same position. (Adapted from M.R. Hübner and D.L. Spector, *Annu. Rev. Biophys.* 39:471–489, 2010. With permission from Annual Reviews.)

regardless of the chromosome examined. And probes that preferentially stain chromosomal regions containing a high density of active genes reveal that most of these regions extend out from the territory of each chromosome into the nucleoplasm and away from the nuclear envelope (Figure 4–51).

Studies of mammalian cells also show that highly folded loops of chromatin expand to occupy an increased volume when a gene within them is expressed. For example, **Figure 4–52** demonstrates how a large, highly transcribed gene in a human cell, which appears as a dot in an interphase cell when inactive, is extended just like a lampbrush loop by its extensive transcription.

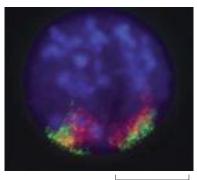

As we shall discuss in Chapter 6, the interior of the nucleus is very heterogeneous, with functionally different regions that are produced by *biomolecular condensates* specialized to speed different biochemical processes—such as RNA synthesis, RNA splicing, and DNA replication. The fact that a section of a chromosome can move away from its chromosome territory, as we have just seen, helps cells to use nuclear condensates to accelerate various reactions. These condensates include the nucleolus specialized for producing ribosomes and the nuclear speckles involved in RNA production (see pp. 353–357).

Although much is known about DNA transcription and how genes are turned on and off at the molecular level, we defer that discussion to Chapters 6 and 7. Here we instead concentrate on the mechanism that packages the long linear DNA molecule in each mammalian chromosome into a series of loops in the cell nucleus.

A Biochemical Technique Called Hi-C Reveals Details of Chromosome Organization

As explained in Chapter 8, new automated technologies allow scientists to determine massive amounts of DNA sequence at low cost. A powerful *chromosome conformation capture* method that exploits this ability, *Hi-C*, has made it possible

Figure 4–51 The looping out of gene-rich regions of the genome from chromosome territories. In this light micrograph of a cell nucleus, DNA has been fluorescently labeled with a dye (blue). In addition, by using a chromosome painting technique, all of the DNA of one particular mouse chromosome has been stained *green*, and the gene-rich regions of that same chromosome have been stained *red*. Figure 4-52 A large gene forms a highly extended chromosome loop when highly expressed in a human interphase cell. The thyroglobulin gene codes for the extracellular protein thyroglobulin, which is secreted by thyroid gland cells. This gene is both unusually large (270 kb) and unusually highly transcribed. DNA and RNA hybridization techniques reveal that it forms a large stiff loop that extends into the interior of the nucleus from each of the two homologous chromosomes that express it. (A) An image of a cell that does not make thyroglobulin reveals the thyroglobulin locus as a small dot. (B) An image of a thyroid gland cell expressing the gene. Experiments demonstrate that these loops retract back to a dot if RNA synthesis is blocked by drug treatment. (Courtesy of Irina Solovei, Ludwig-Maximilians University, Munich.)

to assess the frequency with which any two genomic loci—whether along a single chromosome or between chromosomes—are held together (Figure 4–53).

Application of the Hi-C technique has revealed some fundamental features of chromosome organization. One is that each interphase chromosome occupies its own discrete territory within the nucleus. That is, the genomic loci within a chromosome contact each other more often than they do the loci on different chromosomes, showing that the chromosomes are not extensively entangled. This was expected from the earlier findings of discrete chromosome territories by light microscopy, as just described. In addition, Hi-C and related chromosome capture methods have revealed that the interphase chromosome is folded into a long series of *topologically associated domains*, or *TADs*, in which any two

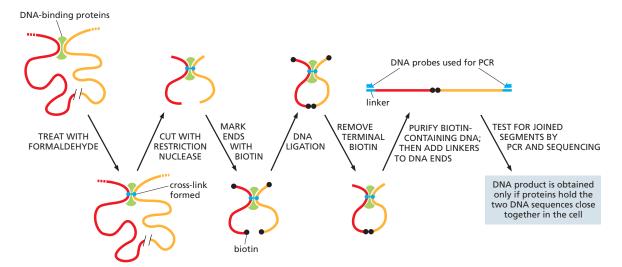

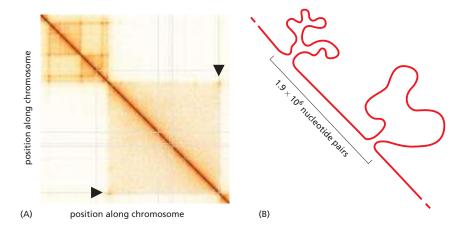

Figure 4–53 Use of Hi-C to determine the frequency with which any two DNA sequences are adjacent to each other in chromosomes. In the Hi-C technique, cells are treated with cross-linking agents such as formaldehyde to create covalent DNA-protein–DNA cross-links, as indicated. The DNA is then treated with an enzyme (called a restriction nuclease) that chops the DNA into many pieces, cutting at strictly defined nucleotide sequences and forming sets of identical "cohesive ends" (see Figure 8–23). These ends are then marked by the incorporation of biotinylated nucleotides, so as to enable their selective purification later. Any two DNA ends can become covalently joined if incubated with a DNA ligase enzyme. But importantly, prior to the DNA ligation step shown, the DNA is diluted so that only the fragments that have been kept in close proximity to each other (through cross-linking) are likely to join. After the ligation step, the cross-links are reversed, and all the biotin at unligated DNA ends is removed. This allows the newly ligated fragments of DNA to be selectively purified through their binding to streptavidin beads, amplified by PCR (polymerase chain reaction), and then sequenced (by methods described in Chapter 8). The results, combined with knowledge of the complete DNA sequence of each chromosome, generate detailed models for the conformation of chromosomes.

MBOC7_ptr_ch04_183-252.indd 222 02/12/21 12:47 PM

DNA sequences are much more likely to encounter each other than they are to encounter DNA sequences outside of that domain. Their locations along each chromosome can be derived from the series of squares observed in plots of results like those in Figure 4–54. These reveal that DNA segments in a contiguous set (those within a TAD) have a relatively high probability (*dark color* in the figure) of becoming ligated together. And because any one DNA segment in a TAD can become ligated to many others in that TAD, one concludes that the chromatin inside each TAD must be folded in a way that allows its DNA sequences to frequently encounter any other DNA sequence within it.

Extensive data of this type have led to the conclusion that all interphase chromosomes are organized as a long linear series of folded *looped domains* of chromatin, with the DNA in each loop being compacted, but highly mobile. Although a typical loop in a human chromosome might contain between 50,000 and 200,000 nucleotide pairs of DNA, loops of a million nucleotide pairs also exist, and there appear to be roughly 10,000 loops in the human genome. How these loops are formed is the subject that we discuss next.

Chromosomal DNA is Organized into Loops by Large Protein Rings

The enormously long DNA molecules that form chromosomes must be organized if they are to be effective as the carriers of the genetic information that every cell requires to survive and multiply. A mechanism for creating this organization that appears to be universal involves the folding of the DNA into loops by an SMC protein complex, a large protein ring that both binds to and encircles the DNA double helix. These rings—which function similarly in archaea, bacteria, and eukaryotes—have the structure illustrated in Figure 4–55A. The subunits that give the complex its name are the pair of long, coiled-coil SMC (structural maintenance of chromosomes) proteins. Each long SMC protein chain folds upon itself to form a globular ATPase domain, and two of these chains join together to create a ring that is large enough for DNA that is packaged in chromatin to readily pass through it (compare ring size to nucleosomes in Figure 4–55B).

By associating with additional proteins, the two ATPase domains in an SMC protein complex allow the ring to motor rapidly along DNA. Why this type of activity is useful to the cell is perhaps most easily understood by considering the role of these rings in bacteria. The bacterial chromosome is a large circular DNA molecule that is duplicated from a single DNA replication origin to produce two identical DNA circles. Each of these two daughter chromosomes must be transferred to a different daughter cell when the parent cell divides. The required segregation process begins when a series of SMC protein complexes is loaded onto the DNA near the DNA replication origin; these protein rings then create a loop on each new DNA double helix and proceed to move continuously along the

Figure 4-54 Chromosome capture techniques reveal topologically associated, looped domains in interphase chromosomes. (A) A plot of results for a small portion of human chromosome 8 in human fibroblasts. The intensity of the orange color denotes the number of times that any DNA sequence from a 2-kilobase (kb) region whose chromosome position is indicated on the X axis was found to be ligated to any DNA sequence from a 2-kb region whose chromosome position is indicated on the Y axis (see Figure 4-53). The darker the color, the more often these two regions were located in close proximity to each other inside the cell. The strong stripe along the diagonal results from the fact that DNA sequences that are very close to each other along the linear chromosome have a high probability of interacting with each other.

The largest square reveals a topologically associated domain (TAD), with the dots in the diagram (highlighted here by black arrowheads) showing the unusually persistent contacts between the DNA sequences located at the base of a simple looped domain that contains about a million nucleotide pairs. The box at the upper left shows a more complex "nested" TAD structure. Here, the multiple dots are interpreted as a "bouquet" of smaller loop subdomains gathered together to form a larger folding domain, as indicated in (B), which schematically compares the structures inferred for the two different TADs. [A, Courtesy of Oliver Rando, University of Massachusetts Medical School. The data for human chromosome 8 (125,034,652 to 126,909,657) are from N. Krietenstein et al., Mol. Cell 78:554-565, 2020.]

MBOC7_ptr_ch04_183-252.indd 223 02/12/21 12:47 PM

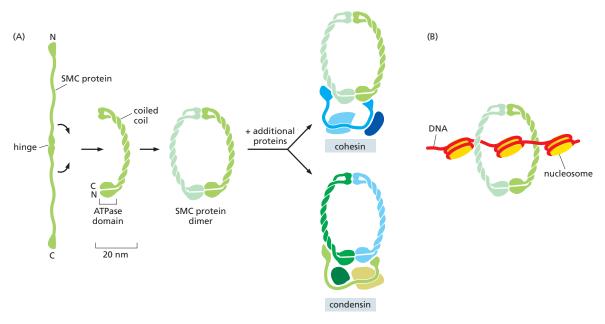

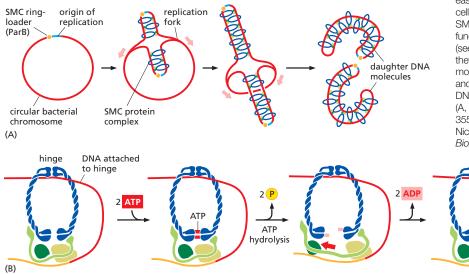

Figure 4–55 SMC protein complex formation. (A) These structures have important roles in bacteria, archaea, and eukaryotes. As indicated, their core forms from a large protein of 1000 to 1500 amino acids that folds on itself to form a antiparallel coiled-coil with a globular head; two of these molecules then pair to produce a ring structure with a flexible hinge at one end and an ATP-binding domain at the other end. Additional subunits are then added to form either cohesin or condensin, as indicated. (B) An SMC complex compared to the size of a nucleosome.

DNA, cleanly separating the two daughter chromosomes from each other in the manner illustrated in Figure 4–56A. A model proposed to explain this movement is likewise shown (Figure 4–56B).

The DNA molecules that form eukaryotic chromosomes are generally much longer than those that form bacterial chromosomes, and many different DNA replication origins are therefore needed to copy each chromosome (see Chapter 5). Moreover, the accurate separation of two daughter chromosomes involves a process that is considerably more elaborate than the process in bacteria (described in Chapter 17). The SMC protein complexes have therefore diversified during the evolution of eukaryotes to play two different roles, each of which is critical for the function of chromosomes.

bacterial chromosomes. (A) A DNA sequence adjacent to the origin of replication on the circular Bacillus subtilis chromosome binds a protein (ParB) that repeatedly loads bacterial SMC protein complexes. These complexes then use the energy released by repeated cycles of ATP hydrolysis to travel along the entire chromosome to the site where the two DNA replication forks that were formed at the origin meet, thereby partitioning the two very large daughter DNA molecules in a way that allows them to be easily segregated into two different daughter cells. (B) One model proposed to explain how SMC complexes move. These complexes function as sophisticated protein machines (see Figure 3-72), and it is still uncertain how they drive loop formation. In this "inchworm" model, the two ATPase domains separate and reioin in sequence to motor along the DNA; for an alternative, see Figure 17-25B. (A, adapted from X. Wang et al., Science 355:524-527, 2017; B, adapted from M.H. Nichols and V.G. Corces, Nat. Struct. Mol. Biol. 25:906-910, 2018.) **DNA** loop

Figure 4-56 How moving SMC-containing

protein rings function to separate

MBOC7_ptr_ch04_183-252.indd 224 02/12/21 12:47 PM

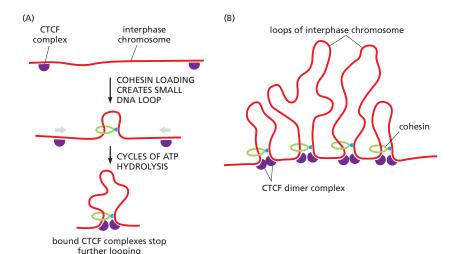

Figure 4–57 Moving cohesin rings divide eukaryotic interphase chromosomes into a long series of looped domains. (A) The SMC protein complex cohesin, aided by accessory proteins that are not shown, is loaded onto chromatin to form a small DNA loop. Then, propelled by the energy of ATP hydrolysis (see Figure 4-56B), moving cohesin rings continually enlarge the loop, stopping when they encounter a DNA-bound CTCF complex on each side. A protein complex containing the CTCF dimer then becomes the loop base. (B) Schematic illustration of a portion of an interphase chromosome, organized as a series of looped domains.

During interphase, it is the SMC protein complex named **cohesin** that is critical (we shall see that its relative, *condensin*, functions in mitosis). Cohesin is thought to function in a manner similar to that of its bacterial counterpart, except that the cohesin rings are loaded at multiple sites along a chromosome and serve to fold the linear chromosomal DNA molecule into a long series of loops. As illustrated in **Figure 4–57A**, because the traveling cohesin rings tend to stop at specific sites on the DNA, a loop is formed at a specific place on a chromosome. In vertebrates, these favored stop sites are usually marked by the sequence-specific DNA-binding protein *CTCF*, which forms a protein complex that not only stalls or stops the moving cohesin ring, but also holds the two ends of each DNA loop together.

As will be described in Chapter 7, CTCF is one of the *insulator proteins* that helps to maintain discrete domains of chromatin function (see Figure 7–28). It can also serve as part of a barrier that prevents the spreading of chromatin structures by reader-writer remodeling complexes (see Figure 4–39A). Because this protein commonly demarks the base of each looped domain in a chromosome, one can propose a general model for the structure of eukaryotic chromosomes that accounts for observations made in a diverse range of organisms. In this view, not only is the very long, linear DNA molecule that forms the core of each chromosome folded into a series of looped domains, but also the chromatin in each domain will often differ with respect to both its non-histone proteins and its covalent histone modifications—just as it does in the insect polytene chromosomes discussed earlier (Figure 4–57B). These differences are important because they help to control the selective expression of genes.

It is satisfying to find that a model recently derived for vertebrate interphase chromosomes is consistent with the observations made many decades ago on *Drosophila* polytene chromosomes and on the lampbrush chromosomes of amphibians. However, new methods that allow the organization of interphase chromosomes to be determined in single cells reveal that—unlike the situation in those special cases—most of the loops in a typical interphase chromosome are unstable: although those loops form in favored locations, their positions can rapidly fluctuate. In addition, loops can form within loops (see Figure 4–54). Thus, during interphase a typical eukaryotic chromosome has a structure that is highly dynamic.

Euchromatin and Heterochromatin Separate Spatially in the Nucleus

The same Hi-C experiments that reveal the boundaries of looped domains (see Figure 4–54) also detect a lower frequency of nearest neighbor contacts between DNA segments that can be either on different chromosomes or far away from

MBOC7_ptr_ch04_183-252.indd 225 02/12/21 12:47 PM

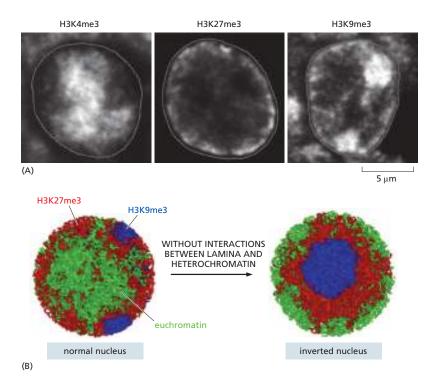

Figure 4-58 The distribution of heterochromatin and euchromatin in an interphase nucleus. (A) In this nucleus from a mouse fibroblast, the chromatin has been stained with antibodies to histones that contain three different covalent modifications: one recognizes the H3K4me3 mark in the active genes in euchromatin (see Table 4-2), and the others recognize either the H3K27me3 or the H3K9me3 silencing mark in heterochromatin (see Table 4-2). This segregation of heterochromatin toward the nuclear periphery is found in nearly all animal cells. (B) Polymer modeling of chromatin can explain the near-universal arrangement of the three types of chromatin in A, as well as the unusual arrangement that is observed in the special inverted nuclei of the photoreceptor cells of nocturnal animals, by assuming that the only difference in the latter nuclei is the absence of lamina-heterochromatin interactions. These models assume that chromatin-chromatin interactions are strongest between heterochromatin of the HK9me3 type, weaker between the heterochromatin of the H3K27me3 type, and nonexistent between euchromatin. (A, courtesy of Irina Solovei; B, adapted from M. Falk et al., Nature 570:395-399, 2019. Reproduced with permission of SNCSC.)

each other with respect to DNA sequence on the same chromosome. Analysis of these segments reveals that every chromosome can be subdivided into two compartments, within which loci preferentially interact with each other but avoid interactions with the other compartment, regardless if from the same or another chromosome. It has been shown that these two compartments closely match euchromatin and heterochromatin with regard to their gene richness, gene expression, and replication timing.

This finding is consistent with the images obtained by treating cells with antibody probes that preferentially stain these different types of chromatin; this staining produces a striking picture of the interphase nucleus, in which H3K9me3 heterochromatin is preferentially located near the nuclear periphery, H3K27me3 heterochromatin interior to that, and the open chromatin clustered in more interior regions (Figure 4–58A).

The tendency of heterochromatin to self-associate can be mimicked in experiments with reconstituted chromatin fragments that contain the abundant, heterochromatin-specific protein HP1 (see Figure 4–40). These experiments have led to a proposal that a phenomenon that resembles phase separation holds heterochromatin together, mediated by many fluctuating weak interactions (Figure 4–59). This self-associating heterochromatin is then tethered to the nuclear periphery through a set of proteins that link heterochromatic

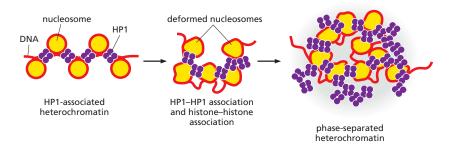

Figure 4–59 A model for the compaction and clustering of heterochromatin through fluctuating, weak associations that drive phase separation. According to this proposal, both associations between HP1 molecules and between transiently exposed histone amino acids in deformed nucleosomes contribute to the multiple weak interactions that condense heterochromatin. For a discussion of phase separation, see p. 173. (Adapted from S. Sanulli et al., Cold Spring Harb. Symp. Quant. Biol. 84:217–225, 2019.)

MBOC7_ptr_ch04_183-252.indd 226 02/12/21 12:47 PM

regions marked with specific histone modifications to the nuclear lamina. And the lamina is in turn anchored to the inner rim of the nuclear envelope by a set of transmembrane proteins embedded in the inner nuclear membrane (see Figure 16–67).

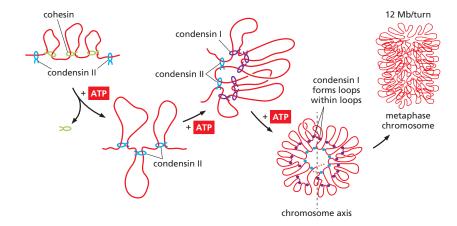

The functional relevance of heterochromatin positioning at the nuclear periphery remains unclear. However, this nuclear arrangement of chromatin prevails in eukaryotes with only one known exception—the so-called *inverted* nuclei of the rod cells of nocturnal mammals, in which euchromatin and heterochromatin have exchanged positions. The very center of the rod nucleus is occupied by highly condensed inert chromatin, whereas active euchromatin with ongoing gene expression is squeezed to the nuclear periphery (Figure 4–58B). Surprisingly, despite the inversion, the rod nuclei remain fully functional and are highly transcriptionally active.

Mitotic Chromosomes Are Highly Condensed

Having discussed the dynamic structure of interphase chromosomes, we now turn to **mitotic chromosomes**. The chromosomes from nearly all eukaryotic cells become readily visible by light microscopy during mitosis, when they coil up to form highly condensed structures. This condensation reduces the length of a typical interphase chromosome by about tenfold, and it produces a dramatic change in chromosome appearance.

A typical mitotic chromosome at the metaphase stage of mitosis was shown in Figure 4–18 (for the stages of mitosis, see Panel 17–1, pp. 1048–1049). The two DNA molecules produced by DNA replication during interphase of the cell-division cycle are separately folded to produce two *sister chromatids* held together at their centromeres. These chromosomes are normally covered with a variety of molecules, including large amounts of RNA–protein complexes. Once this covering has been stripped away, each chromatid can be seen in electron micrographs to be organized into loops of chromatin emanating from a central scaffolding (Figure 4–60).

Recent experiments have begun to decipher how interphase chromosomes condense to form mitotic chromosomes. The process is intimately connected with the progression of the cell cycle that will be the focus of Chapter 17. It begins in early M phase when gene expression shuts down, and specific modifications are made to histones that may help to reorganize the chromatin. Most of the ring-shaped *cohesin* proteins that organize the interphase chromosomes make way for their **condensin** relatives, whose ATP-driven movements—aided by the DNA cutting-and-rejoining enzyme topoisomerase II—drive the compaction and form a linear chromosome axis (**Figure 4–61**). This axis is highly enriched in both condensin II and topoisomerase II, and it is the combined action of these two enzymes that is believed to separate each chromosome into two sister chromatids.

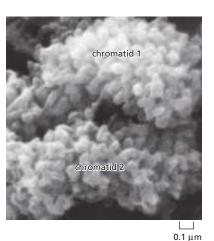

Figure 4–60 A scanning electron micrograph of a region near one end of a typical mitotic chromosome. Each knoblike projection is believed to represent

the tip of a separate looped domain. Note that the two identical paired chromatids can be clearly distinguished. (From M.P. Marsden and U.K. Laemmli, *Cell* 17:849–858, 1979. With permission from Elsevier.)

Figure 4-61 How chromosomes fold in M phase. There are two types of condensins in mammalian cells, designated as condensins I and II. As cells enter mitosis, the interphase organization of the chromatin loops that is created by cohesin (see Figure 4-57) is lost within minutes. A different SMC protein, condensin II, now begins to form very large new chromatin loops by a similar ATP-driven mechanism. These new loops are organized radially by a central chromosome axis, and as the condensin II loops grow ever larger in size, a second set of loops is formed by condensin I inside them. This "loops within loops" organization, when combined with an ever-tighter winding of the chromatin loops around the mitotic chromosome axis, creates the compact chromatin that is observed in the final metaphase chromosome. Not shown are the special cohesin molecules that hold the two sister chromatids together; as described in Chapter 17, these cohesins are released only at anaphase. (Adapted from J.H. Gibcus et al., Science 359:eaao6135, 2018.)

MBOC7_ptr_ch04_183-252.indd 227 02/12/21 12:47 PM

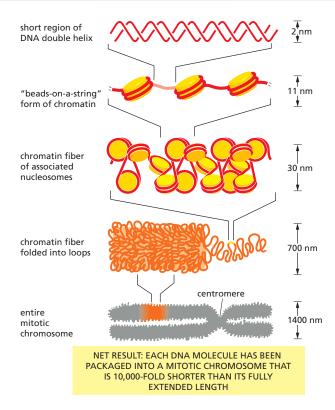

Figure 4–62 Chromosome organization. This model shows some of the levels of chromatin packaging that give rise to the highly condensed mitotic chromosome.

Mitotic chromosome condensation can be thought of as the final level in a hierarchy of chromosome packaging (Figure 4-62). This final DNA folding serves at least two important purposes. First, when condensation is complete (in metaphase), sister chromatids have been disentangled from each other and lie side by side. Thus, the sister chromatids can easily separate when the mitotic apparatus begins pulling them apart. Second, the compaction of chromosomes protects the relatively fragile DNA molecules from being broken as they are pulled to separate daughter cells by the mitotic spindle. These and other critical details of mitosis will be fully discussed in Chapter 17.

Summary

Chromosomes are generally decondensed during interphase, so that the details of their structure are difficult to visualize. Notable exceptions are the specialized lampbrush chromosomes of vertebrate oocytes and the polytene chromosomes in the giant secretory cells of insects. Studies of these two types of interphase chromosomes reveal that each long DNA molecule in a chromosome is divided into a large number of discrete domains organized as long loops of chromatin that are compacted by further folding. When genes contained in a loop are expressed, the loop unfolds and allows the cell's machinery access to the DNA. New studies using sensitive biochemical techniques show that the interphase chromosomes in a wide range of eukaryotes are also folded into a series of looped domains, and they reveal a central folding role for ring-shaped, cohesin protein complexes.

Interphase chromosomes occupy discrete territories in the cell nucleus; that is, they are not extensively intertwined. Much of the chromatin in interphase exists as loosely folded fibers of nucleosomes. However, this open chromatin is interrupted by stretches of heterochromatin, in which the nucleosomes are subjected to additional packing that renders the DNA resistant to gene expression. Heterochromatin has the important property that its type of nucleosome packing can be directly inherited during chromosome replication, thereby generating an epigenetic form of cell memory. Two major classes of heterochromatin contain different

MBOC7_ptr_ch04_183-252.indd 228 02/12/21 12:47 PM

covalent histone marks propagated by distinct reader-writer enzyme complexes. Constitutive heterochromatin is formed on repeated DNA sequences; marked by H3K9me3, it is found in large blocks that remain unchanged in and around centromeres and near telomeres. This heterochromatin blocks both gene expression and genetic recombination. Facultative heterochromatin is present at many other positions on chromosomes, where its presence can be controlled so as to have a critical role in regulating genes. H3K27me3 heterochromatin is always facultative; in contrast, only some of the H3K9me3 heterochromatin is facultative, depending on its location.

The interior of the nucleus is highly dynamic, with heterochromatin often positioned near the nuclear envelope and loops of chromatin moving away from their chromosome territory when genes are very highly expressed. This reflects the existence of nuclear subcompartments, where different sets of biochemical reactions are facilitated by an increased concentration of selected proteins and RNAs.

During mitosis, gene expression shuts down and all chromosomes adopt a highly condensed, organized conformation in a process that begins early in M phase. This condensation packages the two DNA molecules of each replicated chromosome as two separately folded chromatids, and it is catalyzed by the ATP-driven movements of ring-shaped, condensin protein complexes.

HOW GENOMES EVOLVE

In this final section of the chapter, we provide an overview of some of the ways that genes and genomes have evolved over time to produce the vast diversity of modern-day life-forms on our planet. The complete sequencing of the genomes of thousands of organisms is revolutionizing our view of the process of evolution, uncovering an astonishing wealth of information about not only family relationships among organisms, but also the molecular mechanisms by which evolution has proceeded.

Much of life's chemistry is shared between all organisms, from bacteria to humans, and it is thus not surprising that genes with similar functions can be found in a diverse range of living things. But the great revelation of the past 40 years has been the extent to which the actual nucleotide sequences of many genes have been conserved. Homologous genes—that is, genes that are similar in both their nucleotide sequence and function because of a common ancestry—can often be recognized across vast phylogenetic distances. Unmistakable homologs of many human genes are present in organisms as diverse as nematode worms, fruit flies, yeasts, plants, and even bacteria. In many cases, the resemblance is so close that, for example, the protein-coding portion of a yeast gene can be substituted with its human homolog—even though humans and yeast are separated by more than a billion years of evolutionary history.

Now that human genome sequencing is being carried out at the population level, with more than a million genomes thus far available for comparison, the extent to which natural selection constrains our own DNA sequence is being analyzed in intimate detail. The results are useful for revealing exactly which bits of our genome are functional. In addition, the data are advancing the field of *precision medicine*, with health implications both for the individuals whose genomes are sequenced and for their future generations.

As emphasized in Chapter 3, the recognition of sequence similarity has become a major tool for inferring gene and protein function. Although a sequence match does not guarantee similarity in function, it has proved to be an excellent clue. Thus, it is often possible to predict the function of genes in humans for which no biochemical or genetic information is available simply by comparing their nucleotide sequences with the sequences of genes that have been characterized in other more readily studied organisms.

In general, the sequences of individual genes are much more tightly conserved than is overall genome structure. Features of genome organization such as genome size, number of chromosomes, order of genes along chromosomes, abundance and size of introns, and amount of repetitive DNA are found to differ

MBOC7_ptr_ch04_183-252.indd 229 02/12/21 12:47 PM

greatly when comparing distant organisms, as does the number of genes that each organism contains.

Genome Comparisons Reveal Functional DNA Sequences by Their Conservation Throughout Evolution

A first obstacle in interpreting the sequence of the 3.1 billion nucleotide pairs in the human genome is the fact that the nucleotide sequence of most of it (about 90%) is probably functionally unimportant. The regions of the genome that code for the amino acid sequences of proteins (the exons) are typically found in short segments (median size about 130 nucleotide pairs), small islands in a sea of DNA whose exact nucleotide sequence is thought to be mostly of little consequence. This arrangement can make it difficult to identify all the exons in a stretch of DNA, and it is often hard also to determine exactly where a gene begins and ends.

One very important approach to deciphering our genome is to search for DNA sequences that are closely similar between different species, on the principle that DNA sequences that have a function are much more likely to be conserved than those without a function. For example, humans and mice are thought to have diverged from a common mammalian ancestor about 90×10^6 years ago, which is long enough for the majority of nucleotides in their genomes to have been changed by random mutational events. Consequently, the only regions that will have remained closely similar in the two genomes are those in which mutations would have impaired function and put the animals carrying them at a disadvantage, resulting in their elimination from the population by natural selection. Such closely similar pieces of DNA sequence are known as conserved DNA regions. In addition to revealing those DNA sequences that encode functionally important exons and RNA molecules, these conserved regions will include regulatory DNA sequences as well as DNA sequences with functions that are not yet known but which are inferred to be somehow important. In contrast, most nonconserved DNA regions will reflect DNA whose sequence is much less likely to be critical for function.

The power of this method can be increased by including in such comparisons the genomes of large numbers of species whose genomes have been sequenced, such as rat, chicken, fish, dog, and chimpanzee, as well as mouse and human. By revealing in this way the results of a very long natural "experiment," lasting for hundreds of millions of years, such comparative DNA sequencing studies have highlighted some of the most interesting regions in our genome. The comparisons reveal that about 4.5% of the human genome consists of *multispecies conserved sequences*. To our great surprise, only about one-fourth of these sequences code for proteins (see Table 4–1, p. 194). Most of the remaining conserved sequences consist of DNA that is thought to contain clusters of protein-binding sites involved in gene regulation, while others produce RNA molecules that are not translated into protein but are important for other reasons.

When the DNA sequences of hundreds of thousands of individual humans are compared, an additional 5% of our genome shows a reduced variation in the human population, which implies that the sequences in this 5% of the genome are also important. Taken together, these analyses suggest that only about 10% of the human genome contains nucleotide sequences that truly matter.

The important question of how much of the DNA sequence of the human genome is functionally relevant was briefly confused by a set of high-profile publications that appeared in 2012 from a large, federally funded US genome project named ENCODE. These publications, which reported the results of a massive survey using sensitive assays that can detect the presence of RNA molecules in cells at extremely low levels, reported that 76% of the total DNA sequence in human cells is transcribed to produce RNA molecules. Even though many of these transcripts were found at levels of less than a single RNA molecule per cell, the ENCODE scientists used such data to assert that most of human DNA is functional, with very little "junk." This claim received widespread publicity, along with their belief that our genome contains tens of thousands of previously undetected genes that produce RNA molecules that do not code for protein.

MBOC7_ptr_ch04_183-252.indd 230 02/12/21 12:47 PM

As previously stated, there is a strong scientific consensus that most of the human genome consists of DNA whose nucleotide sequence is not relevant to biological function—being the so-called junk. This conclusion rests on the finding that natural selection fails to preserve these sequences in the face of the inevitable random changes to genomes that occur over time, as can be seen both when different species are compared and from detailed analyses of human variation. The fact that these DNA sequences nevertheless produce an occasional RNA molecule can be explained by the occurrence of background "noise" in gene expression. Although gene expression is very accurate, it is not perfect, and biochemical errors occasionally occur. Such errors are to be expected, and so long as they are kept at a low level, they are thought to have little or no consequence for the cell.

Genome Alterations Are Caused by Failures of the Normal Mechanisms for Copying and Maintaining DNA, as Well as by Transposable DNA Elements

Evolution depends on accidents and mistakes followed by nonrandom survival. Most of the genetic changes that occur result simply from failures in the normal mechanisms by which genomes are copied or repaired when damaged, although the movement of transposable DNA elements (discussed shortly) also plays an important part. As we will explain in Chapter 5, the mechanisms that maintain DNA sequences are remarkably precise—but errors will occur. DNA sequences are inherited with such extraordinary fidelity that typically, along a given line of descent, only about one nucleotide pair in a thousand is randomly changed in the human germ line every million years. Even so, in a population of 10,000 diploid individuals, every possible nucleotide substitution will have been "tried out" on about 20 occasions in the course of a million years—a short span of time in relation to the evolution of species.

Errors in DNA replication, DNA recombination, or DNA repair can lead either to simple local changes in DNA sequence—so-called point mutations such as the substitution of one base pair for another—or to large-scale genome rearrangements such as deletions, duplications, inversions, and translocations of DNA from one chromosome to another. In addition to these rare failures of the genetic machinery, genomes contain mobile DNA elements that are an important source of genomic change (see Table 5-3, p. 286). These transposable DNA elements (transposons) are parasitic DNA sequences that can spread within the genomes they colonize. In the process, they often disrupt the function or alter the regulation of existing genes. On occasion, they have created altogether novel genes through fusions between transposon sequences and segments of existing genes. Over long periods of evolutionary time, DNA transposition events have profoundly affected genomes, so much so that nearly half of the DNA in the human genome consists of recognizable relics of past transposition events (Figure 4-63). Even more of our genome is thought to have been derived from transpositions occurring so long ago ($>10^8$ years) that, due to the accumulation of mutations, the sequences can no longer be traced to transposons.

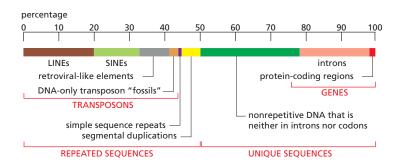

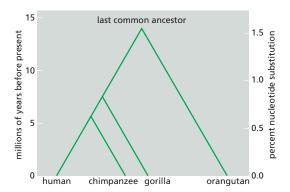

Figure 4-63 A representation of the nucleotide sequence content of the sequenced human genome. The LINEs (long interspersed nuclear elements), SINEs (short interspersed nuclear elements), retroviral-like elements, and DNA-only transposons are mobile genetic elements that have multiplied in our genome by replicating themselves and inserting the new copies in different positions. These mobile genetic elements are discussed in Chapter 5 (see Table 5-3, p. 286). Simple sequence repeats are short nucleotide sequences (fewer than 14 nucleotide pairs) that are repeated again and again for long stretches. Segmental duplications are large blocks of DNA sequence (1000-200,000 nucleotide pairs) that are present at two or more locations in the genome Most of the highly repeated blocks of DNA in heterochromatin have not vet been completely sequenced; therefore, about 10% of human DNA sequences are not represented in this diagram. The Genome Sequences of Two Species Differ in Proportion to the Length of Time Since They Have Separately Evolved

The differences between the genomes of all species alive today have accumulated over more than 3 billion years. Although we lack a direct record of changes over time, scientists can reconstruct the process of genome evolution from detailed comparisons of the genomes of contemporary organisms.

The basic organizing framework for comparative genomics is the phylogenetic tree. A simple example is the tree describing the divergence of humans from the great apes (Figure 4–64). The primary support for this tree comes from comparisons of genome sequences. For example, comparisons between the sequences of human genes or proteins and those of the great apes typically reveal the fewest differences between human and chimpanzee and the most between human and orangutan.

For closely related organisms such as humans and chimpanzees, it is relatively easy to reconstruct the gene sequences of the extinct, last common ancestor of the two species (Figure 4–65). The close similarity between human and chimpanzee

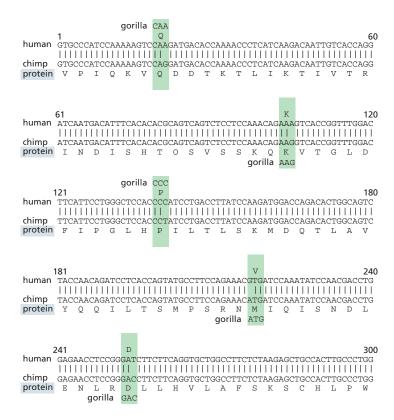

Figure 4-64 A phylogenetic tree showing the relationship between humans and the great apes based on nucleotide sequence data. As indicated, the sequences of homologous portions of the genomes of all four species are estimated to differ from the sequence of the genome of their last common ancestor by a little over 1.5%. Because changes occur independently on both diverging lineages, pairwise comparisons will reveal twice the sequence divergence from the last common ancestor. For example, human-chimpanzee comparisons show divergences of approximately 1.2% (Modified from F.C. Chen and W.H. Li, Am. J. Hum. Genet. 68:444-456, 2001.)

Figure 4-65 Tracing the ancestral sequence from a sequence comparison of the coding regions of human and chimpanzee leptin genes. Reading left to right and top to bottom, a continuous 300-nucleotide segment of a leptin-coding gene is illustrated. Leptin is a hormone that regulates food intake and energy utilization in response to the adequacy of fat reserves. As indicated by the codons boxed in green, only 5 nucleotides (of 441 total) differ between the two species. Moreover, in only one of the five positions does the difference in nucleotide lead to a difference in the encoded amino acid. For each of the five variant nucleotide positions, the corresponding sequence in the gorilla is also indicated. In two cases, the gorilla sequence agrees with the human sequence, while in three cases it agrees with the chimpanzee sequence.

What was the sequence of the leptin gene in the last common ancestor? The most economical assumption is that evolution has followed a pathway requiring the minimum number of mutations consistent with the data. Thus, it seems likely that the leptin sequence of the last common ancestor was the same as the human and chimpanzee sequences when they agree. When they disagree, the gorilla seguence can be used as a tiebreaker, a conclusion that should be tested by including the sequences from other great apes. For convenience, only the first 300 nucleotides of the leptincoding sequences are given. The remaining 141 are identical between humans and chimpanzees.

MBOC7_ptr_ch04_183-252.indd 232 02/12/21 12:47 PM

genes is mainly due to the short time that has been available for the accumulation of mutations in the two diverging lineages, rather than to functional constraints that have kept the sequences the same. Evidence for this view comes from the observation that the human and chimpanzee genomes are nearly identical even where there is no functional constraint on the nucleotide sequence—such as in the third position of "synonymous" codons (codons specifying the same amino acid but differing in their third nucleotide).

For much less closely related organisms, such as humans and chickens (which have evolved separately for about 300 million years), the sequence conservation found in genes is almost entirely due to **purifying selection** (that is, selection that eliminates individuals carrying mutations that interfere with important genetic functions), rather than to an inadequate time for mutations to occur.

Phylogenetic Trees Constructed from a Comparison of DNA Sequences Trace the Relationships of All Organisms

Phylogenetic trees based on molecular sequence data can be compared with the fossil record, and we get our best view of evolution by integrating the two approaches. The fossil record remains essential as a source of absolute dates, which are based on radioisotope decay in the rock formations in which each fossil is found. Because the fossil record has many gaps, however, precise divergence times between species are difficult to establish, even for species that leave good fossils with a distinctive morphology.

Phylogenetic trees whose timing has been calibrated according to the fossil record suggest that changes in the sequences of particular genes or proteins tend to occur at a nearly constant rate, although rates that differ from the norm by as much as twofold are observed in particular lineages. This provides us with a molecular clock for evolution—or rather a set of molecular clocks corresponding to different categories of DNA sequence. As in the example in Figure 4-66, the clock runs most rapidly and regularly in sequences that are not subject to purifying selection. These include portions of introns that lack splicing or regulatory signals, the third position in synonymous codons, and genes that have been irreversibly inactivated by mutation (the so-called pseudogenes). The clock runs most slowly for sequences that are subject to strong functional constraints; for example, the amino acid sequences of proteins such as histones that engage in specific interactions with large numbers of other proteins and whose structure is therefore highly constrained, or the nucleotide sequences that encode the RNA subunits of the ribosome, on which all protein synthesis depends.

Occasionally, rapid change is seen in a previously highly conserved sequence. As discussed later in this chapter, such episodes are especially interesting because they are thought to reflect periods of strong positive selection for mutations that have conferred a selective advantage in the particular lineage where the rapid change occurred.

The pace at which molecular clocks run during evolution is determined not only by the degree of purifying selection but also by the mutation rate. Notably, in animals, although not in plants, clocks based on functionally unconstrained mitochondrial DNA sequences run much faster than clocks based on functionally unconstrained nuclear sequences, because the mutation rate in animal mitochondria is exceptionally high.

Figure 4-66 The very different rates of evolution of exons and introns, as illustrated by comparing a portion of the mouse and human leptin genes. Starting at top left and ending at bottom right, the DNA sequences of one exon and its adjacent intron are compared for human and mouse leptin genes. Positions where the sequences differ by a single nucleotide substitution are boxed in green, and positions that differ by the addition or deletion of nucleotides are boxed in vellow. Note that, thanks to purifying selection, the coding sequence of the exon is much more conserved than is the adjacent intron sequence.

MBOC7_ptr_ch04_183-252.indd 233 02/12/21 12:47 PM

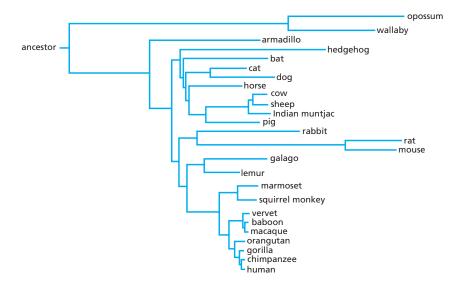

Figure 4–67 A phylogenetic tree showing the evolutionary relationships of some present-day mammals. The length of each line is proportional to the number of neutral substitutions; that is, nucleotide changes at sites where there is assumed to be no purifying selection. (Adapted from G.M. Cooper et al., Genome Res. 15:901–913, 2005. With permission from Cold Spring Harbor Laboratory Press.)

Categories of DNA for which the clock runs fast are most informative for recent evolutionary events; the mitochondrial DNA clock has been used, for example, to chronicle the divergence of the Neanderthal lineage from that of modern *Homo sapiens*. To study ancient evolutionary events, one must examine DNA for which the clock runs unusually slowly; thus, the divergence of the major branches of the tree of life—bacteria, archaea, and eukaryotes—has been deduced from study of the sequences specifying ribosomal RNA.

In general, molecular clocks, appropriately chosen, have a finer time resolution than that of the fossil record, and they are a more reliable guide to the detailed structure of phylogenetic trees than are classical methods of tree construction, which are based on family resemblances in anatomy and embryonic development. For example, the precise family tree of great apes and humans was not settled until sufficient molecular sequence data accumulated in the 1980s to produce the pedigree shown previously in Figure 4–64. And with huge amounts of DNA sequence now determined from a wide variety of mammals, much better estimates of our relationship to them are being obtained (Figure 4–67).

A Comparison of Human and Mouse Chromosomes Shows How the Structures of Genomes Diverge

As would be expected, the human and chimpanzee genomes are much more alike than are the human and mouse genomes, even though all three genomes are roughly the same size and contain nearly identical sets of genes. Mouse and human lineages have had approximately 90 million years to diverge through accumulated mutations, versus 6 million years for humans and chimpanzees. In addition, rodent lineages (represented by the rat and the mouse in Figure 4–67) have unusually fast molecular clocks and have diverged from the human lineage more rapidly than otherwise expected.

While the way that the genome is organized into chromosomes is almost identical between humans and chimpanzees, this organization has diverged greatly between humans and mice. According to rough estimates, a total of about 180 chromosome breakage-and-rejoining events have moved large blocks of DNA sequence in the human and mouse lineages since they last shared a common ancestor. As a result, although the number of chromosomes is similar in the two species (23 per haploid genome in the human versus 20 in the mouse), their overall structures differ greatly. Even so, there are many large blocks of DNA in which the gene order is the same in the human and the mouse. These stretches of conserved gene order in chromosomes are referred to as regions of *synteny*. Figure 4–68 illustrates the extent of this synteny by showing how segments of

MBOC7_ptr_ch04_183-252.indd 234 02/12/21 12:47 PM

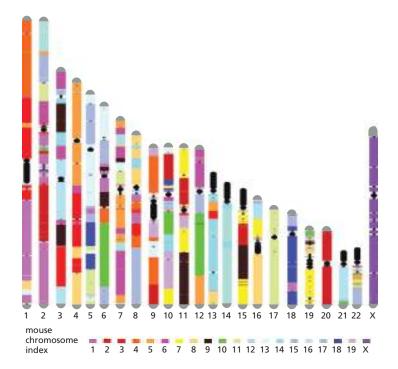

Figure 4–68 Synteny between human and mouse chromosomes. In this diagram, the human chromosome set is shown, with each part of each chromosome colored according to the mouse chromosome with which it is syntenic. The color coding used for each mouse chromosome is shown at the bottom of the figure.

Heterochromatic highly repetitive regions (such as centromeres) that are difficult to sequence cannot be mapped in this way; these are colored *black*. (Adapted from E.E. Eichler and D. Sankoff, *Science* 301:793–797, 2003. With permission from AAAS.)

mouse chromosomes map onto the human chromosome set. For much more distantly related vertebrates, such as chicken and human, the number of breakage-and-rejoining events has been much greater, and the regions of synteny are much shorter; in addition, these regions are often hard to discern because of the divergence of the DNA sequences they contain.

An unexpected conclusion from a detailed comparison of the complete mouse and human genome sequences, confirmed by subsequent comparisons between the genomes of other vertebrates, is that small blocks of DNA sequence are being deleted from and added to genomes at a surprisingly rapid rate. Thus, if we assume that our common ancestor had a genome of human size (about 3.1 billion nucleotide pairs), mice would have lost a total of about 45% of that genome from accumulated deletions during the past 90 million years, while humans would have lost about 25%. However, substantial sequence gains from many small chromosome duplications and from the multiplication of transposons have compensated for these deletions. As a result of this series of gains and losses, the size of our genome is thought to be practically unchanged from that of the last common ancestor of humans and mice, while the mouse genome is smaller by only about 0.4 billion nucleotides.

Good evidence for the loss of DNA sequences in small blocks during evolution can be obtained from a detailed comparison of regions of synteny in the human and mouse genomes. The comparative shrinkage of the mouse genome can be clearly seen from such comparisons, with the net loss of sequences scattered throughout the long stretches of DNA that are otherwise homologous (Figure 4–69).

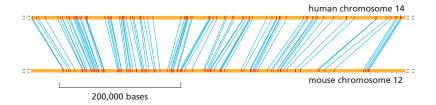

Figure 4-69 Comparison of a syntenic portion of mouse and human genomes. About 90% of the two genomes can be aligned in this way. Note that while there is an identical order of the matched index sequences (red marks), there has been a net loss of DNA in the mouse lineage that is interspersed throughout the entire region. This type of net loss is typical for all such regions, and it accounts for the fact that the mouse genome contains 14% less DNA than does the human genome. (Adapted from Mouse Genome Sequencing Consortium, Nature 420:520-562 published 2002 by Nature Publishing Group. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch04_183-252.indd 235 02/12/21 12:47 PM

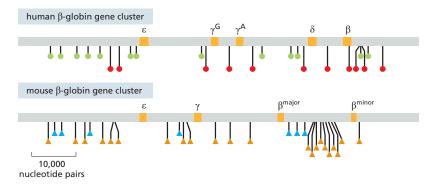

Figure 4–70 A comparison of the β -globin gene cluster in the human and mouse genomes, showing the locations of transposable elements. This stretch of the human genome contains five functional β -globin–like genes (*orange*); the comparable region from the mouse genome has only four. The positions of the human Alu sequences are indicated by *green circles*, and the positions of the human L1 sequences are indicated by *red circles*.

The mouse genome contains different but related transposable elements: the positions of B1 elements (which are related to the human Alu sequences) are indicated by blue triangles, and the positions of the mouse L1 elements (which are related to the human L1 sequences) are indicated by orange triangles. The absence of transposable elements from the globin structural genes can be attributed to purifying selection, which would have eliminated any insertion that compromised gene function. (Courtesy of Ross Hardison and Webb Miller.)

DNA is added to genomes both by the spontaneous duplication of chromosomal segments that are typically tens of thousands of nucleotide pairs long (as will be discussed shortly) and by insertion of new copies of active transposons. Most transposition events are duplicative, because the original copy of the transposon stays where it was when a copy inserts at the new site; see, for example, Figure 5–59. Comparison of the DNA sequences derived from transposons in the human and the mouse readily reveals some of the sequence additions (Figure 4–70). In contrast, the nucleotide sequences and positions of the transposons in human and chimpanzee are very similar, indicating that their movement occurred before the two species diverged.

It remains a mystery why all mammals have maintained genome sizes of roughly 3 billion nucleotide pairs that contain nearly identical sets of genes, even though 90% of this DNA appears not to be under sequence-specific functional constraints.

The Size of a Vertebrate Genome Reflects the Relative Rates of DNA Addition and DNA Loss in a Lineage

In more distantly related vertebrates, genome size can vary considerably, apparently without a drastic effect on the organism or its number of genes. Thus, the chicken genome, at 1 billion nucleotide pairs, is only about one-third the size of the mammalian genome, even though it contains nearly the same number of genes. An extreme example is the puffer fish, *Fugu rubripes* (Figure 4–71A), which has a tiny genome for a vertebrate (0.4 billion nucleotide pairs compared to 1 billion or more for most other fish). The small size of the *Fugu* genome is largely due to the small size of its introns and intergenic regions. Specifically, *Fugu* introns, as well as other noncoding segments of the *Fugu* genome, lack the repetitive DNA that makes up a large portion of the genomes of most well-studied vertebrates. Nevertheless, the positions of the *Fugu* introns between the exons of each gene are almost the same as in mammalian genomes (Figure 4–72).

While initially a mystery, we now have a simple explanation for such large differences in genome size between similar organisms: because all vertebrates experience a continual process of DNA loss and DNA addition, the size of a genome merely depends on the balance between these opposing processes

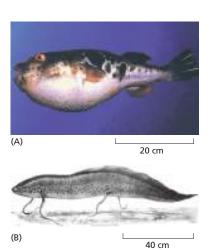

Figure 4–71 Two fish with very different genome sizes. The puffer fish, Fugu rubripes (A), has a genome size that is 300 times smaller than that of the West African lungfish, Protopterus annectens (B). (A, Courtesy of Byrappa Venkatesh; B, History and Art Collection/Alamy Stock Photo.)

MBOC7_ptr_ch04_183-252.indd 236 02/12/21 12:47 PM

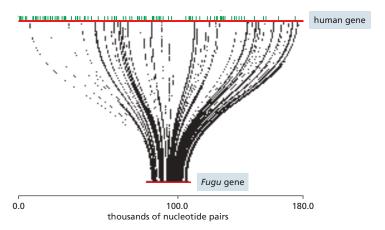

Figure 4–72 Comparison of the genomic sequences of the human and Fugu genes encoding the protein huntingtin. Both genes (indicated in red) contain 67 short exons that align in 1:1 correspondence to one another; these exons are connected by curved lines. The human gene is 7.5 times larger than the Fugu gene (180,000 versus 24,000 nucleotide pairs). The size difference is entirely due to larger introns in the human gene. The larger size of the human introns is due in part to the presence of retrotransposons (discussed in Chapter 5), whose positions are represented by green vertical lines; the Fugu introns lack retrotransposons. In humans, mutation of the huntingtin gene causes Huntington's disease, an inherited neurodegenerative disorder. (Adapted from S. Baxendale et al., Nat. Genet. 10:67–76, published 1995 by Nature Publishing Group. Reproduced with permission of SNCSC.)

acting over millions of years. Suppose, for example, that in the lineage leading to *Fugu*, the rate of DNA addition happened to slow greatly. Over long periods of time, this would result in a major "cleansing" from this fish genome of those DNA sequences whose loss could be tolerated. The result is an unusually compact genome, relatively free of junk and clutter, but retaining through purifying selection the vertebrate DNA sequences that are functionally important. This makes *Fugu*, with its 400 million nucleotide pairs of DNA, a valuable resource for genome research aimed at understanding humans.

At the other end of the scale, some fish—such as the primitive-looking lungfish—have enormous genomes, more than 300 times the size of that of *Fugu* and 30 times the size of that of humans (**Figure 4–71B**). Most of the extra DNA consists of transposons and other repeated DNA sequences, suggesting that genome additions have greatly exceeded losses in this lineage.

Multispecies Sequence Comparisons Identify Many Conserved DNA Sequences of Unknown Function

The mass of DNA sequence now in freely accessible databases (hundreds of billions of nucleotide pairs) provides a rich resource that scientists can mine for many purposes. This information can be used not only to unscramble the evolutionary pathways that have led to modern organisms, but also to provide insights into how cells and organisms function. Perhaps the most remarkable discovery in this realm comes from the observation that a striking amount of DNA sequence that does not code for protein has been conserved during mammalian evolution (see Table 4–1, p. 194). This is most clearly revealed when we align and compare DNA synteny blocks from many different species, thereby identifying large numbers of so-called *multispecies conserved sequences*: some of these code for protein, but most of them do not.

Many of the conserved sequences that do not code for protein are now known to produce untranslated RNA molecules, such as the thousands of *long noncoding RNAs* (*lncRNAs*) that are thought to have important functions in regulating gene transcription. As we shall also see in Chapter 7, many others are regions of DNA scattered throughout the genome that directly bind proteins

MBOC7_ptr_ch04_183-252.indd 237 02/12/21 12:47 PM

involved in gene regulation. But the function of much of the conserved noncoding DNA remains a mystery. This enigma highlights how much more we need to learn about the fundamental biological mechanisms that operate in animals and other complex organisms, and its solution is certain to have profound consequences for medicine.

How can cell biologists tackle the mystery of noncoding conserved DNA? Traditionally, attempts to determine the function of a puzzling DNA sequence begin by looking at the consequences of its experimental disruption. But many DNA sequences that are crucial for an organism in the wild can be expected to have no noticeable effect on its phenotype under laboratory conditions: what is required for a mouse to survive in a laboratory cage is very much less than what is required for it to succeed in nature. Moreover, calculations based on population genetics reveal that just a tiny selective advantage—less than a 0.1% difference in survival—can be enough to strongly favor retaining a particular DNA sequence over evolutionary time spans. One should therefore not be surprised to find that many conserved DNA sequences can be deleted from the mouse genome without any noticeable effect on that mouse in a laboratory.

Changes in Previously Conserved Sequences Can Help Decipher Critical Steps in Evolution

Given genome sequence information, we can tackle another intriguing question: What alterations in our DNA have made humans so different from other animalsor for that matter, what makes any individual species so different from its relatives? For example, as soon as both the human and the chimpanzee genome sequences became available, scientists began searching for DNA sequence changes that might account for the striking differences between us and chimpanzees. With 3.1 billion nucleotide pairs to compare in the two species, this might seem an impossible task. But the job was made much easier by confining the search to 35,000 clearly defined multispecies conserved sequences (a total of about 5 million nucleotide pairs), representing parts of the genome that are most likely to be functionally important. Though these sequences are conserved strongly, they are not conserved perfectly, and when the version in one species is compared with that in another they are generally found to have drifted apart by a small amount corresponding simply to the time elapsed since the last common ancestor. In a small proportion of cases, however, one sees signs of a sudden evolutionary spurt. For example, some DNA sequences that have been highly conserved in other mammalian species are found to have accumulated nucleotide changes exceptionally rapidly during the 6 million years of human evolution since we diverged from the chimpanzees. These human accelerated regions (HARs) are thought to reflect functions that have been especially important in making us different in some useful way.

About 50 such sites were identified in one study, one-fourth of which were located near genes associated with neural development. The sequence exhibiting the most rapid change (18 changes between human and chimpanzee, compared to only two changes between chimpanzee and chicken) was examined further and found to encode a 118-nucleotide noncoding RNA molecule, HAR1F (human accelerated region 1F), that is produced in the human cerebral cortex at a critical time during brain development. The function of this HAR1F RNA is not yet known, but findings of this type are stimulating research studies that may shed light on crucial features of the human brain.

A related approach in the search for the important mutations that contributed to human evolution likewise begins with DNA sequences that have been conserved during mammalian evolution, but rather than screening for accelerated changes in individual nucleotides, it focuses instead on chromosome sites that have experienced deletions in the 6 million years since our lineage diverged from that of chimpanzees. More than 500 such sequences—conserved among other species but deleted in humans—have been discovered. Each deletion removes an average of 95 nucleotides of DNA sequence. Only one of these deletions

MBOC7_ptr_ch04_183-252.indd 238 02/12/21 12:47 PM

affects a protein-coding region: the rest are thought to alter regions that affect how nearby genes are expressed, an expectation that has been experimentally confirmed in a few cases. A large proportion of the presumed regulatory regions identified in this way lie near genes that affect neural function and/or near genes involved in steroid signaling, suggesting that changes in the nervous system and in immune or reproductive functions have played an especially important role in human evolution.

Mutations in the DNA Sequences That Control Gene Expression Have Driven Many of the Evolutionary Changes in Vertebrates

The vast hoard of genomic sequence data now being accumulated can be explored in many other ways to reveal events that happened even hundreds of millions of years ago. For example, one can attempt to trace the origins of the regulatory elements in DNA that have played critical parts in vertebrate evolution. One such study began with the identification of nearly 3 million noncoding sequences, averaging 28 base pairs in length, that have been conserved in recent vertebrate evolution while being absent in more ancient ancestors. Each of these special noncoding sequences is likely to represent a functional innovation peculiar to a particular branch of the vertebrate family tree, and most of them are thought to consist of regulatory DNA that governs the expression of a neighboring gene. Given full genome sequences, one can identify the genes that appear most likely to have fallen under the sway of these novel regulatory elements. By comparing many different species, with known divergence times, one can also estimate when each such regulatory element came into existence as a conserved feature.

The findings suggest remarkable evolutionary differences between the various functional classes of genes (Figure 4-73). Conserved regulatory elements that originated early in vertebrate evolution—that is, more than about 300 million years ago, which is when the mammalian lineage split from the lineage leading to birds and reptiles—seem to be mostly associated with genes that code for transcription regulatory proteins and for proteins with roles in organizing embryonic development. Then came an era when the regulatory DNA innovations arose next to genes coding for receptors for extracellular signals. Finally, over the course of the past 100 million years, the regulatory innovations seem to have been concentrated in the neighborhood of genes coding for proteins (such as protein kinases) that function to modify other proteins post-translationally.

Many questions remain to be answered about these phenomena and what they mean. One possible interpretation is that the logic—the circuit diagram—of the gene regulatory network in vertebrates was established early, and that more recent evolutionary change has mainly occurred through the tuning of quantitative parameters. This could help to explain why, among the mammals, for

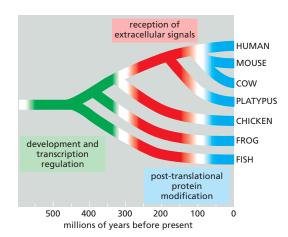

Figure 4–73 The types of changes in gene regulation inferred to have predominated during the evolution of our vertebrate ancestors. To produce the information summarized in this plot, wherever possible the type of gene regulated by each conserved noncoding sequence was inferred from the identity of its closest protein-coding gene. The time when each conserved sequence became fixed in the vertebrate lineage was then used to derive the conclusions shown. (Based on C.B. Lowe et al., *Science* 333:1019–1024, 2011.)

MBOC7_ptr_ch04_183-252.indd 239 02/12/21 12:47 PM

example, the basic body plan—the topology of the tissues and organs—has been largely conserved.

Gene Duplication Also Provides an Important Source of Genetic Novelty During Evolution

Evolution depends on the creation of new genes, as well as on the modification of those that already exist. How does this occur? When we compare organisms that seem very different—a primate with a rodent, for example, or a mouse with a fish—we rarely encounter genes in the one species that have no homolog in the other. Genes without homologous counterparts are relatively scarce even when we compare such divergent organisms as a mammal and a worm. On the other hand, we frequently find gene families that have different numbers of members in different species. To create such families, genes have been repeatedly duplicated, and the copies have then diverged to take on new functions that often vary from one species to another.

Gene duplication occurs at high rates in all evolutionary lineages, contributing to the vigorous process of DNA addition discussed previously. In a detailed study of spontaneous duplications in yeast, duplications of 50,000–250,000 nucleotide pairs were commonly observed, most of which were tandemly repeated. These appeared to result from DNA replication errors that led to the inexact repair of double-strand chromosome breaks. A comparison of the human and chimpanzee genomes reveals that, since the time that these two organisms diverged, such *segmental duplications* have added about 5 million nucleotide pairs to each genome every million years, with an average duplication size being about 50,000 nucleotide pairs (although there are some duplications five times larger). In fact, if one counts nucleotides, duplication events have created more differences between our two species than have single-nucleotide substitutions.

Duplicated Genes Diverge

What is the fate of newly duplicated genes? In most cases, there is presumed to be little or no selection—at least initially—to maintain the duplicated state because either copy can provide an equivalent function. Hence, many duplication events are likely to be followed by loss-of-function mutations in one or the other gene. This cycle would functionally restore the one-gene state that preceded the duplication. Indeed, there are many examples in contemporary genomes where one copy of a duplicated gene can be seen to have become irreversibly inactivated by multiple mutations. Over time, the sequence similarity between such a **pseudogene** and the functional gene whose duplication produced it would be expected to be eroded by the accumulation of many mutations in the pseudogene—the homologous relationship eventually becoming undetectable.

An alternative fate for gene duplications is for both copies to remain functional, while diverging in their sequence and pattern of expression, thus taking on different roles. This process of *duplication and divergence* almost certainly explains the presence of large families of genes with related functions in biologically complex organisms, and it is thought to play a critical role in the evolution of increased biological complexity. An examination of many different eukaryotic genomes suggests that the probability that any particular gene will undergo a duplication event that spreads to most or all individuals in a species is approximately 1% every million years.

Whole-genome duplications offer particularly dramatic examples of the duplication-divergence cycle. A whole-genome duplication can occur quite simply: all that is required is one round of genome replication in a germ-line cell lineage without a corresponding cell division. Initially, the chromosome number simply doubles. Such abrupt increases in the ploidy of an organism are common, particularly in fungi and plants. After a whole-genome duplication, all genes exist as duplicate copies. However, unless the duplication event occurred so recently that there has been little time for subsequent alterations in genome structure,

MBOC7_ptr_ch04_183-252.indd 240 02/12/21 12:47 PM

the results of a series of segmental duplications—occurring at different times—are hard to distinguish from the end product of a whole-genome duplication. In mammals, for example, the role of whole-genome duplications versus a series of piecemeal duplications of DNA segments is quite uncertain. Nevertheless, it is clear that a great deal of gene duplication has occurred in the distant past.

Analysis of the genome of the zebrafish, in which at least one whole-genome duplication is thought to have occurred hundreds of millions of years ago, has cast some light on the process of gene duplication and divergence. Although many duplicates of zebrafish genes appear to have been lost by mutation, a significant fraction—perhaps as many as 30-50%—have diverged functionally while both copies have remained active. In many cases, the most obvious functional difference between the duplicated genes is that they are expressed in different tissues or at different stages of development. One attractive theory to explain such an end result imagines that different, mildly deleterious mutations occur quickly in both copies of a duplicated gene set. For example, one copy might lose expression in a particular tissue as a result of a regulatory mutation, while the other copy loses expression in a second tissue. After such an occurrence, both gene copies would be required to provide the full range of functions that were once supplied by a single gene; hence, both copies would now be protected from loss through inactivating mutations. Over a longer period, each copy could then undergo further changes through which it could acquire new, specialized features.

The Evolution of the Globin Gene Family Shows How DNA Duplications Contribute to the Evolution of Organisms

The globin gene family provides an especially good example of how DNA duplication generates new proteins, and its evolutionary history has been worked out particularly well. The unmistakable similarities in amino acid sequence and structure among the present-day globins indicate that they all must derive from a common ancestral gene, even though some are now encoded by widely separated genes in the mammalian genome.

We can reconstruct some of the past events that produced the various types of oxygen-carrying hemoglobin molecules by considering the different forms of the protein in organisms at different positions on the tree of life. A molecule like hemoglobin was necessary to allow multicellular animals to grow to a large size, because large animals cannot simply rely on the diffusion of oxygen through the body surface to oxygenate their tissues adequately. But oxygen plays a vital part in the life of nearly all living organisms, and oxygen-binding proteins homologous to hemoglobin can be recognized even in plants, fungi, and bacteria. In animals, the simplest oxygen-carrying molecule is a globin polypeptide chain of about 150 amino acids that is found in many marine worms, insects, and primitive fish. The hemoglobin molecule in more complex vertebrates, however, is composed of two kinds of globin chains. It appears that about 500 million years ago, just before fish and mammals diverged from their common ancestor, a series of gene mutations and duplications occurred. These events established two slightly different globin genes in the genome of each individual, coding for α -globin and β -globin chains that associate to form a hemoglobin molecule consisting of two α chains and two β chains (Figure 4–74). The four oxygen-binding sites in the $\alpha_2\beta_2$ molecule interact, allowing a cooperative allosteric change in the molecule as it binds and releases oxygen, which enables hemoglobin to take up and release oxygen more efficiently than can the single-chain version.

Still later, during the evolution of mammals, the β -chain gene apparently underwent duplication and mutation to give rise to a second β -like chain that

Figure 4–74 A comparison of the structure of one-chain and four-chain globins. The four-chain globin shown is hemoglobin, which is a complex of two α -globin and two β -globin chains. The one-chain globin present in some primitive vertebrates represents an intermediate in the evolution of the four-chain globin. With oxygen bound it exists as a monomer; without oxygen it dimerizes. MBOC7_ptr_ch04_183-252.indd 241 02/12/21 12:47 PM

is synthesized specifically in the fetus. The resulting hemoglobin molecule has a higher affinity for oxygen than that of adult hemoglobin and thus helps in the transfer of oxygen from the mother to the fetus. The gene for the new β -like chain subsequently duplicated and mutated again to produce two new genes, ϵ and γ , the ϵ chain being produced earlier in development (to form $\alpha_2\epsilon_2$) than the fetal γ chain, which forms $\alpha_2\gamma_2$. A duplication of the adult β -chain gene occurred still later, during primate evolution, to give rise to a δ -globin gene and thus to a minor form of hemoglobin ($\alpha_2\delta_2$) that is found only in adult primates (Figure 4–75).

Each of these duplicated genes has been modified by point mutations that affect the properties of the final hemoglobin molecule, as well as by changes in regulatory regions that determine the timing and level of expression of the gene. As a result, each globin is made in different amounts at different times of human development.

The history of these gene duplications is reflected in the arrangement of hemoglobin genes in the genome. In the human genome, the genes that arose from the original β gene are arranged as a series of homologous DNA sequences located within 50,000 nucleotide pairs of one another on a single chromosome. A similar cluster of human α -globin genes is located on a separate chromosome. Not only other mammals, but birds too have their α -globin and β -globin gene clusters on separate chromosomes. In the frog Xenopus, however, they are together, suggesting that a chromosome translocation event in the lineage of birds and mammals separated the two gene clusters about 300 million years ago, soon after our ancestors and those of amphibians diverged (see Figure 4–75).

There are several duplicated globin DNA sequences in the α -globin and β -globin gene clusters that are not functional genes but pseudogenes. These have a close sequence similarity to the functional genes but have been disabled by mutations that prevent their expression as functional proteins. The existence of such pseudogenes makes it clear that, as expected, not every DNA duplication leads to a new functional gene. Indeed, the human genome is thought to contain more pseudogenes than genes.

Genes Encoding New Proteins Can Be Created by the Recombination of Exons

The role of DNA duplication in evolution is not confined to the expansion of gene families. It can also act on a smaller scale to create single genes by stringing together short duplicated segments of DNA. The proteins encoded by genes generated in this way can be recognized by the presence of repeating similar protein domains, which are covalently linked to one another in series. The immunoglobulins (Figure 4–76), for example, as well as most fibrous proteins (such as collagens) are encoded by genes that have evolved by repeated duplications of a primordial DNA sequence.

In genes that have evolved in this way, as well as in many other genes, each separate exon often encodes an individual protein folding unit, or domain. It is believed that the organization of DNA coding sequences as a series of such exons separated by long introns has greatly facilitated the evolution of new proteins. The duplications necessary to form a single gene coding for a protein with repeating domains, for example, can easily occur by breaking and rejoining the DNA anywhere in the long introns on either side of an exon. Without introns there would be only a few sites in the original gene at which a recombinational exchange between DNA molecules could duplicate the domain and not disrupt it. Moreover, introns often contain sequences that are repeated many times in a genome, facilitating recombination between different introns. By enabling recombination at many potential sites rather than just a few, introns increase the probability that a duplication event will produce a new protein.

More generally, we know from genome sequences that the various parts of genes—both their individual exons and their regulatory elements—have served as modular elements that have been duplicated and moved about the genome to create the great diversity of living things. Thus, for example, many present-day

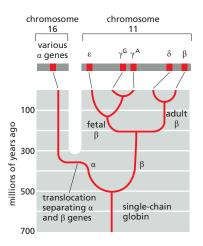

Figure 4–75 An evolutionary scheme for the globin chains that carry oxygen in the blood of animals. The scheme emphasizes the β -like globin gene family. A relatively recent gene duplication of the γ -chain gene produced γ^G and γ^A , which are fetal β -like chains of identical function. The location of the globin genes in the human genome is shown at the top of the figure.

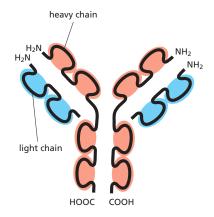

Figure 4–76 Schematic view of an antibody (immunoglobulin) molecule. This molecule is a complex of two identical heavy chains (orange) and two identical

heavy chains (orange) and two identical light chains (blue). Each heavy chain contains four similar, covalently linked domains, while each light chain contains two such domains. Each of these domains is encoded by a separate exon, and all of the exons are thought to have evolved by the serial duplication of a single ancestral

proteins are formed as a patchwork of domains from different origins, reflecting their complex evolutionary history (see Figure 3–15).

Neutral Mutations Often Spread to Become Fixed in a Population, with a Probability That Depends on Population Size

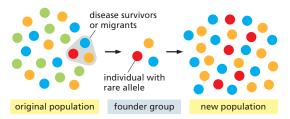

In comparisons between two species that have diverged from one another by millions of years, it makes little difference which individuals from each species are compared. For example, typical human and chimpanzee DNA sequences differ from one another by about 1%. In contrast, when the same region of the genome is sampled from two randomly chosen humans, the differences are typically about 0.1%. For more distantly related organisms, the interspecies differences outshine intraspecies variation even more dramatically. However, each "fixed difference" between the human and the chimpanzee (in other words, each difference that is now characteristic of all or nearly all individuals of each species) started out as a new mutation in a single individual. If the size of the interbreeding population in which the mutation occurred is N, the initial allele frequency for a new mutation would be 1/(2N) for a diploid organism. How does such a rare mutation become fixed in the population, and hence become a characteristic of the species rather than of a few scattered individuals?

The answer to this question depends on the functional consequences of the mutation. If the mutation has a significantly deleterious effect, it will simply be eliminated by purifying selection and will not become fixed. (In the most extreme case, the individual carrying the mutation will die without producing progeny.) Conversely, the rare mutations that confer a major reproductive advantage on individuals who inherit them can spread rapidly in the population. Because humans reproduce sexually and genetic recombination occurs each time a gamete is formed (discussed in Chapter 5), the genome of each individual who has inherited the mutation will be a unique recombinational mosaic of segments inherited from a large number of ancestors. The selected mutation along with a modest amount of neighboring sequence—ultimately inherited from the individual in which the mutation occurred—will simply be one piece of this huge mosaic.

The great majority of mutations that are not harmful are not beneficial either. These selectively *neutral* mutations can also spread and become fixed in a population. In fact, neutral mutations make a large contribution to evolutionary change in genomes. For example, as we saw earlier, they account for most of the DNA sequence differences between apes and humans. The spread of neutral mutations is not as rapid as the spread of the rare strongly advantageous mutations. It depends on a random variation in the number of mutation-bearing progeny produced by each mutation-bearing individual: through a sort of "random walk" process, the mutant allele may eventually become extinct or it may become commonplace. This can be modeled mathematically for an idealized interbreeding population, on the assumption of constant population size and random mating. While neither of these assumptions matches human population history, this idealized case reveals the general principles.

When a new neutral mutation occurs in a population of constant size N that is undergoing random mating, the probability that it will ultimately become fixed is approximately 1/(2N). This is because there are 2N copies of the gene in the diploid population, and each of them has an equal chance of becoming the predominant version in the long run. For those mutations that do become fixed, the mathematics shows that the average time to fixation is approximately 4N generations. Detailed analyses of data on human genetic variation have suggested an ancestral population size of approximately 10,000 at the time when the current pattern of genetic variation was largely established. With a population that has reached this size, the probability that a new, selectively neutral mutation would become fixed is small (1/20,000), while the average time to fixation would be on the order of 800,000 years (assuming a 20-year generation time). Thus, while we know that the human population has grown enormously since the development

MBOC7_ptr_ch04_183-252.indd 243 02/12/21 12:47 PM

of agriculture approximately 15,000 years ago, most of the present-day set of common human genetic variants reflects a mixture of variants that was already present long before this time, when the human population was still small.

Similar arguments explain another phenomenon with important practical implications for genetic counseling. In an isolated community descended from a small group of founders, such as the people of Iceland or the Jews of Eastern Europe, a variant form of a gene that is rare in the human population as a whole can often be present at a high frequency, even if that variant is mildly deleterious (Figure 4-77).

We Can Trace Human History by Analyzing Genomes

The genomes of ancestral organisms can be inferred, but most can never be directly observed. DNA is very stable compared with most organic molecules, but it is not perfectly stable, and its progressive degradation, even under the best circumstances, means that it is extremely difficult to extract sequence information from fossils that are more than a million years old. Although a modern organism such as the horseshoe crab looks remarkably similar to fossil ancestors that lived 200 million years ago, there is every reason to believe that the horseshoe-crab genome has been changing during all that time in much the same way as in other evolutionary lineages, and at a similar rate. Selection must have maintained key functional properties of the horseshoe-crab genome to account for the morphological stability of the lineage. However, comparisons between different present-day organisms show that the fraction of the genome subject to purifying selection is small; hence, it is fair to assume that the sequence of the genome of the modern horseshoe crab, while preserving features critical for function, must differ greatly from that of its extinct ancestors, known to us only through the fossil record.

It is possible to get direct sequence information by examining DNA samples from ancient materials if these are not too old. In recent years, technical advances have allowed DNA sequencing from exceptionally well-preserved bone fragments that date from more than 100,000 years ago. Although any DNA this old will be imperfectly preserved, genome sequences can be reconstructed from many millions of short DNA sequences. In 2010, investigators completed their analysis of the first Neanderthal genome, obtained from DNA that was extracted from a fossilized bone fragment found in a cave in Croatia. The average difference in DNA sequence between humans and Neanderthals shows that our two lineages diverged somewhere between 270,000 and 440,000 years ago, well before the time that humans are believed to have migrated out of Africa. Neanderthals are one of our closest evolutionary relatives, and they lived side by side with the ancestors of modern humans in Europe and Western Asia. By comparing the Neanderthal genome sequence with those of people from different parts of the world, these studies revealed that many modern humans—particularly those from Europe and Asia—share about 2% of their genomes with Neanderthals. This genetic overlap indicates that our ancestors mated with Neanderthals—before outcompeting or actively exterminating them—on the way out of Africa. These and other ancient relationships still being discovered have thus left a permanent mark in the human genome (Figure 4-78).

But what about deciphering the genomes of much older ancestors, those for which no useful DNA samples can be isolated? For organisms that are as closely

Figure 4–77 How founder effects can determine the set of genetic variants in a population of individuals belonging to the same species. In this diagram, each dot is used to represent an individual, with different colors used to denote the different variants of a particular gene. This example illustrates how, by a chance event that greatly reduces population size, an allele that is initially rare in a large population (red) can become established at high frequency in a new population, even though the mutation that produced it has no selective advantage—or is even mildly deleterious.

MBOC7_ptr_ch04_183-252.indd 244 02/12/21 12:47 PM

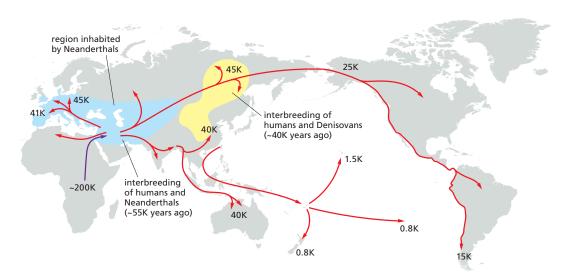

Figure 4–78 Tracing the course of human history by analyses of genome sequences. Modern humans arose in Africa approximately 200,000–300,000 years ago, where the earliest fossils of *Homo sapiens* are found. One small group—perhaps as few as 10,000 individuals—migrated northward, and their descendants spread across the globe. As these ancestral humans left Africa, around 60,000–80,000 years ago (*purple arrow*), they encountered Neanderthals who inhabited the region indicated in *blue*. As a result of interbreeding, the humans who subsequently spread throughout Europe and Asia (*red arrows*) carried with them traces of Neanderthal DNA. Many of those moving eastward would later also interbreed with Denisovans (*yellow*), a second type of ancient human. Later, ancestral humans continued their global spread to the New World, reaching North America approximately 25,000 years ago and the southern regions of South America 10,000 years later. This scenario is based on many types of data, including fossil records, anthropological studies, and the genome sequences of Neanderthals, Denisovans, and modern humans from around the world. (Adapted from M.A. Jobling et al., Human Evolutionary Genetics, 2nd ed. New York: Garland Science, 2014.)

related as human and chimpanzee, we saw that this may not be difficult: reference to the gorilla sequence can be used to sort out which of the few sequence differences between human and chimpanzee are inherited from our common ancestor some 6 million years ago (see Figure 4–65). And for an ancestor that has generated a large number of different species alive today, the DNA sequences of the existing species can be compared simultaneously to unscramble much of the ancestral sequence, allowing scientists to derive DNA sequences much farther back in time. For example, from the genome sequences obtained for dozens of modern placental mammals, it should be possible to infer much of the genome sequence of their 100-million-year-old common ancestor—the precursor of species as diverse as dog, mouse, rabbit, armadillo, and human (see Figure 4–67).

Once the amino acid sequence of an ancestral protein has been inferred, that protein can be readily produced in pure form using the recombinant DNA methods described in Chapter 8. By thus "resurrecting" the extinct protein, its biochemical properties can be compared to those of its modern counterparts. These procedures can be repeated at several branch points in the protein's evolutionary history, allowing that protein's stepwise evolution over many millions of years to be directly measured. This approach provides scientists with a powerful way to visualize evolution in action. It can also help us to understand why modern proteins look and behave the way they do.

The Sequencing of Hundreds of Thousands of Human Genomes Reveals Much Variation

Even though the common variant alleles among modern humans originate from the variants present in a comparatively tiny group of ancestors, the total number of variants that exist among modern humans is huge. This is because unavoidable errors occur in the replication and maintenance of our DNA sequences, as will be explained in Chapter 5. As a result, every person is born with 50–100 new changes,

MBOC7_ptr_ch04_183-252.indd 245 02/12/21 12:47 PM

termed *de novo* mutations, in the DNA sequences that they inherit from their parents. Thus, new mutations are constantly occurring and accumulating in human populations. But the vast majority of the variants they create are extremely rare in the human population as a whole, because they arose among a huge number of relatively recent births.

Modern DNA sequencing technologies have made it possible to determine the genome sequences for millions of humans, at costs that have now dropped below \$1000 per genome. Before introducing what these data show, it is important to define a few basic terms. A *variant* is typically defined as a genomic location at which two or more versions of a sequence exist in the human population, while an *allele* refers to the specific form that each such variant takes in a given person. Because humans are diploid organisms, harboring two haploid genomes in their cells (one from their mother and one from their father), if alleles A and B exist for a variant X, an individual's genotype can be either "A/A," "A/B," or "B/B" at that site.

Each human genome sequence is compared to a "reference human genome assembly" that was produced by the public Human Genome Project on the basis of the initial sequences from several individuals. For this comparison, sequence "reads" for millions or billions of DNA fragments obtained from an individual are aligned by a computer to the reference assembly (which is a haploid representation and includes only one allele at each location). The locations at which the sequenced individual displays "alternative" alleles relative to the reference are then identified.

When this is done for many individuals, single-nucleotide variants (SNVs) are found to compose the vast majority of differences among humans. *SNVs* are points in the genome sequence where some haploid human genomes have one nucleotide, while some have another. They have been extensively characterized because of their abundance, their relative ease of detection, and their value for genetic studies. Historically, the term single-nucleotide polymorphism, or SNP, was reserved for SNVs present at a frequency above 1% in the human population. Today, however, no precise threshold is used to differentiate "rare" and "common" variations, which span frequencies ranging from a singleton "private" variation (present in only one haploid genome within one person) to as high as 50% (a variant with two alleles that exist at equal frequency among human genomes).

Importantly, SNVs are only one type of variation that exists among humans. *Structural variants*, such as deletions, duplications, inversions, or rearrangements of a variety of lengths, are also prevalent features in our genomes. Additional types of variation—including mobile-element insertions and low-complexity repeat expansions or contractions—are also important components of human genetic diversity.

Two haploid human genomes sampled from the modern world population will differ from one another at roughly 1 per 1,000 nucleotides. This number, however, varies considerably between human populations, and it is affected by historical factors such as population bottlenecks, breeding patterns, and ancestral population sizes. And the more closely related two individuals are to one another, the more similar their genomes will be. The above number does not include the considerable structural diversity present among human genomes. Indeed, because they often affect tens or even hundreds of thousands of nucleotides, structural variants are a large contributor to the total number of nucleotide-level differences between any two human genomes (Table 4–3).

Most of the Variants Observed in the Human Population Are Common Alleles, with at Most a Weak Effect on Phenotype

A comparison of any one human genome with the reference human genome will typically find 3–5 million locations at which the sequenced individual harbors at least one allele different from that seen in the reference assembly. Some of these variants are heterozygous within that person, which is to say the individual harbors two distinct alleles, typically one that matches the reference and one "alternative" allele. More than 95% of the variant alleles observed within

MBOC7_ptr_ch04_183-252.indd 246 02/12/21 12:47 PM

TABLE 4-3 Typical Differences Between Any One Human Being's Genome Sequence and the Reference Human Genome		
Type of difference	Size in nucleotide pairs	Differences per genome
Single-nucleotide variation (SNV)	1	3–4 million
Small deletion or insertion (indel)	1–49	0.4–0.5 million
Low-complexity simple sequence repeats (microsatellite and satellite DNA repeats)	1–200	100,000
Mobile-element insertion (SINE, LINE)	300–7000	2000
Structural variation (deletions, duplications, and inversions)	50 to >1,000,000	Tens of thousands; length is inversely correlated with frequency
Karyotypically visible abnormalities (e.g., aneuploidies)	Chromosome scale	Very rare; most are lethal

Courtesy of Greg Cooper and Rick Myers, HudsonAlpha Institute for Biotechnology, Huntsville, AL; based on H.J. Abel et al., *Nature* 583:83–88, 2020; gnomAD (https://www.nature.com/immersive /d42859-020-00002-x/index.html; and https://www.internationalgenome.org).

any given person are relatively common, reflecting their ancient origin. A small fraction of variant alleles will be rare; some of these, as described earlier, represent *de novo* mutations and are extremely rare, potentially existing within only that individual.

As will be described in Chapter 8, those SNVs that are frequent in the human genome have been extremely useful for genetic mapping analyses, known as genome-wide association studies (GWAS). Here, one attempts to associate specific human traits (phenotypes) with a large set of alleles that are relatively common in the human population (see p. 526). Most of these frequent SNVs have little or no effect on human fitness. This is as expected, as the deleterious SNVs will have been selected against during human evolution and should therefore be rare. Importantly, this property is generally true of all variation, including structural variation. Indeed, common structural variants also tend to not be deleterious because, if they were, they would not have arisen to appreciable frequencies. Across all forms of variation then, allele frequency is of crucial importance: common variant alleles tend to have at most weak effects on human phenotypes, and large-effect variants tend to be rare. On the other hand, it is important to note that just because a variant is rare does not mean it influences a phenotype; most rare variants, in fact, have little to no effect.

In recent years, GWAS research has identified many associations between common traits, including common diseases, and common alleles. This is a result of the fact that while common alleles tend to have at most weak effects, the combined effects of many common alleles can ultimately produce a large impact on phenotype.

Forensic Analyses Exploit Special DNA Sequences with Unusually High Mutation Rates

While mutation rates in humans are generally quite low, typically estimated to be on the order of 10^{-8} (that is, roughly one mutation every 100 million base pairs), certain sequences with exceptionally high mutation rates stand out. A dramatic

MBOC7_ptr_ch04_183-252.indd 247 02/12/21 12:47 PM

example is provided by CACA repeats, which are abundant in the human genome and in the genomes of other eukaryotes. Segments of the genome with the motif $(CA)_n$ are replicated with relatively low fidelity because a slippage occurs between the template and the newly synthesized strands during DNA replication; hence, the precise value of n can vary over a considerable range from one genome to the next. These repeats make ideal DNA-based genetic markers because most humans are heterozygous at each of these loci, having inherited one repeat length (n) from their mother and a different repeat length from their father. While the value of n changes sufficiently rarely that most parent–child transmissions propagate CACA repeats faithfully, the changes are sufficiently frequent to maintain high levels of heterozygosity in the human population. Because of this, these and other simple repeats that display exceptionally high variability provide a DNA fingerprint that is widely used for identifying individuals by DNA analysis in crime investigations, paternity suits, and other forensic applications (see Figure 8–37).

An Understanding of Human Variation Is Critical for Improving Medicine

While most variations in the human genome are thought to have weak effects on phenotype, a subset of our genome sequence variations must be responsible for the heritable aspects of human individuality. Because it is now possible to sequence individual genomes cheaply and rapidly, we can link even rare alleles with specific phenotypes. We know that even a single nucleotide change that alters one amino acid in a protein can cause a serious disease, as for example in sickle-cell disease, which, although not rare, is caused by such a mutation in hemoglobin (Movie 4.3). We also know that gene dosage—a doubling or halving of the copy number of some genes—can have a profound effect on development by altering the level of gene product, as can a change in one of the many regulatory DNA sequences that are dispersed throughout the vast expanse of noncoding DNA in the human genome (see Chapter 7).

Some of the many differences between the genomes of any two human beings will have substantial effects on human health, physiology, behavior, and physique. A major challenge in modern human genetics is to discriminate those differences from the majority that are of little consequence. Significant progress is being made; for instance, we now know the nucleotide changes that give rise to thousands of rare inherited traits and diseases. These and many other results are greatly expanding our understanding of human biology. This understanding is critical for the new field of precision medicine, in which both disease prevention and disease treatments will be tailored to take account of individual genetic differences.

Summary

Comparisons of the nucleotide sequences of present-day genomes have revolutionized our understanding of gene and genome evolution. Because of the extremely high fidelity of DNA replication and DNA repair processes, random errors in maintaining the nucleotide sequences in genomes occur rarely (for example, only 50–100 new mutations for every person born). Not surprisingly, therefore, a comparison of human and chimpanzee chromosomes—which are separated by about 12 million years of evolution (double the ~6 million years since humans and chimps shared a common ancestor)—reveals fixed changes at only ~1% of base pairs. Not only are our protein-coding sequences highly similar, but also their order on each chromosome is almost identical. Although a substantial number of segmental duplications and segmental deletions have occurred, even the positions of the transposable elements that make up a major portion of our noncoding DNA are mostly unchanged.

When one compares the genomes of two more distantly related organisms such as a human and a mouse, separated by about 90 million years—one finds

MBOC7_ptr_ch04_183-252.indd 248 02/12/21 12:47 PM

PROBLEMS 249

many more changes. While selection leaves detectable signatures at all time scales, including for example through comparisons of human genomes to one another or through comparisons of the closely related human and chimp genomes, at greater distances the actions of selection are more pronounced. Comparison of human and mouse genomes, for example, reveal that most coding sequences (exons) and many regulatory regions have been highly conserved by the actions of selection, while huge fractions of our respective genomes have been altered to such an extent that one can detect no similarity at all among them.

Because of purifying selection, the comparison of the genome sequences of multiple related species is an especially powerful way to find DNA sequences with important functions. While it has been estimated that between 8 and 10% of the human genome has been conserved as a result of purifying selection, the function of the majority of this DNA (tens of thousands of sequence elements conserved across mammalian evolution) remains mysterious. Experiments that characterize their functions continue to teach us many new lessons about vertebrate biology.

Other sequence comparisons show that a great deal of the genetic complexity of present-day organisms is due to the expansion of ancient gene families. DNA duplication followed by sequence divergence has clearly been a major source of genetic novelty during evolution. On a more recent time scale, the diploid genomes of any two humans will differ from each other both because of nucleotide substitutions (single-nucleotide variations) and because of inherited DNA gains and DNA losses (structural variations). Deciphering the effects of these differences will improve both medicine and our understanding of human biology.

PROBLEMS

Which statements are true? Explain why or why not.

- 4–1 Human females have 23 different chromosomes, whereas human males have 24.
- **4–2** The four core histones are relatively small proteins with a very high proportion of positively charged amino acids; the positive charge helps the histones bind tightly to DNA, regardless of its nucleotide sequence.
- 4–3 Nucleosomes bind DNA so tightly that they cannot move from the positions where they are first assembled.
- 4–4 The long linear DNA molecule in an interphase chromosome is organized into loops of chromatin that appear to emanate from a central axis.
- 4–5 In a comparison between the DNAs of related organisms such as humans and mice, identifying the conserved DNA sequences facilitates the search for functionally important regions.
- **4–6** Gene duplication and divergence are thought to have played a critical role in the evolution of increased biological complexity.

Discuss the following problems.

4–7 DNA isolated from the bacterial virus M13 contains 25% A, 33% T, 22% C, and 20% G. Do these results

strike you as peculiar? Why or why not? How might you explain these values?

4–8 A segment of DNA from the interior of a single strand is shown in **Figure Q4–1**. Should this sequence be written as ACT or TCA? Why?

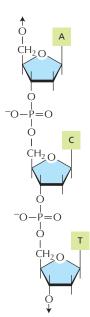

Figure Q4–1 Three nucleotides from the interior of a single strand of DNA (Problem 4–8). *Arrows* at the ends of the DNA strand indicate that the structure continues in both directions.

02/12/21 12:47 PM

MBOC7_ptr_ch04_183-252.indd 249

- 4–9 Human DNA contains 20% C on a molar basis. What are the mole percents of A, G, and T?
- **4–10** In contrast to histone acetylation, which always correlates with gene activation, histone methylation can lead to either transcriptional activation or repression. How do you suppose that the same modification—methylation—can mediate different biological outcomes?
- **4–11** Why is a chromosome with two centromeres (a dicentric chromosome) unstable? Would a backup centromere not be a good thing for a chromosome, giving it two chances to form a kinetochore and attach to microtubules during mitosis? Surely, a backup centromere would ensure that the chromosome did not get left behind at mitosis.
- 4-12 Look at the two yeast colonies in Figure Q4-2. Each of these colonies contains about 100,000 cells descended from a single yeast cell, originally somewhere in the middle of the clump. A white colony arises when the Ade2 gene is expressed from its normal chromosomal location. When the Ade2 gene is moved near a telomere, however, it is packed into heterochromatin and inactivated in most cells, giving rise to colonies that are mostly red. In these largely red colonies, white sectors fan out from the middle of the colony. In both the red portions and the white sectors, the Ade2 gene is still located near telomeres. Explain why white sectors have formed near the rim of the red colony. On the basis of the patterns observed, what can you conclude about the propagation of the transcriptional state of the Ade2 gene from mother to daughter cells in this experiment?

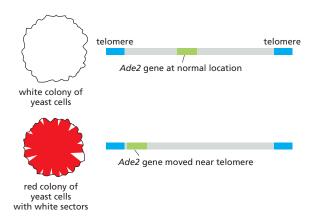

Figure Q4–2 Position effect on expression of the yeast *Ade2* gene (Problem 4–12). The *Ade2* gene codes for one of the enzymes for adenosine biosynthesis, and the absence of the *Ade2* gene product leads to the accumulation of a red pigment. Therefore, a colony of cells that express *Ade2* is *white*, and one composed of cells in which the *Ade2* gene is not expressed is *red*.

4–13 Chromosomes from different amphibians form typical lampbrush chromosomes when injected into oocytes as demembranated sperm heads. When the sperm heads from *Rana pipiens* (northern leopard frog), which

forms large loops in its own oocyte chromosomes, were injected into *Xenopus laevis* oocytes, the resulting lampbrush chromosomes had the small loops typical of those found in *X. laevis* oocytes. Similarly, when the sperm heads from *X. laevis* were injected into *Notophthalmus viridescens* (red-spotted newt) oocytes, the resulting lampbrush chromosomes had the very large loop structure typical of *N. viridescens*.

Do these heterologous injection experiments support the idea that loop structure is a fixed property of a chromosome? Why or why not?

Mobile pieces of DNA—transposable elements that insert themselves into chromosomes and accumulate during evolution make up more than 40% of the human genome. Transposable elements of four types—long interspersed nuclear elements (LINEs), short interspersed nuclear elements (SINEs), long terminal repeat (LTR) retrotransposons, and DNA transposons—are inserted more or less randomly throughout the human genome. These elements are conspicuously rare at the four homeobox gene clusters, HoxA, HoxB, HoxC, and HoxD, as illustrated for *HoxD* in Figure Q4–3, along with an equivalent region of chromosome 22, which lacks a Hox cluster. Each Hox cluster is about 100 kilobases (kb) in length and contains 9-11 genes, whose differential expression along the anteroposterior axis of the developing embryo establishes the basic body plan for humans (and for other animals). Why do you suppose that transposable elements are so rare in the *Hox* clusters?

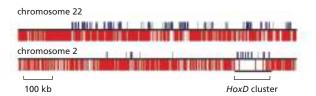

Figure Q4–3 Transposable elements and genes in 1-megabase regions of chromosomes 2 and 22 (Problem 4–14). Blue lines that project upward indicate exons of known genes. Red lines that project downward indicate transposable elements; they are so numerous (constituting more than 40% of the human genome) that they merge into nearly a solid block outside the Hox clusters. (Adapted from E. Lander et al., Nature 409:860–921, 2001. With permission from Springer Nature.)

4–15 Chromosome 3 in orangutans differs from chromosome 3 in humans by two inversion events that occurred in the human lineage (**Figure Q4–4**). Draw the

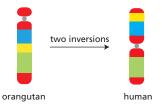

Figure Q4–4 Chromosome 3 in orangutans and humans (Problem 4–15). Differently colored blocks indicate segments of the chromosomes that are homologous in DNA sequence. REFERENCES 251

intermediate chromosome that resulted from the first inversion and explicitly indicate the segments included in each inversion.

4–16 There has been a colossal snafu in the maternity ward at your local hospital. Four sets of male twins, born within an hour of each other, were inadvertently shuffled in the excitement occasioned by that unlikely event. You have been called in to set things right. As a first step, you want to get the twins matched up. To that end, you analyze a small blood sample from each infant using a hybridization probe that detects differences in the numbers of simple sequence repeats such as $(CA)_n$ located in widely scattered regions of the genome. The results are shown in Figure Q4–5.

A. Which infants are brothers? Are they all identical twins?

B. How will you match brothers to the correct parents?

Figure Q4–5 DNA fingerprint analysis of shuffled twins (Problem 4–16).

DNA Replication, Repair, and Recombination

CHAPTER

5

The ability of cells to maintain a high degree of order in a chaotic universe depends on the accurate duplication of vast quantities of genetic information carried in chemical form as DNA. This process, called *DNA replication*, must occur before a cell can produce two genetically identical daughter cells. Maintaining order also requires the continued surveillance and repair of this genetic information, because DNA inside cells is repeatedly damaged by chemicals and radiation from the environment, as well as by thermal accidents and reactive molecules generated inside the cell. In this chapter, we describe the protein machines that replicate and repair the cell's DNA. These machines catalyze some of the most rapid and accurate processes that take place within cells, and their mechanisms provide clear illustrations of the elegance and efficiency of cell chemistry.

The short-term survival of a cell depends on preventing harmful changes in its DNA. But the long-term survival of a species requires that these same DNA sequences be changeable over many generations to permit evolutionary adaptation to changing circumstances. We shall see that, despite the great efforts that cells make to protect their DNA, occasional changes in DNA sequences are unavoidable. These changes produce the genetic variation that is required for natural selection to drive the evolution of organisms.

We begin this chapter with a brief discussion of the changes that occur in DNA as it is passed down from generation to generation. Next, we discuss the mechanisms—DNA replication and DNA repair—that are responsible for minimizing these changes. Finally, we consider some of the most intriguing pathways that alter DNA sequences—those of *DNA recombination*. These pathways include the movement within chromosomes of special DNA sequences called transposable elements.

THE MAINTENANCE OF DNA SEQUENCES

The survival of an individual organism demands a high degree of genetic stability. Only rarely do the cell's DNA-maintenance processes fail, resulting in permanent change in the DNA. Such a change is called a *mutation*, and it can destroy an organism if it occurs in a vital position in the DNA sequence.

Mutation Rates Are Extremely Low

The **mutation rate**, the rate at which changes occur in DNA sequences, can be determined directly from experiments carried out with a bacterium such as *Escherichia coli*—a resident of our intestinal tract and a commonly used laboratory organism (see Figure 1–38). Under laboratory conditions, an *E. coli* cell divides about once every 30 minutes; as a result, a single cell can generate a very large population—several billion—in less than a day. In such a population, it is possible to detect the small fraction of bacteria that have suffered a damaging mutation in a particular gene. For example, the mutation rate of a gene specifically required for cells to use the sugar lactose as an energy source can be determined by growing the cells in the presence of a different sugar, such as

Transposition and Conservative Site-specific Recombination

MBOC7_ptr_ch05_253-320.indd 253 02/12/21 12:46 PM

glucose, and testing them subsequently to see how many have lost the ability to survive on a lactose diet. The fraction of damaged genes will underestimate the actual mutation rate because many mutations are *silent* (for example, those that change a codon but not the amino acid it specifies or those that change an amino acid without affecting the activity of the protein coded for by the gene). After correcting for these silent mutations, one finds that bacteria display a mutation rate of about three nucleotide changes per 10¹⁰ nucleotides copied.

It is also possible to measure the germ-line mutation rate in more complex, sexually reproducing organisms such as humans. In this case, the complete genomes from a family—parents and offspring—are directly sequenced, and a careful comparison reveals that approximately 70 new single-nucleotide mutations typically arise in the germ lines of each offspring. Normalized to the size of the human genome, the mutation rate is one nucleotide change per 10^8 nucleotides per human generation. (This is a slight underestimate because some germ-line mutations will be lethal and will therefore be absent from progeny; however, because relatively little of the human genome carries critical information, this consideration has a negligible effect on the true mutation rate.) It is estimated that approximately 100 cell divisions occur in the germ line from the time of conception to the time of production of the eggs and sperm that go on to make the next generation. Thus, the human mutation rate, expressed in terms of cell divisions (instead of human generations), is approximately one nucleotide change per 10^{10} nucleotides copied.

Although *E. coli* and humans differ greatly in their modes of reproduction and in their generation times, when the mutation rates of each are normalized to a single round of DNA replication, they are both extremely low and within a factor of 3 of each other. We shall see later in the chapter that the basic mechanisms that ensure these low rates of mutation have been conserved since the very early history of cells on Earth.

Low Mutation Rates Are Necessary for Life as We Know It

Because many mutations are deleterious, no species can afford to allow them to accumulate at a high rate in its germ cells. Even though the observed mutation frequency is very low, it is thought to limit the number of essential genes that any organism can rely on to perhaps 30,000. More essential genes than this, and the probability that at least one critical component will suffer a damaging mutation becomes catastrophically high. By an extension of the same argument, a mutation frequency tenfold higher would limit an organism to about 3000 essential genes. In this case, evolution would have been limited to organisms considerably less complex than a fruit fly.

The cells of a sexually reproducing animal or plant are of two types: germ cells and somatic cells. The germ cells transmit genetic information from parent to offspring; the somatic cells form the body of the organism (Figure 5-1). We have seen that germ cells must be protected against high rates of mutation to maintain the species. However, the somatic cells of multicellular organisms must also be protected from genetic change to properly maintain the organized structure of the body. Nucleotide changes in somatic cells can give rise to variant cells, some of which, through "local" natural selection, proliferate rapidly at the expense of the rest of the organism. In an extreme case, the result is the uncontrolled cell proliferation that we know as cancer. This condition is due largely to an accumulation of changes in the DNA sequences of somatic cells, as discussed in Chapter 20. Any significant increase in the mutation frequency would presumably cause a disastrous increase in the incidence of cancer by accelerating the rate at which dangerous somatic-cell variants arise. Thus, both for the perpetuation of a species with a large number of genes (germ-cell stability) and for the prevention of cancer resulting from mutations in somatic cells (somaticcell stability), multicellular organisms like ourselves absolutely depend on the remarkably high fidelity with which their DNA sequences are replicated and maintained.

MBOC7_ptr_ch05_253-320.indd 254 02/12/21 12:46 PM

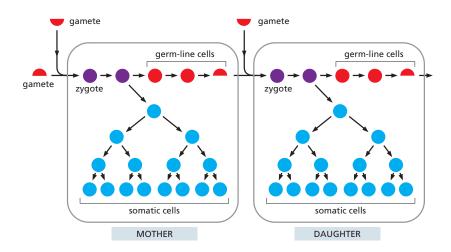

Figure 5-1 Germ-line cells and somatic cells carry out fundamentally different functions. In sexually reproducing organisms, genetic information is propagated into the next generation exclusively by germ-line cells (red). This cell lineage includes the specialized reproductive cells—the gametes (eggs and sperm, half circles)—which contain only half the number of chromosomes as that contained in the other cells in the body (full circles). When two gametes come together during fertilization, they form a fertilized egg, or zygote (purple), which once again contains a full set of chromosomes. The zygote gives rise to both germ-line cells and somatic cells (blue). Somatic cells form the body of the organism but do not contribute their DNA to the next generation.

Summary

In all cells, DNA sequences are maintained and replicated with extremely high fidelity. The mutation rate, approximately one nucleotide change per 10^{10} nucleotides each time the DNA is replicated, is very similar for organisms as different as bacteria and humans. Because of this remarkable accuracy, the sequence of the human genome (approximately 3.1×10^9 nucleotide pairs) is unchanged or changed by only a few nucleotides each time a typical human cell divides. This allows humans to pass accurate genetic instructions from one generation to the next and also—for most of us—to avoid the changes in somatic cells that lead to cancer.

DNA REPLICATION MECHANISMS

All organisms duplicate their DNA with extraordinary accuracy before each cell division. In this part of the chapter, we explore how an elaborate "replication machine" achieves this accuracy, while duplicating DNA at rates as high as 1000 nucleotides per second.

Base-pairing Underlies DNA Replication and DNA Repair

As introduced in Chapter 1, *DNA templating* is the mechanism the cell uses to copy the nucleotide sequence of one DNA strand into a complementary DNA sequence (Figure 5–2). This process requires the separation of the DNA helix into two template strands, and it entails the recognition of each nucleotide in the DNA *template strands* by a free (unpolymerized) complementary nucleotide. The separation of the DNA helix exposes the hydrogen-bond donor and acceptor groups on each DNA base to allow its base-pairing with the appropriate incoming free nucleotide, aligning it for its enzyme-catalyzed polymerization into a new DNA chain.

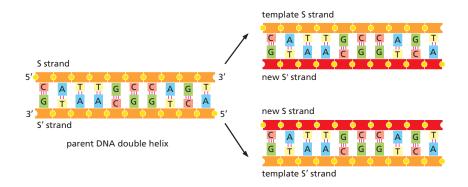

Figure 5–2 DNA acts as a template for its own replication. Because the nucleotide A will successfully pair only with T, and G with C, each strand of a DNA double helix—labeled here as the S strand and its complement, the S' strand—can serve as a template to specify the sequence of nucleotides in a complementary strand. In this way, both strands of a DNA double helix can be copied with precision, producing two exact copies of the original double helix. How complementary nucleotides base-pair is shown in Figure 4–5.

MBOC7_ptr_ch05_253-320.indd 255 02/12/21 12:46 PM

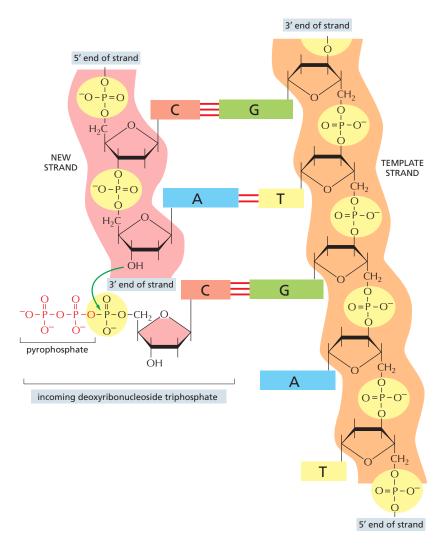

Figure 5–3 The chemistry of DNA synthesis. Nucleotides enter the reaction as deoxyribonucleoside triphosphates, and the addition of a deoxyribonucleotide to the 3′ end of a polynucleotide chain is the fundamental reaction by which DNA is synthesized. As shown, base-pairing between an incoming deoxyribonucleoside triphosphate and an existing strand of DNA (the template strand) guides the formation of the new strand of DNA and ensures that its nucleotide sequence is complementary to that of the template.

The first nucleotide-polymerizing enzyme, **DNA polymerase**, was discovered in 1957. The free nucleotides that serve as substrates for this enzyme were found to be deoxyribonucleoside triphosphates, and their polymerization into DNA required a single-strand DNA template. **Figure 5–3** and **Figure 5–4** illustrate the stepwise mechanism of this reaction.

The DNA Replication Fork Is Asymmetrical

During DNA replication inside a cell, each of the two original DNA strands serves as a template for the formation of an entire new strand. Because each of the two daughters of a dividing cell inherits a new DNA double helix containing one original and one new strand (**Figure 5–5**), the DNA double helix is said to be replicated *semiconservatively*. How is this feat actually accomplished?

Analyses carried out in the early 1960s on the whole replicating chromosome of an *E. coli* bacterium revealed a localized region of replication that moves progressively along the parent DNA double helix. Because of its Y-shaped structure,

MBOC7_ptr_ch05_253-320.indd 256 02/12/21 12:46 PM

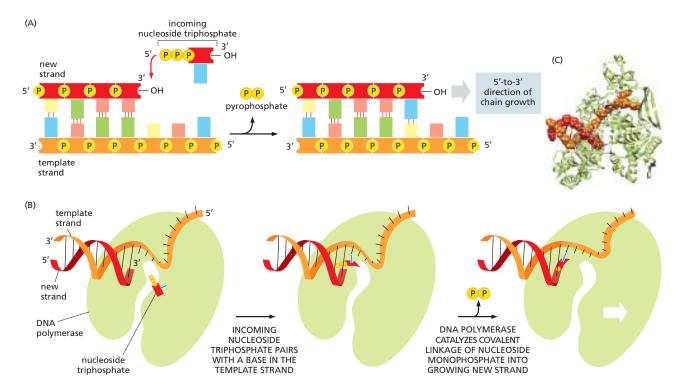

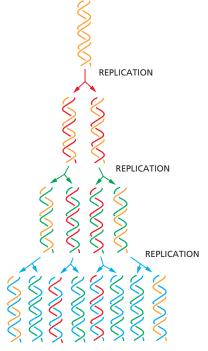

Figure 5–4 How DNA polymerase adds a deoxyribonucleotide to the end of a growing DNA strand. (A) An incoming deoxynucleoside triphosphate forms a base pair with its partner in the template strand. It is then covalently attached to the free 3'-hydroxyl (3'-OH) end of the growing DNA strand. The new DNA strand is therefore synthesized in the 5'-to-3' direction. The energy for the polymerization reaction comes from the hydrolysis of a high-energy phosphate bond in the incoming nucleoside triphosphate and the release of pyrophosphate, which is subsequently hydrolyzed to yield two molecules of inorganic phosphate (not shown). (B) The reaction is catalyzed by the enzyme DNA polymerase (light green). The polymerase guides the incoming nucleoside triphosphate to the template strand and positions it such that its 5' triphosphate will be able to react with the 3'-hydroxyl group on the newly synthesized strand. The white arrow indicates the direction of polymerase movement. (C) Structure of DNA polymerase, as determined by x-ray crystallography, also showing the replicating DNA. The template strand is the longer, orange strand, and the DNA strand being synthesized is colored red. See Movie 5.1. (C, PDB code: 1KRP.)

this active region is called a **replication fork** (Figure 5–6). At the replication fork, a multienzyme complex that contains the DNA polymerase synthesizes the DNA of both new daughter strands.

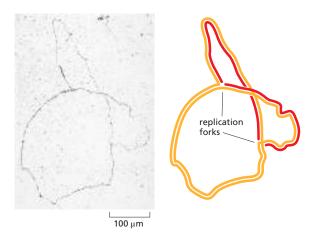

Initially, the simplest mechanism of DNA replication seemed to be the continuous growth of both new strands, nucleotide by nucleotide, at the replication fork as it moves from one end of a DNA molecule to the other. But because of the antiparallel orientation of the two DNA strands in the DNA double helix (see Figure 5–2), this mechanism would require one daughter strand to polymerize in the 5'-to-3' direction and the other in the 3'-to-5' direction. Such a replication fork would require two distinct types of DNA polymerase enzymes. However, as attractive as this model might seem, the DNA polymerases at replication forks can synthesize only in the 5'-to-3' direction.

How, then, can a DNA strand grow in the 3'-to-5' direction? The answer came from an experiment performed in the late 1960s. Researchers added highly radioactive ³H-thymidine to dividing bacteria for a few seconds, so that only the most recently replicated DNA—that just behind the replication fork—became radiolabeled. This experiment revealed the transient existence of pieces of

Figure 5–5 In each round of DNA replication, each of the two strands of DNA is used as a template for the formation of a new, complementary strand. DNA replication is semiconservative because each daughter DNA double helix is composed of one conserved (old) strand and one newly synthesized strand.

MBOC7_ptr_ch05_253-320.indd 257 02/12/21 12:46 PM

DNA that were 1000–2000 nucleotides long, now commonly known as *Okazaki fragments* (named for their discoverer), at the growing replication fork. Similar replication intermediates were later found in eukaryotes, where they are only 100–200 nucleotides long. The Okazaki fragments were shown to be synthesized only in the 5′-to-3′ chain direction and to be joined together after their synthesis to create long DNA chains.

Each replication fork therefore has an asymmetric structure (**Figure 5-7**). The DNA daughter strand that is synthesized continuously is known as the **leading strand**. Its synthesis slightly precedes the synthesis of the daughter strand that is synthesized discontinuously, known as the **lagging strand**. For the lagging strand, the direction of nucleotide polymerization is opposite to the overall direction of DNA chain growth. The synthesis of this strand by a discontinuous "backstitching" mechanism means that DNA replication requires only the 5'-to-3' type of DNA polymerase.

The High Fidelity of DNA Replication Requires Several Proofreading Mechanisms

As discussed at the beginning of the chapter, the fidelity of copying DNA during replication is such that only about one mistake occurs for every 10^{10} nucleotides copied. This accuracy is much higher than one would expect solely from the

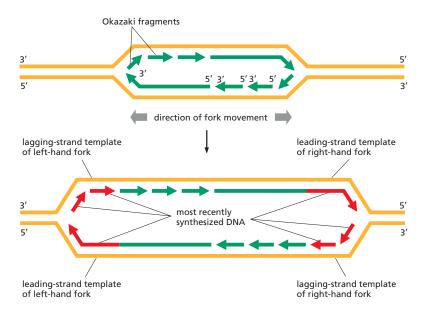

Figure 5-6 Two replication forks moving in opposite directions on the E. coli chromosome, a large circular DNA molecule. Each replication fork has a Y-shaped structure and moves progressively along the DNA, spinning out newly replicated DNA behind it. The stem of the Y is the parent DNA double helix, and the two arms of the Y contain the newly synthesized DNA. The image on the left was obtained by feeding E. coli radioactive thymine for several hours, gently isolating the DNA on filter paper, and placing a piece of photographic film next to the DNA. Because radioactivity exposes photographic film, an image of the DNA was captured when the film was developed and viewed under a light microscope. The diagram on the right is an interpretation of the result, with parent DNA strands in orange and newly synthesized DNA strands in red. During its isolation for this experiment, the E. coli DNA folded on itself, accounting for the crossing of the double helix. (From J. Cairns, Cold Spring Harb. Symp. Quant. Biol. 38:43-46, 1963. With permission from Cold Spring Harbor Laboratory Press.)

Figure 5-7 At each replication fork, the lagging DNA strand is synthesized in pieces. The upper diagram shows two replication forks moving in opposite directions on a double-helical DNA molecule, as in Figure 5-6; the lower diagram shows the same two forks a short time later. Because both of the new strands at a replication fork are synthesized in the 5'-to-3' direction, the lagging strand of DNA must be made initially as a series of short DNA strands, which are later ioined together. To replicate the lagging strand, the DNA polymerase molecule on that side of the fork uses a backstitching mechanism: it synthesizes a short piece of DNA in the 5'-to-3' direction, stops, and is then moved by its protein machine back toward the fork in order to synthesize the next fragment.

MBOC7_ptr_ch05_253-320.indd 258 02/12/21 12:46 PM

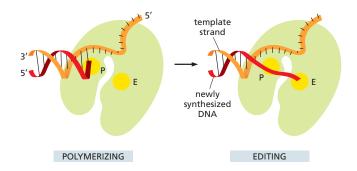

properties of complementary base-pairing. The standard complementary base pairs (see Figure 4–5) are not the only ones possible. For example, with small changes in helix geometry, two hydrogen bonds can form between G and T in DNA. In addition, rare configurations of the four DNA bases (known as tautomers) occur transiently in ratios of 1 part to 10^4 or 10^5 . These forms mispair without a change in helix geometry: the rare tautomeric form of C pairs with A instead of G, for example.

If the DNA polymerase did nothing special when a mispairing occurred between an incoming deoxyribonucleoside triphosphate and the DNA template, the wrong nucleotide would often be incorporated into the new DNA chain, producing frequent mutations. The high fidelity of DNA replication, however, depends not only on the initial base-pairing, but also on several "proofreading" mechanisms that act sequentially to correct any initial mispairings that might have occurred

DNA polymerase performs the first proofreading step just before a new nucleotide is covalently added to the growing chain. After complementary nucleotide binding, but before the nucleotide is covalently added to the growing chain, the enzyme must undergo a conformational change in which its "grip" tightens around the active site. Because this change occurs more readily with correct than incorrect base-pairing, it allows the polymerase to "double-check" the exact base-pair geometry before it catalyzes the addition of the nucleotide. Incorrectly paired nucleotides are harder to add and therefore more likely to diffuse away before the polymerase can mistakenly add them.

The next error-correcting reaction, known as exonucleolytic proofreading, takes place immediately after those rare instances in which an incorrect nucleotide is covalently added to the growing chain. DNA polymerase enzymes are highly discriminating in the types of DNA chains they will elongate: they require a previously formed, base-paired 3'-OH end of a primer strand (see Figure 5-4). Those DNA molecules with a mismatched (improperly base-paired) nucleotide at the 3'-OH end of the primer strand are not effective as templates because the polymerase has difficulty extending such a strand. DNA polymerase molecules correct such a mismatched primer strand by means of a separate catalytic site (either in a separate subunit or in a separate protein domain of the polymerase molecule, depending on the polymerase). This 3'-to-5' proofreading exonuclease clips off any unpaired or mispaired residues at the primer terminus, continuing until enough nucleotides have been removed to regenerate a correctly base-paired 3'-OH terminus that can prime DNA synthesis. In this way, DNA polymerase functions as a "self-correcting" enzyme that removes its own polymerization errors as it moves along the DNA (Figure 5-8 and Figure 5-9).

Because the self-correcting properties of DNA polymerase depend on its requirement for a perfectly base-paired primer terminus, it is apparently not possible for such an enzyme to start DNA synthesis *de novo* without an existing primer. By contrast, the RNA polymerase enzymes involved in gene transcription do not need such an efficient exonucleolytic proofreading mechanism: errors in making RNA are not passed on to the next generation, and the occasional defective RNA molecule that is produced has no long-term significance. As a result,

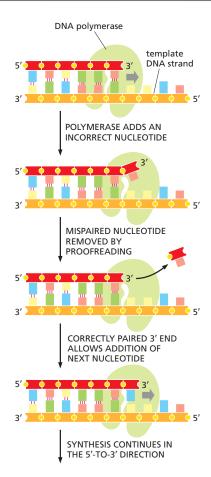

Figure 5–8 During DNA synthesis, DNA polymerase proofreads its own work. If an incorrect nucleotide is accidentally added to a growing strand, the DNA polymerase stops, cleaves it from the strand, and replaces it with the correct nucleotide before continuing.

Figure 5-9 DNA polymerase contains separate sites for DNA synthesis and proofreading. The DNA polymerase, which cradles the DNA molecule being replicated, is shown in the polymerizing mode (left) and in the proofreading, or editing, mode (right). The catalytic sites for the polymerization activity (P) and editing activity (E) are indicated. When the polymerase adds an incorrect nucleotide, the newly synthesized DNA strand (red) transiently unpairs from the template strand (orange), and its 3' end moves into the editing site (E) to allow the incorrect nucleotide to be removed. These diagrams are based on the structure of an E. coli DNA polymerase molecule, as determined by x-ray crystallography.

MBOC7_ptr_ch05_253-320.indd 259 02/12/21 12:46 PM

TABLE 5-1 The Three Steps That Give Rise to High-Fidelity DNA Synthesis		
Replication step	Errors per nucleotide added	
5'→3' polymerization	1 in 10 ⁵	
3'→5' exonucleolytic proofreading	1 in 10 ²	
Strand-directed mismatch repair	1 in 10 ³	
Combined	1 in 10 ¹⁰	

The third step, strand-directed mismatch repair, is described later in this chapter. For the polymerization step, "errors per nucleotide added" describes the probability that an incorrect nucleotide will be added to the growing chain. For the other two steps, "errors per nucleotide added" describes the probability that an error will not be corrected. Each step therefore reduces the chance of a final error by the factor shown.

RNA polymerases do not require a base-paired end 3'-OH for nucleotide addition and are able to start new polynucleotide chains without a primer.

On average, about one mistake is made for every 10^4 polymerization events both in RNA synthesis and in the separate process of translating mRNA sequences into protein sequences. This error rate is over 100,000 times greater than that in DNA replication, where, as we have seen, a series of proofreading processes makes the process unusually accurate (Table 5–1).

DNA Replication in the 5'-to-3' Direction Allows Efficient Error Correction

The need for accuracy probably explains why DNA replication occurs only in the 5′-to-3′ direction. If there were a DNA polymerase that added deoxyribonucle-oside triphosphates in the 3′-to-5′ direction, the growing 5′ end of the chain, rather than the incoming mononucleotide, would have to provide the activating triphosphate needed for the covalent linkage (see Figure 5–3). In this case, the mistakes in polymerization could not be simply hydrolyzed away, because the bare 5′ end of the chain thus created would immediately terminate DNA synthesis. It is therefore possible to correct a mismatched base only if it has been added to the 3′ end of a DNA chain. Although the backstitching mechanism for DNA replication seems complex, it preserves the 5′-to-3′ direction of polymerization that is required for exonucleolytic proofreading.

Despite these safeguards against DNA replication errors, DNA polymerases occasionally leave mistakes behind in the DNA that they produce. However, as we shall see later in this chapter, cells have yet another chance to correct these errors by a process called *strand-directed mismatch repair*. Before discussing this mechanism, however, we describe the other types of proteins that function at the replication fork as part of a large protein machine that replicates DNA.

A Special Nucleotide-polymerizing Enzyme Synthesizes Short RNA Primer Molecules

For the leading strand, a primer is needed only at the start of replication: once a replication fork is established, the DNA polymerase is continuously presented with a base-paired chain end on which to add new nucleotides. On the lagging side of the fork, however, each time the DNA polymerase completes a short DNA Okazaki fragment (which takes a few seconds), it must start synthesizing a completely new fragment at a site further along the template strand (see Figure 5–7). Each time this occurs, a special mechanism is required to produce a base-paired primer strand for the DNA polymerase to elongate. This requires an enzyme called **DNA primase** that uses ribonucleoside triphosphates to synthesize short **RNA primers** on the lagging strand (**Figure 5–10**). In eukaryotes, these primers are about 10 nucleotides long and are made at intervals of 100–200 nucleotides

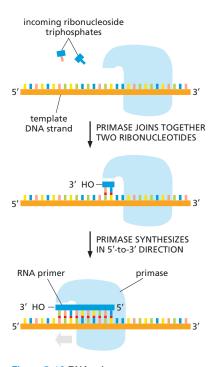

Figure 5–10 RNA primers are synthesized by an RNA polymerase called DNA primase, which uses a DNA strand as a template. Like DNA polymerase, primase synthesizes in the 5'-to-3' direction. Unlike DNA polymerase, however, primase can start a new polynucleotide chain by joining together two nucleoside triphosphates without the need for a base-paired 3' end as a starting point. A DNA primase uses ribonucleoside triphosphates rather than deoxyribonucleoside triphosphates, and it is much less accurate than a DNA polymerase.

Figure 5–11 Different enzymes act in series to synthesize DNA on the lagging strand. In eukaryotes, RNA primers are made at intervals of about 200 nucleotides on the lagging strand, and each RNA primer is approximately 10 nucleotides long. These primers are extended by DNA polymerases at the replication fork to produce Okazaki fragments. The primers are subsequently removed by nucleases that recognize the RNA strand in an RNA–DNA hybrid helix and destroy it; this leaves gaps that are filled in by an accurate "repair" DNA polymerase that proofreads as it fills in the gaps. The completed DNA fragments are finally joined together by an enzyme called DNA ligase, which catalyzes the formation of a phosphodiester bond between the 3'-hydroxyl end of one fragment and the 5'-phosphate end of the next, thus linking up the sugar–phosphate backbones. This nick-sealing reaction requires an input of energy in the form of ATP (see Figure 5–12).

on the lagging strand. The synthesis of the leading strand also requires an RNA primer, but only at its very beginning.

RNA was introduced in Chapter 1 and is described in detail in Chapter 6. Here, we note only that RNA is very similar in structure to DNA. A strand of RNA can form base pairs with a strand of DNA, generating a DNA-RNA hybrid double helix if the two nucleotide sequences are complementary. Thus, the same templating principle used for DNA synthesis guides the synthesis of RNA primers. Because an RNA primer contains a properly base-paired nucleotide with a 3'-OH group at one end, it can be elongated by the DNA polymerase at this end to begin an Okazaki fragment.

The synthesis of each Okazaki fragment ends when this DNA polymerase runs into the RNA primer attached to the 5' end of the previous fragment. To produce a continuous DNA chain from the many DNA fragments made on the lagging strand, a special DNA repair system acts quickly to remove the RNA primers and replace them with DNA. An enzyme called **DNA ligase** then joins the 3' end of the new DNA fragment to the 5' end of the previous one to complete the process (**Figure 5–11** and **Figure 5–12**).

Why might an erasable RNA primer be used instead of a DNA primer? The argument that a self-correcting polymerase cannot start chains *de novo* also implies the converse: an enzyme that starts chains anew cannot be efficient at self-correction. Thus, any enzyme that primes the synthesis of Okazaki fragments will of necessity make a relatively inaccurate copy. If these inaccurate copies were allowed to remain, the resulting increase in the overall mutation rate would be enormous. It therefore seems likely that the use of RNA rather than DNA for priming brings a powerful advantage to the cell: the ribonucleotides in the primer automatically mark these sequences as "suspect copy" to be efficiently removed and replaced by DNA produced by a highly accurate DNA polymerase.

Special Proteins Help to Open Up the DNA Double Helix in Front of the Replication Fork

For DNA synthesis to proceed, the DNA double helix must be opened up ahead of the replication fork so that the incoming deoxyribonucleoside triphosphates can form base pairs with the template strand. The DNA double helix is very stable under physiological conditions: the base pairs are locked in place so strongly that it requires temperatures approaching that of boiling water to separate the two strands in a test tube. For this reason, two additional types of replication proteins—DNA helicases and single-strand DNA-binding proteins—are needed

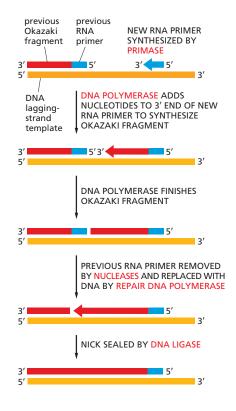

Figure 5–12 DNA ligase joins together Okazaki fragments on the lagging strand during DNA synthesis. The ligase enzyme uses a molecule of ATP to activate the 5' phosphate of one fragment (step 1) before forming a new bond with the 3' hydroxyl of the other fragment (step 2).

MBOC7_ptr_ch05_253-320.indd 261 02/12/21 12:46 PM

Figure 5–13 How DNA helicase enzymes can separate strands as they move along a DNA single strand. An experiment is diagrammed, in which a short, complementary DNA fragment is base-paired to a longer DNA strand to form a region of DNA double helix. Because the purified DNA helicase added acts as a "moving wedge," the double helix is pulled apart as the helicase runs unidirectionally along the DNA single strand, releasing the short DNA strand in a reaction that requires the presence of both the helicase protein and ATP. The rapid stepwise movement of the helicase is powered by its ATP hydrolysis (shown schematically in Figure 3–71A). As indicated, many DNA helicases are composed of a ring of six subunits.

to open the double helix and present an appropriate single-stranded DNA template for the DNA polymerase to copy.

DNA helicases were first isolated as proteins that hydrolyze ATP when they are bound to single strands of DNA. As described in Chapter 3, the binding and hydrolysis of ATP can change the shape of a protein molecule in a cyclical manner that allows the protein to perform mechanical work. DNA helicases use this principle to propel themselves rapidly along a single DNA strand. When they encounter a region of double helix, they continue to move along their strand, thereby prying apart the helix ahead of them. This unidirectional movement can occur at rates of up to 1000 nucleotides per second (**Figure 5–13** and **Figure 5–14**).

The two strands of DNA have opposite polarities, and, in principle, a helicase could unwind the DNA double helix in front of a replication fork by moving either in the 5'-to-3' direction along one strand or in the 3'-to-5' direction along the other strand. In fact, both types of DNA helicase exist. In the best-understood replication systems in bacteria, a helicase moving 5'-to-3' along the lagging-strand template has the predominant role.

Single-strand DNA-binding (SSB) proteins bind tightly and cooperatively to the single-stranded DNA that is produced by helicases. Through cooperative binding, SSB proteins coat and straighten out all regions of single-stranded DNA, thereby preventing the formation of the short hairpin helices that otherwise form in these single strands (**Figure 5–15** and **Figure 5–16**). These regions occur routinely on the lagging-strand template, and if not removed, they can impede the DNA synthesis catalyzed by DNA polymerase.

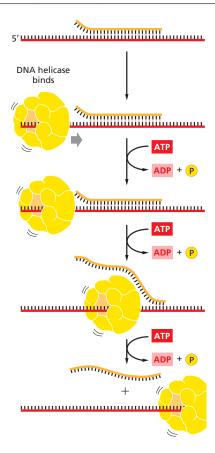

A Sliding Ring Holds a Moving DNA Polymerase onto the DNA

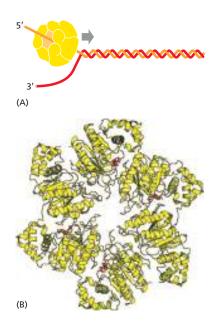

On their own, most DNA polymerase molecules will synthesize only a short string of nucleotides before falling off the DNA template. However, an accessory protein (called PCNA in eukaryotes) forms a **sliding clamp** that keeps the polymerase firmly on the DNA when it is moving but releases the polymerase as soon as it runs into a double-strand region of DNA.

How can a sliding clamp prevent the polymerase from dissociating without impeding the polymerase's rapid movement along DNA? The three-dimensional structure of the clamp protein revealed that it forms a large ring around the DNA double helix. One face of the ring binds to the back of the DNA polymerase, and the whole ring slides freely along the DNA as the polymerase moves. The assembly of the clamp around the DNA requires a special protein complex, the **clamp loader**, that can open and close the ring in a regulated manner.

The moving DNA polymerase is tightly bound to the clamp, and, on the leading strand, the two remain associated for a very long time. The DNA polymerase on the lagging-strand template also makes use of the clamp, but each time the polymerase reaches the 5' end of the preceding Okazaki fragment, the polymerase

Figure 5–14 The structure of a DNA helicase. (A) Diagram of the protein, a hexameric ring, drawn to scale with a replication fork. (B) Detailed structure of the bacteriophage T7 replicative helicase, as determined by x-ray diffraction. Six identical subunits bind and hydrolyze ATP in an ordered fashion to propel this molecule, like a rotary engine, along a DNA single strand that passes through the central hole. Bound ATP molecules in the structure are indicated in red (Movie 5.2). (PDB code: 1E0J.)

MBOC7_ptr_ch05_253-320.indd 262 02/12/21 12:46 PM

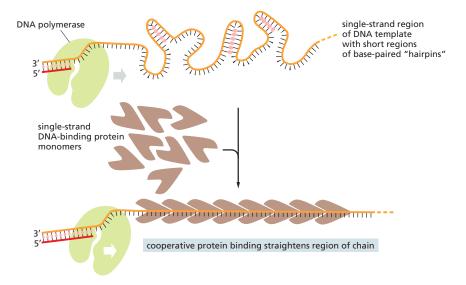

Figure 5–15 The effect of single-strand DNA-binding proteins (SSB proteins) on the structure of single-stranded DNA. Because each protein molecule prefers to bind next to a previously bound molecule, long rows of this protein form on a DNA single strand. This cooperative binding straightens out the DNA template and facilitates the DNA polymerization process. The "hairpin helices" shown in the bare, single-stranded DNA result from a chance matching of short regions of complementary nucleotide sequence.

releases itself from the clamp and dissociates from the template. With the help of the clamp loader, which hydrolyzes ATP as it loads a new clamp onto a primer-template junction (Figure 5–17), this lagging-strand polymerase molecule then associates with the new clamp that is assembled on the RNA primer of the next Okazaki fragment.

The Proteins at a Replication Fork Cooperate to Form a Replication Machine

Although we have discussed DNA replication as though it were performed by a set of proteins all acting independently, in reality most of these proteins are held together in a large and orderly multienzyme complex that rapidly synthesizes DNA. This complex can be likened to a tiny sewing machine composed of protein

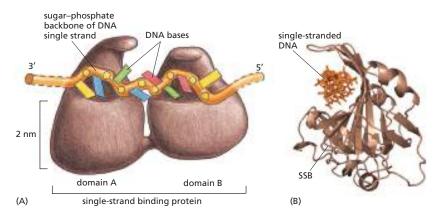

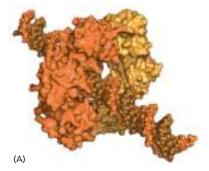

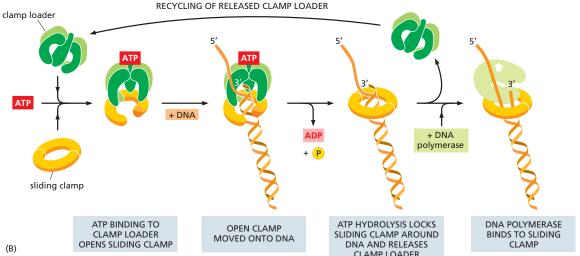

Figure 5–16 Human single-strand binding protein bound to DNA. (A) Front view of the two DNA-binding domains of the protein (called RPA), which cover a total of eight nucleotides. Note that the DNA bases remain exposed in this protein–DNA complex. (B) Diagram showing the three-dimensional structure, with the DNA strand (orange) viewed end on. (PDB code: 1JMC.)

MBOC7_ptr_ch05_253-320.indd 263 02/12/21 12:46 PM

Figure 5–17 The sliding clamp that holds DNA polymerase on the DNA. (A) The structure of the clamp protein from *E. coli*, as determined by x-ray crystallography, with a DNA helix added to indicate how the protein fits around DNA (Movie 5.3). (B) Schematic illustration showing how the clamp is loaded onto DNA. The structure of the clamp loader (green) resembles a screw nut, with its threads matching the grooves of double-stranded DNA. The loader binds to a free clamp molecule, forcing a gap in its ring of subunits, which enables it to slip around DNA. The loader then "screws" the open clamp onto double-stranded DNA until it encounters the 3' end of a primer, at which point the loader hydrolyzes ATP and releases the clamp, allowing it to close around the DNA. In the simplified reaction shown here, the clamp loader dissociates once the clamp has been assembled. At bacterial replication forks, the clamp loader remains bound to the polymerase so that, on the lagging strand, it is ready to assemble a new clamp at the start of each new Okazaki fragment. (A, from X.P. Kong et al., *Cell* 69:425–437, 1992; PDB code: 3BEP; B, adapted from B.A. Kelch et al., *Science* 334:1675–1680, 2011.)

parts and powered by nucleoside triphosphate hydrolysis. Like a sewing machine, the replication complex probably remains stationary with respect to its immediate surroundings; the DNA can be thought of as a long strip of cloth being rapidly threaded through it. Although the replication complex has been most intensively studied in *E. coli* and several of its viruses, a very similar complex also operates in eukaryotes, as we shall see below.

How the different proteins at the replication fork work together in bacteria is shown in Figure 5-18. At the front of the replication fork, DNA helicase opens the DNA helix. Several identical DNA polymerase molecules work at the fork, one on the leading strand and two on the lagging strand. Whereas the DNA polymerase molecule on the leading strand can operate in a continuous fashion, the DNA polymerase molecules on the lagging-strand alternate at short intervals, using the short RNA primers made by DNA primase to begin each Okazaki fragment. The close association of all these protein components increases the efficiency of replication, and it is made possible by a folding back of the lagging strand as shown in the figure. This arrangement facilitates the loading of the polymerase clamp each time that an Okazaki fragment is synthesized: the clamp loader and the lagging-strand DNA polymerase molecule are kept in place at the replication fork even when they detach from their DNA template. The replication proteins are thus linked together into a single large unit (total molecular mass >10⁶ daltons), enabling DNA to be synthesized on both sides of the replication fork in a coordinated and efficient manner.

On the lagging strand, the DNA replication machine leaves behind a series of unsealed Okazaki fragments, which still contain the RNA that primed their synthesis at their 5' ends. As discussed earlier, this RNA is removed, and the resulting

MBOC7_ptr_ch05_253-320.indd 264 02/12/21 12:46 PM

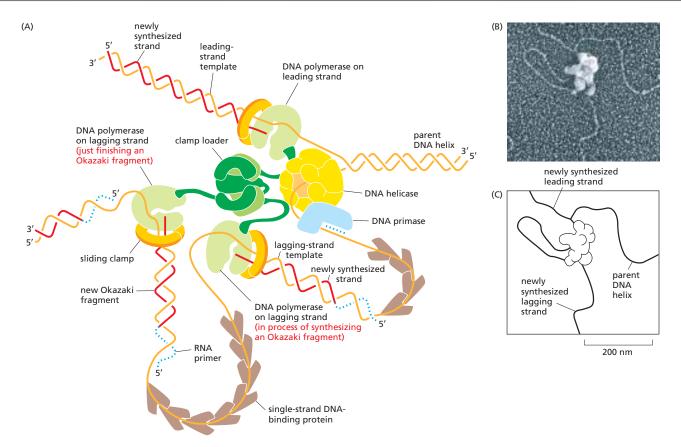

Figure 5–18 A bacterial replication fork. (A) In this case, a single DNA polymerase molecule synthesizes the leading strand while two DNA polymerases are used—in alternating fashion—for lagging-strand DNA synthesis. All of these polymerase molecules, which are identical, are held in place at the fork by flexible "arms" that extend from the clamp loader. Additional interactions (for example, between the DNA helicase and primase) ensure that all the individual components function together as a well-coordinated protein machine (Movie 5.4). (B) An electron micrograph showing the replication machine from the bacteriophage T4 as it moves along a template synthesizing DNA behind it. (C) An interpretation of the micrograph is given in the sketch: note especially the DNA loop on the lagging strand. Apparently, during the preparation of this sample for electron microscopy, the replication proteins became partly detached from the very front of the replication fork. (B, from P.D. Chastain et al., J. Biol. Chem. 278:21276–21825, 2003. With permission from American Society for Biochemistry and Molecular Biology.)

gap is filled in by DNA repair enzymes that operate behind the replication fork (see Figure 5–11).

DNA Replication Is Fundamentally Similar in Eukaryotes and Bacteria

Much of what we know about DNA replication was first derived from studies of purified bacterial and bacteriophage multienzyme systems capable of DNA replication *in vitro*. The development of these systems in the 1970s was greatly facilitated by the prior isolation of mutants in a variety of replication genes; these mutants were exploited to identify and purify the corresponding replication proteins. The first eukaryotic replication system that accurately replicated DNA *in vitro* was described in the mid-1980s, and mutations in genes encoding nearly all of the replication components have now been isolated and analyzed in the yeast *Saccharomyces cerevisiae*. As a result, much is known about the detailed enzymology of DNA replication in eukaryotes, and it is clear that the fundamental features of DNA replication—including replication-fork geometry and the use of $5' \rightarrow 3'$ DNA polymerases, helicases, clamps, clamp loaders, and single-strand binding proteins—are similar.

MBOC7_ptr_ch05_253-320.indd 265 02/12/21 12:46 PM

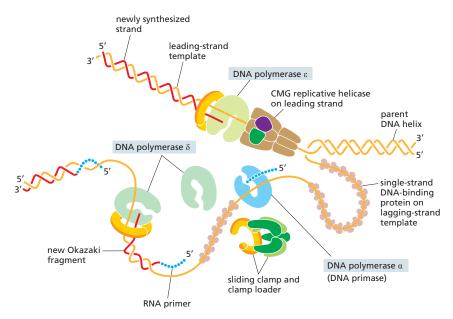

Figure 5–19 Schematic diagram of a eukaryotic replication fork. Unlike the bacterial replication proteins, those from eukaryotes are thought to function largely independently, perhaps accounting for the slower speed of the eukaryotic replication fork (Movie 5.5). Note that the eukaryotic CMG helicase moves unidirectionally along the leading-strand template, whereas the bacterial helicase discussed earlier moves in one direction along the lagging-strand template (see Figure 5–18). In both cases, the DNA duplex is rapidly pried apart at the front of the moving replication fork by harnessing the energy of ATP hydrolysis.

However, there are some important differences in how bacteria and eukaryotes replicate their DNA. Perhaps most important, eukaryotes use three different kinds of DNA polymerase at each replication fork (Figure 5–19). Polymerase ϵ (Pol ϵ) synthesizes the leading strand, whereas Pol α and Pol δ synthesize the lagging-strand Okazaki fragments. Each type of polymerase has special properties that make it well suited for its job. Pol ϵ binds to both the sliding clamp and the replicative helicase, allowing it to synthesize very long stretches of leading-strand DNA without dissociating. Pol α includes DNA primase as one of its subunits, which begins all new chains by synthesizing a short length of RNA. This RNA is extended by a different subunit of Pol α , which adds only about 20 nucleotides of DNA before dissociating. Finally, Pol δ , which is loaded in conjunction with a sliding clamp, takes over and completes synthesis of each Okazaki fragment to produce a total length of about 200 nucleotides.

The use of three different kinds of DNA polymerase at the replication fork is part of a trend toward higher complexity observed for eukaryotic DNA replication compared to that of bacteria. As another example, the eukaryotic single-strand binding protein is formed from three different subunits, while only a single subunit is found in bacteria. Likewise, the eukaryotic replicative helicase (known as the CMG helicase) is composed of 11 different protein subunits, while the bacterial enzyme is a hexamer of 6 identical subunits. We do not know why the eukaryotic replication machinery is so much more complex than that of bacteria; however, there are several possibilities. In eukaryotes, DNA replication must be coordinated with the elaborate process of mitosis; it must also deal with DNA packaged into nucleosomes, topics we discuss in the next part of the chapter. It is also possible that the difference in complexity between bacteria and eukaryotes largely reflects evolutionary pressure for bacteria to make do with fewer genes.

Another important distinction between eukaryotic and bacterial replication protein complexes lies in the detailed structures of their individual protein

MBOC7_ptr_ch05_253-320.indd 266 02/12/21 12:46 PM

components. With the exception of the sliding clamp, the replication proteins in bacteria have completely different structures and amino acid sequences than those of their eukaryotic counterparts. The simplest interpretation of this surprising fact is that, over hundreds of millions of years, the DNA replication machinery in eukaryotes and bacteria evolved independently, yet converged on the same basic mechanisms. This situation is in contrast to other fundamental processes in the cell, such as transcription and translation, where the fundamental components (RNA polymerase and the ribosome) are very similar between bacteria and eukaryotes—and where the structures are conserved from an ancient, common ancestor.

A Strand-directed Mismatch Repair System Removes Replication Errors That Remain in the Wake of the Replication Machine

Because bacteria such as *E. coli* are capable of dividing once every 30 minutes, it is relatively easy to screen large populations to find a rare mutant cell that is altered in a specific process. One interesting class of mutants consists of those with alterations in so-called *mutator genes*, which greatly increase the rate of spontaneous mutation. Not surprisingly, one such mutant makes a defective form of the 3'-to-5' proofreading exonuclease that is a part of the DNA polymerase enzyme (see Figures 5–8 and 5–9). The mutant DNA polymerase no longer proofreads effectively, and many replication errors that would otherwise have been removed accumulate in the DNA.

The study of other *E. coli* mutants exhibiting abnormally high mutation rates uncovered an additional proofreading system, common to all cells on Earth, that removes those rare replication errors that were made by the polymerase and missed by its proofreading exonuclease. These errors leave mismatched base pairs behind the replication fork, which are subsequently recognized and corrected by a **strand-directed mismatch repair** system. This system picks out mismatches from normal DNA by monitoring their potential to distort the DNA double helix, which is greatly increased by the misfit between noncomplementary base pairs. However, if the repair system simply recognized a mismatch in newly replicated DNA and randomly corrected one of the two mismatched nucleotides, it would mistakenly "correct" the original template strand to match the error exactly half the time, thereby failing to lower the overall error rate. To be effective, such a proofreading system must be able to remove only the nucleotide on the newly synthesized strand, where the error occurred.

The strand-distinction mechanism used by the mismatch proofreading system in *E. coli* depends on the methylation of selected A residues in the DNA. Methyl groups are added to all A residues in the sequence GATC, but not until some time after the GATC has been synthesized. As a result, the only unmethylated GATC sequences lie in the newly synthesized strands just behind a replication fork. The recognition of these unmethylated GATCs (which are base-paired to methylated GATCs) allows the new DNA strands to be transiently distinguished from old ones, as required if their mismatches are to be selectively removed. The five-step error-correction process involves recognition of a mismatch, identification of the newly synthesized strand, excision of the portion containing the misincorporated nucleotide, resynthesis of the excised segment using the old strand as a template, and ligation to seal the DNA backbone. This strand-directed mismatch repair system reduces the number of errors made during DNA replication by an additional factor of 100–1000 (see Table 5–1, p. 260).

A similar mismatch proofreading system functions in eukaryotic cells, but it uses a different way to distinguish the newly synthesized DNA strands from the parent strands. On the lagging strand, the newly synthesized DNA will contain transient single-strand gaps before the series of Okazaki fragments are processed and ligated together. Each gap will usually carry a sliding clamp, which remains on the DNA after the DNA polymerase has dissociated from it to begin the next fragment. Together, the clamp and the single-strand break signal to the mismatch

MBOC7_ptr_ch05_253-320.indd 267 02/12/21 12:46 PM

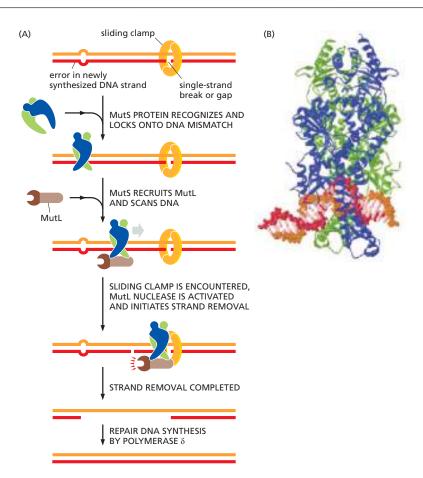

Figure 5–20 Strand-directed mismatch repair in eukaryotes. (A) The MutS protein binds to a mismatched base pair, recruits the MutL protein, and the complex scans the nearby DNA for a gap and a sliding clamp whose orientation determines which strand is to be cut and its nucleotides replaced. When these are encountered, MutL is activated and begins to cleave the DNA. In most organisms, MutL is joined by another nuclease and, together, they remove the newly synthesized DNA starting at the gap and extending past the mismatch. The gap is then filled in by DNA polymerase δ and sealed by DNA ligase. (B) The structure of the MutS protein bound to a DNA mismatch. This protein is a dimer, which grips the DNA double helix as shown, kinking the DNA at the mismatched base pair. It seems that the MutS protein scans the DNA for mismatches by testing for sites that can be readily kinked, which are those with an abnormal base pair. (PDB code: 1EWQ.)

repair proteins to correct the mismatch using the parent DNA strand as the template (Figure 5-20).

The two faces of the clamp differ, and the clamp loader always loads the clamp in the same orientation with respect to the 3' end of the previously synthesized Okazaki fragment. Because all the clamps on the DNA "face" in the same direction relative to the replication process, the oriented clamps can be used by the mismatch repair machinery to distinguish newly synthesized DNA from parent DNA. It is not known for certain how strand discrimination occurs on the leading strand (where gaps in newly synthesized DNA should be rare), but because oriented sliding clamps are also left behind by the leading-strand polymerase, they can signal old from new DNA in the same way that they do on the lagging strand. The recent discovery of a correction system that removes misincorporated ribonucleotides suggests a further possibility for distinguishing newly synthesized DNA from parent DNA, as we discuss in the next section.

Mismatch correction is crucial for all cells; its importance for humans is seen in individuals who inherit one defective copy of a mismatch repair gene (along

MBOC7_ptr_ch05_253-320.indd 268 02/12/21 12:46 PM

with a functional gene on the other copy of the chromosome). These individuals have a marked predisposition for certain types of cancers. For example, in a type of colon cancer called *hereditary nonpolyposis colorectal cancer* (*HNPCC*), a spontaneous deleterious mutation of the one functional gene will produce a clone of somatic cells that, because they are deficient in mismatch proofreading, accumulate mutations unusually rapidly. Because most cancers arise in cells that have accumulated many mutations (as discussed in Chapter 20), cells deficient in mismatch proofreading have a greatly enhanced chance of becoming cancerous. Fortunately, most of us inherit two good copies of each gene that encodes a mismatch proofreading protein; this protects us, because it is highly unlikely that both copies will become mutated in the same cell.

The Accidental Incorporation of Ribonucleotides During DNA Replication Is Corrected

We have seen that cells have several ways to correct mistakes where the wrong deoxynucleotide has been incorporated in newly replicated DNA. Occasionally, however, DNA polymerases make a different kind of mistake, one that is not caused by improper base-pairing: in this case, they accidently incorporate a ribonucleotide instead of a deoxyribonucleotide. These molecules differ by a single –OH group in the sugar portion of the nucleotide. Yet, when incorporated into DNA, they weaken the DNA chain at that point, rendering it highly susceptible to breakage. If left unrepaired, these "weak links" would cause high mutation rates and genome rearrangements. Even if it does not cause a break, an incorporated ribonucleotide distorts the DNA double helix and can stall some polymerases during the next cycle of DNA replication.

Although DNA polymerases much prefer deoxyribonucleotides over ribonucleotides (by a factor of about a million), the concentration of ribonucleotides in the cell is much higher than that of their deoxy counterparts, as much as 500-fold for ATP, which has many different uses in the cell. This concentration imbalance means that a ribonucleotide is accidentally incorporated approximately once per several thousand nucleotides of DNA synthesized. These mistakes are corrected by specific nucleases that cleave the DNA chain when they encounter a ribonucleotide, leading to the excision of the ribonucleotide and its replacement by DNA, much in the same way that RNA primers are replaced by DNA to complete lagging-strand synthesis (see Figure 5–11). Because this repair process produces gaps only in newly synthesized DNA, it has been proposed that these transient lesions help the mismatch repair system "know" which strand to repair; in particular, these cues may be especially important on the leading strand.

DNA Topoisomerases Prevent DNA Tangling During Replication

As a replication fork moves along double-stranded DNA, it creates what has been called the "winding problem." The two parent strands that are wound around each other must be unwound and separated for replication to occur. For every 10 nucleotide pairs replicated at the fork, one complete turn of the parent double helix must be unwound. In principle, this unwinding can be achieved by rapidly rotating the entire chromosome ahead of a moving fork; however, this is energetically highly unfavorable (particularly for long chromosomes). Instead, the DNA in front of a replication fork becomes overwound (Figure 5–21). This overwinding is continually relieved by enzymes known as *DNA topoisomerases*.

A **DNA topoisomerase** can be viewed as a reversible nuclease that adds itself covalently to a DNA backbone phosphate, thereby breaking a phosphodiester bond in a DNA strand. This reaction is reversible, and the phosphodiester bond re-forms as the protein leaves.

One type of topoisomerase, called *topoisomerase I*, produces a transient single-strand break; this break in the phosphodiester backbone allows the

MBOC7_ptr_ch05_253-320.indd 269 02/12/21 12:46 PM

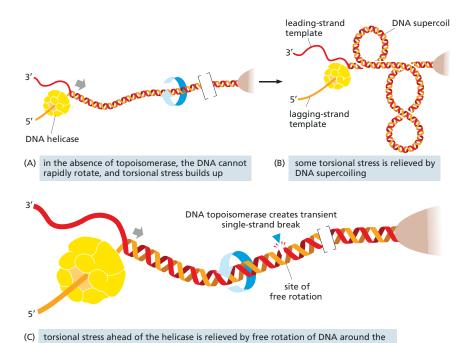

Figure 5-21 The "winding problem" that arises during DNA replication. (A) For a bacterial replication fork moving at 500 nucleotides per second, the parent DNA helix ahead of the fork must rotate at about 50 revolutions per second. The brackets represent about 20 turns of DNA. (B) If the ends of the DNA double helix remain fixed (or difficult to rotate), tension builds up in front of the replication fork as it becomes overwound. Some of this tension can be taken up by supercoiling, whereby the DNA double helix twists around itself. However, if the tension continues to build up, the replication fork will eventually stop because further unwinding requires more energy than the DNA helicase at the fork can provide. (C) DNA topoisomerases relieve this stress by generating temporary singlestrand breaks in the DNA, which allow rapid rotation around the single strands opposite the break.

two sections of DNA helix on either side of the nick to rotate freely relative to each other, using the phosphodiester bond in the strand opposite the nick as a swivel point (Figure 5–22). Any tension in the DNA helix will drive this rotation in the direction that relieves the tension. As a result, DNA replication can occur with the rotation of only a short length of helix—the part just ahead of the fork. Because the covalent linkage that joins the DNA topoisomerase protein to a DNA phosphate retains the energy of the cleaved phosphodiester bond, resealing is rapid and does not require additional energy input. In this respect, the rejoining mechanism differs from that catalyzed by the enzyme DNA ligase, discussed previously (see Figure 5–12).

phosphodiester bond opposite the single-strand break; the same DNA topoisomerase

molecule that produced the break reseals it

A second type of DNA topoisomerase, *topoisomerase II*, forms a covalent linkage to both strands of the DNA helix at the same time, making a transient *double-strand break* in the helix. These enzymes are activated by sites on chromosomes where two double helices cross over each other, such as those generated by supercoiling in front of a replication fork (see Figure 5–21B). As illustrated in Figure 5–23, once a topoisomerase II molecule binds to such a crossing site, the protein uses ATP hydrolysis to perform the following set of reactions: (1) it breaks one double helix reversibly to create a DNA "gate"; (2) it causes the second, nearby double helix to pass through this opening; and (3) it then reseals the break and dissociates from the DNA. At crossover points generated by supercoiling, passage of the double helix through the gate occurs in the direction that will reduce supercoiling. In this way, type II topoisomerases—like type I topoisomerases—can relieve the overwinding tension generated in front of a replication fork.

Their reaction mechanism also allows type II DNA topoisomerases to efficiently separate any intertwined DNA molecules. This ability of topoisomerase II is especially important for preventing the severe DNA tangling problems that would otherwise arise from DNA replication. This role is nicely illustrated by mutant yeast cells that produce, in place of the normal topoisomerase II, a version that is inactive above 37°C. When the mutant cells are warmed to this temperature, their daughter chromosomes remain intertwined after DNA replication and are unable to separate. The enormous usefulness of topoisomerase II for untangling

MBOC7_ptr_ch05_253-320.indd 270 02/12/21 12:46 PM

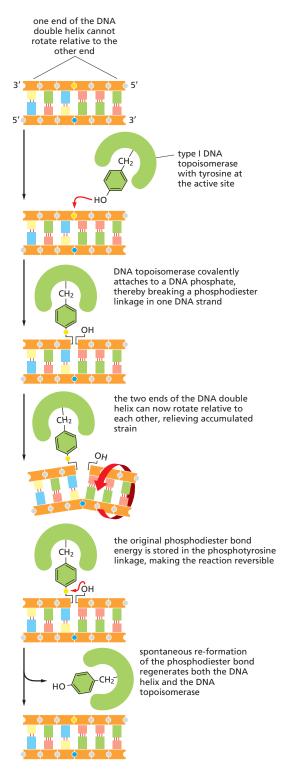

Figure 5–22 The reversible DNA nicking reaction catalyzed by a DNA topoisomerase I enzyme. As indicated, these enzymes transiently form a single covalent bond with DNA; this allows free rotation of the DNA around the covalent backbone bonds linked to the *blue* phosphate. On reversal of the reaction, the enzyme and the DNA are restored, the only difference being the relaxation of tension in the DNA.

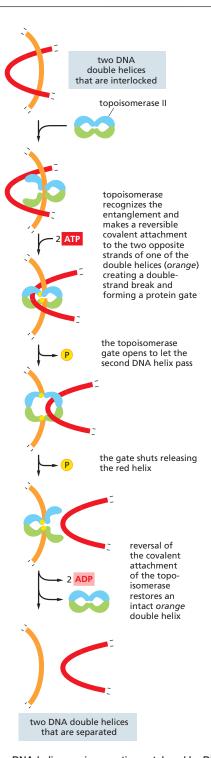

Figure 5–23 The DNA-helix-passing reaction catalyzed by DNA topoisomerase II. Unlike type I topoisomerases, type II enzymes hydrolyze ATP, which is needed to release and reset the enzyme after each cycle. The small yellow circles represent the 5' phosphates in the DNA backbone that become covalently bonded to the topoisomerase. Type II topoisomerases are especially important for rapidly dividing cells; partly for that reason, they are effective targets for a large class of antibiotics, the fluoroquinolones, used to treat many different kinds of bacterial infections. These drugs inhibit bacterial topoisomerase II at the third step in the figure and thereby produce high levels of double-strand breaks that are lethal to rapidly dividing cells.

MBOC7_ptr_ch05_253-320.indd 271 02/12/21 12:46 PM

chromosomes before mitosis begins can readily be appreciated by anyone who has struggled to remove a severe tangle from a fishing line—or from a large ball of thread—without the aid of scissors.

Summary

DNA replication takes place at a Y-shaped structure called a replication fork. Self-correcting DNA polymerase enzymes catalyze nucleotide polymerization in a 5'-to-3' direction, copying a DNA template strand with remarkable fidelity. Because the two strands of a DNA double helix are antiparallel, this 5'-to-3' DNA synthesis can take place continuously on only one of the strands at a replication fork (the leading strand). On the lagging strand, short DNA fragments must be made by a "backstitching" process. Because the self-correcting DNA polymerases cannot start a new chain, these lagging-strand DNA fragments are primed by short RNA primer molecules that are subsequently erased and replaced with DNA.

DNA replication requires the cooperation of many proteins. These include (1) DNA polymerases and DNA primases to catalyze nucleoside triphosphate polymerization; (2) DNA helicases and single-strand DNA-binding (SSB) proteins to help in opening up the DNA helix so that it can be copied; (3) clamps and clamp loaders to enable DNA polymerases to copy longer stretches of DNA; (4) DNA ligases and enzymes that degrade RNA primers to seal together the discontinuously synthesized lagging-strand DNA fragments; and (5) DNA topoisomerases to help to relieve helical winding and DNA tangling problems. Many of these proteins associate with each other at a replication fork to form a highly efficient "replication machine," through which the activities and spatial movements of the individual components are coordinated.

The self-correcting DNA polymerases make mistakes only rarely when copying DNA; when they do, a variety of enzymes inspect the DNA shortly after it is made and correct any mishaps. Given the number of proteins dedicated to the task, copying DNA with extreme accuracy is clearly of great importance to all cells on Earth.

THE INITIATION AND COMPLETION OF DNA REPLICATION IN CHROMOSOMES

We have seen how a set of replication proteins rapidly and accurately generates two daughter DNA double helices behind a replication fork. But how is this replication machinery assembled in the first place, and how are replication forks created on an intact, double-strand DNA molecule? In this part of the chapter, we discuss how cells initiate DNA replication and how they carefully regulate this process to ensure that it takes place only at the proper time and chromosomal sites. We also discuss special problems that the replication machinery in eukaryotic cells must overcome including the need to replicate the enormously long DNA molecules found in eukaryotic chromosomes, as well as the need to copy DNA molecules that are tightly complexed with nucleosomes.

DNA Synthesis Begins at Replication Origins

As discussed previously, the DNA double helix is normally very stable: the two DNA strands are locked together firmly by the hydrogen bonds formed between the bases on each strand. To begin DNA replication, the double helix must first be opened up and the two strands separated to expose unpaired bases. As we shall see, the process of DNA replication is begun by special *initiator proteins* that bind to double-stranded DNA and pry the two strands apart, breaking the hydrogen bonds between the bases.

The positions at which the DNA helix is first opened are called **replication origins** (**Figure 5–24**). In simple cells like those of bacteria or budding yeast, origins are specified by DNA sequences several hundred nucleotide pairs in

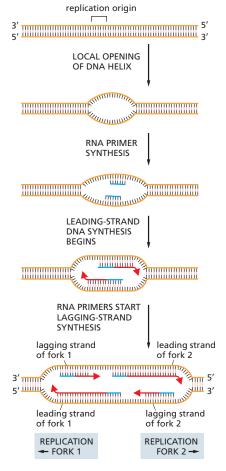

Figure 5–24 A replication bubble formed by replication-fork initiation. This diagram outlines the major steps in the initiation of replication forks at replication origins. In the last step, two replication forks move away from each other, separated by an expanding replication bubble.

MBOC7_ptr_ch05_253-320.indd 272 02/12/21 12:46 PM

length. This DNA contains both short sequences that attract initiator proteins and stretches of DNA that are especially easy to open. We saw in Figure 4-5A that an A-T base pair is held together by fewer hydrogen bonds than is a G-C base pair. Therefore, DNA rich in A-T base pairs is relatively easy to pull apart, and regions of DNA enriched in A-T base pairs are typically found at replication origins.

Although the basic process of replication-fork initiation depicted in Figure 5–24 is fundamentally the same for bacteria and eukaryotes, the detailed way in which this process is performed and regulated differs considerably between these two groups of organisms. We first consider the case in bacteria and then turn to the more complex situation found in yeasts, mammals, and other eukaryotes.

Bacterial Chromosomes Typically Have a Single Origin of DNA Replication

The genome of E. coli is contained in a single circular DNA molecule of 4.6 \times 10⁶ nucleotide pairs. DNA replication begins at a single origin of replication, and the two replication forks assembled there proceed (at approximately 1000 nucleotides per second) in opposite directions until they meet up roughly halfway around the chromosome (Figure 5-25). The only point at which E. coli can control DNA replication is initiation: once the forks have been assembled at the origin, they synthesize DNA at a relatively constant speed until replication is finished. Therefore, it is not surprising that the initiation step of DNA replication is tightly regulated. The process begins when specialized initiator proteins (in their ATP-bound state) bind in multiple copies to specific DNA sites located at the replication origin, wrapping the DNA around the proteins to form a large protein-DNA filament that introduces torsional stress on the DNA double helix (Figure 5-26). This stress is partially relieved by melting of the adjacent AT-rich sequences. The protein-DNA complex then attracts two DNA helicases, each bound to a helicase loader, and these are placed—facing in opposite directions around adjacent DNA single strands whose bases have been exposed by the assembly of the initiator protein-DNA complex. The helicase loader is analogous to the clamp loader we encountered earlier; it has the additional job of keeping the helicase in an inactive form until it is properly loaded. Once the helicases are properly positioned on DNA, the loaders dissociate and the helicases begin to unwind DNA, exposing enough single-stranded DNA for DNA primases to synthesize the first RNA primers. This quickly leads to the assembly of the remaining replication proteins to create two replication forks that move in opposite directions away from the replication origin, each synthesizing new DNA as they travel.

In *E. coli*, the interaction of the initiator proteins with the replication origin is carefully regulated, with initiation occurring only when sufficient nutrients are available for the bacterium to complete an entire round of replication. Initiation is also controlled to ensure that only one round of DNA replication occurs for each cell division. After replication is initiated, the initiator protein is inactivated by hydrolysis of its bound ATP molecule, and the origin of replication experiences a *refractory period*. The refractory period is caused by a delay in the methylation of newly incorporated A nucleotides in the origin (**Figure 5–27**). Initiation cannot occur again until the A's are methylated and the initiator protein is restored to its ATP-bound state, conditions that are met only when the cell is capable of carrying out a new round of DNA replication.

Eukaryotic Chromosomes Contain Multiple Origins of Replication

We have seen how two replication forks begin at a single replication origin in bacteria and proceed in opposite directions, moving away from the origin until all of the DNA in the single circular chromosome is replicated. The bacterial genome is sufficiently small for these two replication forks to duplicate the genome in about

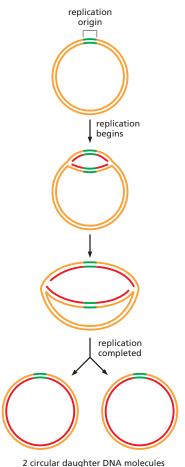

Figure 5–25 DNA replication of a

bacterial genome. It takes *E. coli* about 30 minutes to duplicate its genome of 4.6×10^6 nucleotide pairs. For simplicity, Okazaki fragments are not shown on the lagging strand.

MBOC7_ptr_ch05_253-320.indd 273 02/12/21 12:46 PM

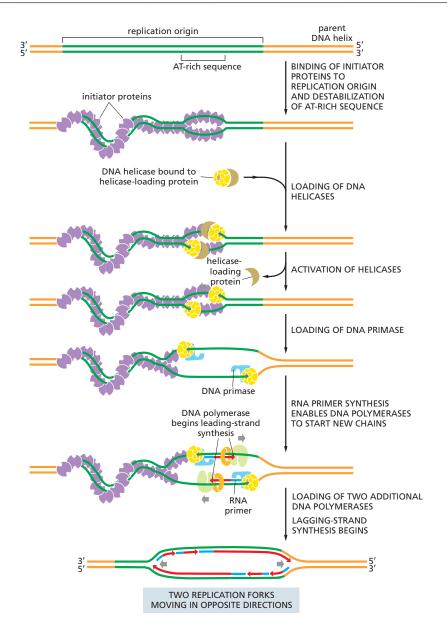

Figure 5–26 The proteins that initiate DNA replication in bacteria. The mechanism shown was established by studies in vitro with mixtures of highly purified proteins. For E. coli DNA replication, the major initiator protein (purple), the helicase (yellow), and the primase (blue) are the dnaA, dnaB, and dnaG proteins, respectively. In the first step, many molecules of the initiator protein bind to specific DNA sequences at the replication origin and destabilize the double helix by forming a filamentous structure in which the DNA is wrapped around the protein. Next, two helicases are brought in by helicase-loading proteins (the dnaC proteins; brown), which inhibit the helicases until they are properly loaded at the replication origin. (The helicase-loading proteins prevent the replicative DNA helices from inappropriately entering other singlestrand stretches of DNA in the bacterial genome.) Aided by single-strand binding protein (not shown), the loaded helicases further separate the DNA strands, thereby enabling primases to enter and synthesize initial primers. In subsequent steps, two complete replication forks are assembled at the origin and move in opposite directions away from the replication origin. The initiator proteins are displaced as the lefthand fork moves through them.

30 minutes. Because of the much greater size of most eukaryotic chromosomes, a different strategy is required to allow their replication in a timely manner.

A method for determining the general pattern of eukaryotic chromosome replication was developed in the early 1960s that is similar to the strategy we saw earlier for visualizing bacterial replication (see Figure 5–6). Human cells growing

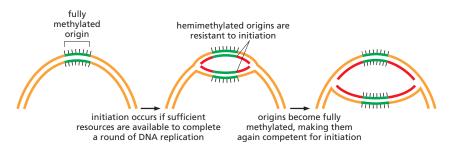

Figure 5–27 Methylation of the *E. coli* replication origin creates a refractory period for DNA initiation. DNA methylation occurs at GATC sequences,

11 of which are found in the origin of replication (spanning approximately 250 nucleotide pairs). In its hemimethylated state (that is, one strand of the DNA methylated, the other unmethylated), the origin of replication is bound by an inhibitor protein (Seq A, not shown), which blocks the ability of the initiator proteins to unwind the origin DNA. About 15 minutes after replication is initiated, the hemimethylated origins become fully methylated by a DNA methylase enzyme; Seq A then dissociates allowing the origin of replication to become active.

A single enzyme, the *Dam* methylase, is responsible for methylating all *E. coli* GATC sequences. As discussed earlier in the chapter, a lag in methylation after the replication of GATC sequences is also used by the *E. coli* mismatch proofreading system to distinguish the newly synthesized DNA strand from the parent DNA strand; in that case, the relevant GATC sequences are scattered throughout the chromosome, and they are not bound by Seq A.

MBOC7_ptr_ch05_253-320.indd 274 02/12/21 12:46 PM

in culture are labeled for a short time with ³H-thymidine so that the DNA synthesized during this period becomes highly radioactive. The cells are then gently lysed, and the DNA is stretched on the surface of a glass slide coated with a photographic emulsion. Development of the emulsion in the dark reveals the pattern of labeled DNA through a technique known as autoradiography. The time allotted for radioactive labeling is chosen to allow each replication fork to move several micrometers along the DNA, so that the replicated DNA can be detected in the light microscope as lines of silver grains (radioactivity exposes photographic emulsion much as light does), even though the DNA molecule itself is too thin to be visible. In this way, both the rate and the direction of replication-fork movement can be determined (Figure 5-28). From the rate at which tracks of replicated DNA increase in length with increasing labeling time, the eukaryotic replication forks are estimated to travel at about 50 nucleotides per second. This is approximately twentyfold slower than the rate at which bacterial replication forks move, possibly reflecting the increased difficulty of replicating DNA that is packaged in chromatin.

An average-size human chromosome contains a single linear DNA molecule of about 150 million nucleotide pairs. It would take 0.02 seconds/nucleotide \times 150 \times 106 nucleotides = 3.0 \times 106 seconds (about 35 days) to replicate such a DNA molecule from end to end with a single replication fork moving at a rate of 50 nucleotides per second. As expected, therefore, the autoradiographic experiments just described reveal that many forks, belonging to separate replication bubbles, are moving simultaneously on each eukaryotic chromosome.

Much more sophisticated methods now exist for monitoring DNA replication initiation and tracking the movement of DNA replication forks across whole genomes. If a population of cells can be synchronized so they all begin DNA replication at the same time, the amount of each segment of DNA in the genome can be determined at specific time points using one of the DNA sequencing methods described in Chapter 8. Because a segment of a genome that has been replicated will contain twice as much DNA as an unreplicated segment, replication-fork initiation and fork movement can be accurately monitored across an entire genome.

Experiments of this type have shown the following: (1) Approximately 30,000–50,000 origins of replication are used each time a human cell divides. (2) The human genome has many more (perhaps tenfold more) potential origins than this, and different cell types use different sets of origins. This excess of origins may allow a cell to coordinate its active origins with other features of its chromosomes such as which genes are being expressed. The excess origins also provide "backups" in case a primary origin fails. (3) Origins of replication do not all "fire" simultaneously; rather, they often are activated in a prescribed order in a given cell type. (4) Regardless of when a given origin fires or where on the chromosome it is located, the replication forks all move at approximately the same speed. (5) As in bacteria, replication forks are formed in pairs and create an expanding

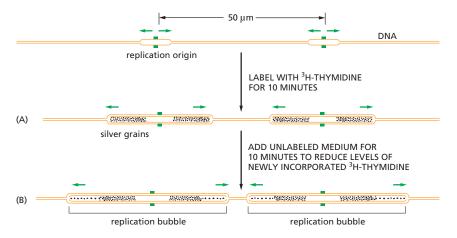

Figure 5-28 The experiments that first demonstrated the pattern in which replication forks are formed and move on eukaryotic chromosomes. The new DNA made in human cells in culture was labeled briefly with a pulse of highly radioactive thymidine (3H-thymidine). (A) In this experiment, the cells were lysed, and the DNA was stretched out on a glass slide that was subsequently covered with a photographic emulsion. After several months, the emulsion was developed, revealing a line of silver grains over the radioactive DNA. The brown DNA in this figure is shown only to help with the interpretation of the autoradiograph; the unlabeled DNA is invisible in such experiments. (B) This experiment was the same except that a further incubation in unlabeled medium allowed additional DNA, with a lower level of radioactivity, to be replicated. The pairs of dark tracks in B were found to have silver grains tapering off in opposite directions, demonstrating bidirectional fork movement from a central replication origin where a replication bubble forms (see Figure 5-24). A replication fork is thought to stop only when it encounters a replication fork moving in the opposite direction or when it reaches the end of the chromosome; in this way, all the DNA is eventually replicated.

MBOC7_ptr_ch05_253-320.indd 275 02/12/21 12:46 PM

replication bubble as they move in opposite directions away from a common point of origin, stopping only when they meet a replication fork moving in the opposite direction or when they reach a chromosome end. In this way, many replication forks operate independently on each chromosome and yet form two complete daughter DNA helices.

In Eukaryotes, DNA Replication Takes Place During Only One Part of the Cell Cycle

When growing rapidly, bacteria replicate their DNA nearly continually. In contrast, DNA replication in most eukaryotic cells occurs only during a specific part of the cell-division cycle, called the *DNA synthesis phase*, or **S phase** (Figure 5–29). In a mammalian cell, the S phase typically lasts for about 8 hours; in simpler eukaryotic cells such as yeasts, the S phase can be as short as 40 minutes. By its end, each chromosome has been replicated to produce two complete copies, which remain joined together at their centromeres until the *M phase* (M for *mitosis*), which soon follows. Although different origins of replication fire at different times, all DNA replication is begun and completed during S phase. In Chapter 17, we describe the control system that runs the cell cycle, and we explain how entry into each phase of the cycle requires the cell to have successfully completed the previous phase.

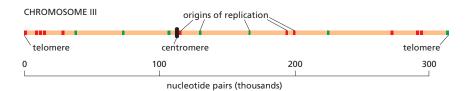

In the following sections, we explore how DNA replication begins on eukaryotic chromosomes and how this event is coordinated with the cell cycle.

Eukaryotic Origins of Replication Are "Licensed" for Replication by the Assembly of an Origin Recognition Complex

Having seen that a eukaryotic chromosome is replicated using many origins of replication, each of which fires at a characteristic time in S phase of the cell cycle, we turn to the nature of these origins of replication. We saw earlier in this chapter that replication origins have been precisely defined in bacteria as specific DNA sequences that attract initiator proteins, which then assemble the DNA replication machinery. We shall see that this is also the case for the single-cell budding yeast *S. cerevisiae*, but it appears not to be strictly true for many other eukaryotes.

For budding yeast, the location of every origin of replication on each chromosome has been determined. The particular chromosome shown in Figure 5–30—chromosome III from *S. cerevisiae*—is one of the smallest chromosomes known, with a length less than 1/100 that of a typical human chromosome. Its major origins are spaced an average of 30,000 nucleotide pairs apart, but only a subset of these origins is used by a given cell. Nonetheless, this chromosome can be replicated in about 15 minutes.

The minimal DNA sequence required for directing DNA replication initiation in *S. cerevisiae* has been determined by taking a segment of DNA that spans an origin of replication and testing smaller and smaller DNA fragments for their ability to function as origins. These DNA sequences that can serve as an origin of replication are found to contain (1) a binding site for a large, multisubunit initiator protein called ORC, for origin recognition complex; (2) a stretch of DNA that is rich in A's and T's and therefore easy to pull apart; and (3) at least one binding site for proteins that facilitate ORC binding, probably by adjusting the local chromatin structure.

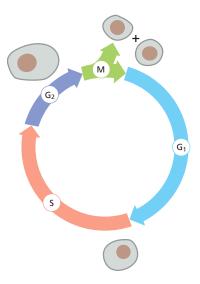

Figure 5–29 The four successive phases of a standard eukaryotic cell cycle. During the G_1 , S, and G_2 phases, the cell grows continually. During M phase growth stops, the nucleus divides, and the cell divides in two. DNA replication is confined to the part of the cell cycle known as S phase. G_1 is the gap between M phase and S phase and M phase. Many eukaryotic cells spend only a small fraction of their time in S phase.

Figure 5–30 The origins of DNA replication on chromosome III of the yeast *S. cerevisiae*. This chromosome, one of the smallest eukaryotic chromosomes known, carries a total of 180 genes. As indicated, it contains 18 replication origins, although they are used with different frequencies. Those in *red* are typically used in less than 10% of cell divisions, while those in *green* are used about 90% of the time.

MBOC7_ptr_ch05_253-320.indd 276 02/12/21 12:46 PM

Features of the Human Genome That Specify Origins of Replication Remain to Be Fully Understood

Compared with the situation in budding yeast, the determinants of replication origins in humans have been difficult to discover. It has been possible to identify specific human DNA sequences, each several thousand nucleotide pairs in length, that are sufficient to serve as replication origins. These origins continue to function when moved to a different chromosomal region by recombinant DNA methods, as long as they are placed in a region where the chromatin is relatively uncondensed. However, comparisons of such DNA sequences have not revealed DNA sequences in common as in the origins of bacteria and yeasts.

Despite this, a human ORC that is very similar to the yeast ORC binds to origins of replication and initiates DNA replication in humans. Many of the other proteins that function in the initiation process in yeast likewise have central roles in humans. The yeast and human initiation mechanisms are thus similar, although some property of the genome other than a specific DNA sequence has the central role in attracting an ORC to a mammalian origin of replication. Origins of replication are often nucleosome-free, and it has been proposed that DNA that is difficult to fold onto a histone core may help define origins of replication. Nearby transcriptional activity on the genome may also play a role in activating certain origins, by altering the local chromatin structures, as we discuss in Chapter 7. This idea helps to explain why different cell types—which express different sets of genes—often use different origins. Consistent with this idea, origins that fire the earliest in S phase tend to be located near highly transcribed regions of the genome.

Finally, origins located in proximity to each other tend to fire together, and it seems likely that the three-dimensional structure of chromosomes organizes origins of replication into domains, such that all the origins in a given domain fire simultaneously. All of these influences probably work together to determine how mammalian origins of replication are selected by the cell, thereby explaining the difficulty scientists have had in precisely defining their salient features.

Properties of the ORC Ensure That Each Region of the DNA Is Replicated Once and Only Once in Each S Phase

In bacteria, once the initiator protein is properly bound to the single origin of replication, the assembly of the replication forks seems to follow more or less automatically. In eukaryotes, the situation is significantly different because of a profound problem eukaryotes have in replicating chromosomes: with so many places to begin replication, how is the process regulated to ensure that all the DNA is copied once and only once?

The answer lies in how the assembly of the replication-fork protein at the origins of replication is regulated. We discuss this process in more detail in Chapter 17, where we consider the machinery that underlies the cell-division cycle. In brief, during G_1 phase, a symmetrical complex of two incomplete helicases is loaded onto DNA by the bound ORC. Then, upon passage from G_1 phase to S phase, specialized protein kinases come into play and direct the final assembly of the two replicative helicases, positioning one on each of the two complementary DNA single strands, where they move in opposite directions to begin opening the DNA double helix. At this point, the additional replication proteins are brought to the DNA, and two complete replication forks move in opposite directions away from the origin of replication (Figure 5–31).

The same protein kinases that trigger the final assembly of the helicases prevent the binding of new helicases to that origin until the next M phase resets the entire cycle (for details, see pp. 1043–1045). They do this, in part, by phosphorylating ORC, rendering it unable to accept new helicases. Thus, the kinases specify a single window of opportunity for precursor helicases to be loaded at origins of replication (G_1 phase, when kinase activity is low) and a second window for

MBOC7_ptr_ch05_253-320.indd 277 02/12/21 12:46 PM

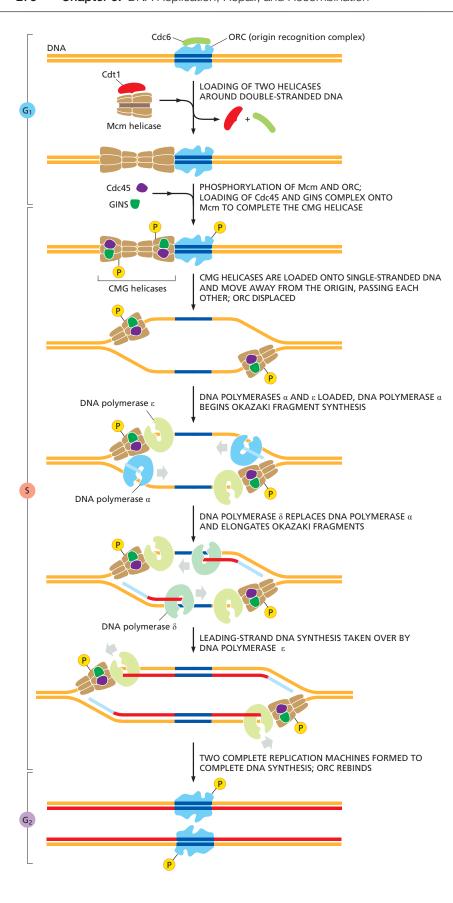

Figure 5-31 DNA replication initiation in eukaryotes. This mechanism ensures that each origin of replication is activated only once per cell cycle. An origin of replication can be used only if two Mcm helicases (which form the enzymatic cores of the replicative helicases) are loaded in G₁ phase. At the beginning of S phase, specialized kinases phosphorylate both the Mcm helicases and ORC, activating the former and inactivating the latter. These kinases also guide the assembly of additional proteins that complete the helicases to form the fully active replicative helicases, known as the CMG helicases. New Mcm helicases cannot be loaded at the origin until the cell progresses through mitosis to the next G_1 phase, when ORC is dephosphorylated. The name CMG derives from Cdc45, Mcm, and GINS, the components of the active helicase (see Figure 5-19).

MBOC7_ptr_ch05_253-320.indd 278 02/12/21 12:46 PM

them to be assembled into their active form (S phase, when kinase activity is high). Because these two phases of the cell cycle are mutually exclusive and occur in a prescribed order, each origin of replication can fire only once during each cell cycle.

Because there are many more potential replication origins on a eukaryotic chromosome than are actually used in any one cell cycle (see Figure 5-30), the DNA at many ORC-bound replication origins will be replicated by forks formed at a neighboring region of the chromosome. Thus, preventing any single origin from firing more than once during an S phase is not enough to avoid the re-replication of DNA in eukaryotes. In addition, any ORC-DNA complex that is passed by a replication fork must be inactivated, and it is the combination of the two mechanisms that guarantees that each region of the DNA is replicated once and only once in each S phase.

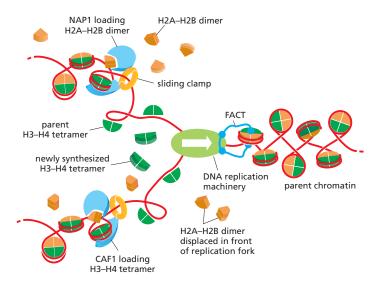

New Nucleosomes Are Assembled Behind the Replication Fork

Several additional aspects of DNA replication are specific to eukaryotes compared with bacteria. As discussed in Chapter 4, eukaryotic chromosomes are composed of roughly equal mixtures of DNA and protein. Chromosome duplication therefore requires not only the replication of DNA but also the synthesis of new chromosomal proteins and their assembly onto the DNA behind each replication fork. Although we are far from understanding this process in detail, we are beginning to learn how the fundamental unit of chromatin packaging, the nucleosome, is duplicated. The cell requires a large amount of new histone protein, approximately equal in mass to the newly synthesized DNA, each time it divides. For this reason, most eukaryotic organisms possess multiple copies of the gene for each histone. Vertebrate cells, for example, have about 20 repeated gene sets, most containing the genes that encode all five histones (H1, H2A, H2B, H3, and H4).

Unlike most proteins, which are made continually, histones are synthesized mainly in S phase, when the level of histone mRNA increases about fiftyfold as a result of both increased transcription and decreased mRNA degradation. The major histone mRNAs are degraded within minutes when DNA synthesis stops at the end of S phase. The mechanism depends on special properties of the 3' ends of these mRNAs, as discussed in Chapter 7. In contrast to their mRNAs, the histone proteins themselves are remarkably stable and may survive for many generations. The tight linkage between DNA synthesis and histone synthesis appears to reflect a feedback mechanism that monitors the level of free histone to ensure that the amount of histone made exactly matches the amount of new DNA synthesized.

As a replication fork advances it must pass through the parent nucleosomes. In the cell, efficient replication requires chromatin remodeling complexes (discussed in Chapter 4) and histone chaperone proteins (discussed below) to destabilize the DNA-histone interfaces. Aided by such specialized proteins, replication forks can transit even highly condensed chromatin. As a replication fork passes through chromatin, the histones are transiently displaced leaving about 600 nucleotide pairs of "free" DNA in its wake. The reestablishment of nucleosomes behind a moving fork occurs in an intriguing way. When a nucleosome is traversed by a replication fork, the histone octamer is broken into an H3-H4 tetramer and two H2A-H2B dimers (discussed in Chapter 4), all of which are released from DNA. The H3-H4 tetramers remain in the vicinity of the fork by loosely binding to several of the proteins at the replication fork (primarily the CMG helicase) and are distributed at random to one or the other daughter duplexes as the fork moves forward. In contrast, the H2A-H2B dimers are released completely from the fork and may diffuse to entirely different chromosomes. Freshly made H3-H4 tetramers are added to the newly synthesized DNA to fill in the "spaces," and H2A-H2B dimers—half of which are old and half new—are then added at random

MBOC7_ptr_ch05_253-320.indd 279 02/12/21 12:46 PM

to complete the nucleosomes behind the fork (Figure 5–32). The formation of new nucleosomes behind a replication fork has an important consequence for the process of DNA replication itself. As DNA polymerase δ discontinuously synthesizes the lagging strand (see Figure 5–19), the length of each Okazaki fragment is determined by the point at which DNA polymerase δ is blocked by a newly formed nucleosome. This tight coupling between nucleosome duplication and DNA replication probably explains why the length of Okazaki fragments in eukaryotes (~200 nucleotides) is approximately the same as the nucleosome repeat length.

The orderly and rapid addition of new H3–H4 tetramers and H2A–H2B dimers behind a replication fork requires **histone chaperones** (also called *chromatin assembly factors*). These multisubunit complexes bind the highly basic histones and release them on DNA only in the appropriate context. For example, some of the histone chaperones, along with their histone cargoes, are directed to newly replicated DNA through a specific interaction with the sliding clamp (see Figure 5–32). As we have seen, these clamps remain on the DNA behind replication forks, and some appear to linger just long enough for the histone chaperones to complete their tasks. Because they bind so well to histones, some histone chaperones also help to disassemble nucleosomes. Of particular importance to DNA replication is the FACT chaperone, which moves at the front of the replication machinery, disassembling nucleosomes as it moves forward (see Figure 5–32).

Termination of DNA Replication Occurs Through the Ordered Disassembly of the Replication Fork

We saw earlier in this chapter that *E. coli* DNA replication begins at a single origin, and two replication forks proceed bidirectionally around the circular genome, meeting at a spot opposite to the origin of replication. Here, the two forks do not simply collide with each other running at full speed; rather, this spot on the *E. coli* genome has a special DNA sequence that slows down and stalls the movement of each fork, causing them to disassemble. The remaining gaps in the daughter DNA molecules are filled in and sealed by repair DNA polymerases and DNA ligase (see Figures 5–11 and 5–12), and the two completed bacterial genomes are separated using topoisomerases (see Figure 5–23).

As might be expected, the situation in eukaryotes is more complicated. First, each round of replication requires many termination events, roughly as many as there are initiation events at origins of replication. Thus, in mammalian cells, approximately 30,000–50,000 termination events occur in every S phase. Second, the termination of replication forks in eukaryotes is largely independent of any underlying DNA sequence in the genome. Rather, the principal termination

Figure 5-32 Formation of nucleosomes behind a replication fork. Parent H3-H4 tetramers remain associated with the fork and are distributed at random to the daughter DNA molecules, with roughly equal numbers inherited by each daughter. In contrast, H2A-H2B dimers are released completely from the fork as it passes. This release begins just in front of the replication fork and is facilitated by the histone chaperone FACT, which moves with the fork, FACT has several globular protein domains connected by flexible linkers and can make multiple contacts with a nucleosome to aid in its disassembly. Additional histone chaperones (NAP1 and CAF1) restore the full complement of histones to daughter molecules using both parent and newly synthesized histones. Although not shown in the figure, it has been proposed that FACT directly hands off parent H3-H4 tetramers to components of the replication machinery, which in turn hand them off to CAF1 chaperones, which deposit them evenly on the two daughter molecules. The way in which histones are distributed behind a replication fork means that some daughter nucleosomes contain only parent histones or only newly synthesized histones, but most are hybrids of old and new. For simplicity, the DNA double helix is shown as a single red line.

MBOC7_ptr_ch05_253-320.indd 280 02/12/21 12:46 PM

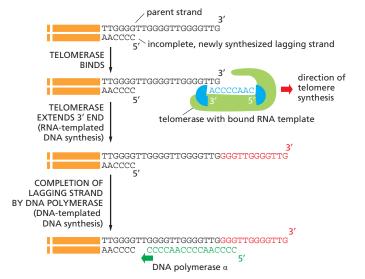

signal is a head-on encounter with a fork moving in the opposite direction. When two forks meet, the CMG helicase at each fork is covalently modified by addition of ubiquitin (see Figure 3–65), which causes its disassembly and removal from DNA. Without the helicase, the other replication proteins rapidly dissociate from the fork. Repair DNA polymerase and DNA ligase subsequently fill in and seal any remaining gaps. Eukaryotic replication forks must also contend with the ends of chromosomes. Here, it is believed that the CMG helicase simply slides off the end of the DNA molecule, leading to the dissociation of the other fork proteins. However, replicating DNA to the very end of a chromosome presents a special challenge to the eukaryotic cell, as we describe next.

Telomerase Replicates the Ends of Chromosomes

We saw earlier in the chapter that synthesis of the lagging strand at a replication fork must occur discontinuously through a backstitching mechanism that produces short DNA fragments attached to RNA primers. The final RNA primer synthesized on the lagging-strand template cannot be replaced by DNA because there is no primer ahead of it to provide a 3'-OH end for the repair polymerase. Without a mechanism to deal with this problem, DNA would be lost from the ends of all chromosomes each time a cell divides.

Bacteria avoid this "end-replication" problem by having circular DNA molecules as chromosomes, as we have seen. Eukaryotes solve it in a different way: they have specialized nucleotide sequences at the ends of their chromosomes that are incorporated into structures called *telomeres* (discussed in Chapter 4). Telomeres contain many tandem repeats of a short sequence that is similar in organisms as diverse as protozoa, fungi, plants, and mammals. In humans, the sequence of the repeat unit is GGGTTA, and it is repeated roughly a thousand times at each telomere.

Telomere DNA sequences are recognized by sequence-specific DNA-binding proteins that attract an enzyme, called **telomerase**, that replenishes these sequences each time a cell divides. Telomerase recognizes the tip of an existing telomere DNA repeat sequence and elongates it in the 5'-to-3' direction, using an RNA template that is a component of the enzyme itself to synthesize new DNA copies of the repeat (**Figure 5–33**). The enzymatic portion of telomerase resembles other *reverse transcriptases*, proteins that synthesize DNA using an RNA template, although, in this case, the telomerase RNA also contributes to the active site and is essential for efficient catalysis. After extension of the parent DNA strand by telomerase, replication of the lagging strand at the chromosome end can be completed by the conventional DNA polymerases, using these extensions as a template to synthesize the complementary strand (**Figure 5–34**).

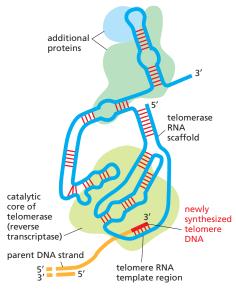

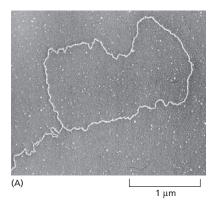

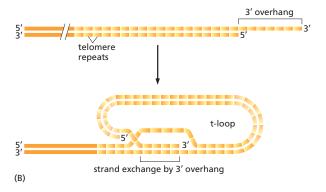

Figure 5-33 Schematic structure of human telomerase. This large enzyme is composed of 10 protein subunits and an RNA of 451 nucleotides. The RNA forms the scaffold of the complex, provides the template for synthesizing new DNA telomere repeats, and helps form the active site. The synthesis reaction itself is carried out by the reverse transcriptase domain of the protein, shown in liaht green, in conjunction with the RNA. A reverse transcriptase is a special form of polymerase enzyme that uses an RNA template to make a DNA strand; telomerase is unique in carrying its own RNA template with it. Telomerase also contains several additional protein complexes (some of which are shown in dark green and blue) that are needed to assemble the enzyme and, for many organisms but not humans, to bring it to the ends of chromosomes. (Modified from T.H.D. Nguyen et al., Nature 557: 190-195, 2018.)

Figure 5-34 Telomere replication. Shown here is the reaction that synthesizes the repeating sequences that form the ends of the chromosomes (telomeres) of eukaryotes. The 3' end of the parent lagging-strand template is extended by RNA-templated DNA synthesis; this allows the incomplete daughter DNA strand that is paired with it to be synthesized to the end of the chromosome. The synthesis of the final bit of lagging strand is carried out by DNA polymerase α , which carries a DNA primase as one of its subunits (Movie 5.6). DNA polymerase α is the same enzyme used to begin the synthesis of each Okazaki fragment on the lagging strand; it begins its synthesis with RNA (not shown) and continues with DNA (green). The telomere sequence illustrated is that of the ciliate Tetrahymena, in which these reactions were first discovered.

MBOC7_ptr_ch05_253-320.indd 281 02/12/21 12:46 PM

Telomeres Are Packaged into Specialized Structures That Protect the Ends of Chromosomes

The ends of chromosomes present cells with an additional problem. As we will see in the next part of this chapter, when a chromosome is accidently broken into two pieces, the break is rapidly repaired. Telomeres must clearly be distinguished from these accidental breaks; otherwise, the cell will attempt to "repair" telomeres, generating chromosome fusions and other genetic abnormalities. Telomeres have several features to prevent this from happening.

A specialized nuclease chews back the 5' end of a telomere leaving a protruding, single-strand 3' end. This protruding end—in combination with the GGGTTA repeats in telomeres—attracts a group of proteins that form a protective chromosome cap known as *shelterin*. In particular, shelterin protects telomeres from being treated as damaged DNA. Another feature of telomeres may offer additional protection. When human telomeres are artificially cross-linked and viewed by electron microscopy, structures known as "t-loops" can be observed in which the protruding single-strand end of the telomere loops back and tucks itself into the duplex DNA of the telomere repeat sequence (Figure 5–35). An attractive idea is that t-loops are orchestrated by shelterin to help "hide" the very ends of chromosomes.

Telomere Length Is Regulated by Cells and Organisms

Because the processes that grow and shrink each telomere sequence are only approximately balanced, chromosome ends contain variable numbers of telomeric repeats. Not surprisingly, many cells, including stem cells and germ cells, have homeostatic mechanisms that maintain the number of these repeats within a limited range (Figure 5–36).

In most of the dividing somatic cells of humans, however, telomeres gradually shorten, and it has been proposed that this provides a counting mechanism that helps prevent the unlimited proliferation of wayward cells in adult tissues. In its simplest form, this idea holds that our somatic cells start off in the embryo with a full complement of telomeric repeats. These are then eroded to different extents in different cell types. Some stem cells, notably those in tissues that must be replenished at a high rate throughout life—bone marrow or gut lining, for example—retain full telomerase activity. However, in many other types of cells, the level of telomerase is reduced so that the enzyme cannot quite keep up with chromosome duplication. Such cells lose 100–200 nucleotides from each telomere every time they divide. After many cell generations, the descendant cells will inherit chromosomes that lack functioning telomeres, and, as a result of this defect, activate a DNA-damage response causing them to withdraw permanently from the cell cycle and cease dividing—a process called *replicative cell senescence* (discussed in Chapters 17 and 20). In theory, such a mechanism could provide a

Figure 5–35 A t-loop at the end of a mammalian chromosome. (A) Electron micrograph of the DNA at the end of an interphase human chromosome. The chromosome was fixed, deproteinated, and artificially thickened before viewing. The loop seen here is approximately 15,000 nucleotide pairs in length. (B) Schematic diagram of t-loop formation. MBOC7_ptr_ch05_253-320.indd 282 02/12/21 12:46 PM

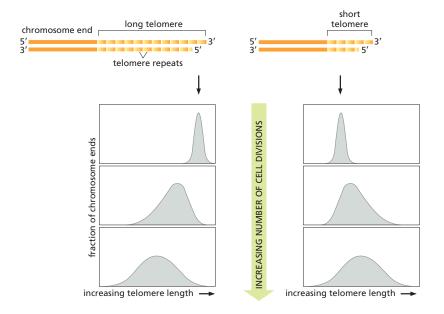

Figure 5–36 A demonstration that yeast cells control the length of their telomeres. In this experiment, the telomere at one end of a particular chromosome is artificially made either longer (left) or shorter (right) than average. After many cell divisions, the chromosome recovers, showing an average telomere length and a length distribution that is typical of the other chromosomes in the yeast cell. A similar feedback mechanism for controlling telomere length has been proposed for the germ-line cells and stem cells of mammals.

safeguard against the uncontrolled cell proliferation of abnormal cells in somatic tissues, thereby helping to protect us from cancer.

The idea that telomere length acts as a "measuring stick" to count cell divisions and thereby regulate the lifetime of the cell lineage has been tested in several ways. For certain types of human cells grown in tissue culture, the experimental results support such a theory. Human fibroblasts normally proliferate for about 60 cell divisions in culture before undergoing replicative cell senescence. Like most other somatic cells in humans, fibroblasts produce only low levels of telomerase, and their telomeres gradually shorten each time they divide. When telomerase is provided to the fibroblasts by inserting a fully active telomerase gene, telomere length is maintained and many of the cells now continue to proliferate indefinitely. Also consistent with these ideas is the observation that, in approximately 90% of cancer cells, the telomerase gene has become reactivated, thereby circumventing the normal safety mechanism (see pp. 1073–1074).

It has been proposed that this type of control on cell proliferation may contribute to the aging of animals like ourselves. These ideas have been tested by producing transgenic mice that lack telomerase entirely. The telomeres in mouse chromosomes are about five times longer than human telomeres, and the mice must therefore be bred through three or more generations before their telomeres have shrunk to the normal human length. It is therefore perhaps not surprising that the first generations of mice develop normally. However, the mice in later generations develop progressively more defects in some of their highly proliferative tissues. In addition, these mice show signs of premature aging and have a pronounced tendency to develop tumors. In these and other respects, these mice resemble humans with the genetic disease *dyskeratosis congenita*. Individuals afflicted with this disease carry one functional and one nonfunctional copy of the telomerase RNA gene; they have prematurely shortened telomeres and typically die of progressive bone marrow failure. These individuals also develop lung scarring and liver cirrhosis and show abnormalities in various epidermal structures including skin, hair follicles, and nails.

The above observations demonstrate that controlling cell proliferation by telomere shortening poses a risk to an organism, because not all of the cells that begin losing the ends of their chromosomes will stop dividing. Some apparently become genetically unstable, but continue to divide, giving rise to variant cells that can lead to cancer. As discussed above, many of these variant cells

MBOC7_ptr_ch05_253-320.indd 283 02/12/21 12:46 PM

ultimately produce high levels of telomerase, thereby ensuring their continued survival. Clearly, the use of telomere shortening as a regulating mechanism is not foolproof and, like many mechanisms in the cell, it must strike a balance between benefit and risk.

Summary

The proteins that initiate DNA replication bind to DNA sequences at a replication origin to catalyze the formation of a replication bubble with two outward-moving replication forks. The process begins when an initiator protein–DNA complex is formed that subsequently loads a DNA helicase onto the DNA template. Other proteins are then added to form the multienzyme "replication machine" that catalyzes DNA synthesis at each replication fork.

In bacteria and some simple eukaryotes, replication origins are defined by specific DNA sequences that are several hundred nucleotide pairs long. In other eukaryotes, such as humans, features that specify an origin of DNA replication are less well defined, and probably depend more on structural features of chromosomes than on specific DNA sequences.

Bacteria typically have a single origin of replication in a circular chromosome. With fork speeds of up to 1000 nucleotides per second, they can replicate their genome in less than an hour. Eukaryotic DNA replication takes place in only one part of the cell cycle, the S phase. The replication fork in eukaryotes moves about 20 times more slowly than the bacterial replication fork, and the much longer eukaryotic chromosomes each require many replication origins to complete their replication in an S phase, which typically lasts for 8 hours in human cells. The different replication origins in these eukaryotic chromosomes are activated in a sequence, determined in part by which genes are currently being transcribed and the structure of chromatin across each chromosome. After the replication fork has passed, chromatin structure is re-formed by the addition of new histones to the old histones that are directly inherited by each daughter DNA molecule.

Eukaryotes solve the problem of replicating the ends of their linear chromosomes with a specialized end structure, the telomere, maintained by a special nucleotide-polymerizing enzyme called telomerase. Telomerase extends one of the DNA strands at the end of a chromosome by using an RNA template that is an integral part of the enzyme itself, producing a highly repeated DNA sequence that typically extends for thousands of nucleotide pairs at each chromosome end. Telomeres have specialized structures that distinguish them from broken ends of chromosomes, ensuring that they are not treated as damaged DNA.

DNA REPAIR

Maintaining the genetic stability that an organism needs for its survival requires not only an extremely accurate mechanism for replicating DNA but also mechanisms for repairing the many accidental lesions that DNA continually suffers. Most such spontaneous changes in DNA are temporary because they are immediately corrected by a set of processes that are collectively called **DNA repair**. Of the tens of thousands of random changes created every day in the DNA of a human cell by heat, metabolic accidents, radiation of various sorts, and exposure to substances in the environment, only a few (less than 0.02%) accumulate as permanent mutations in the DNA sequence. The rest are eliminated with remarkable efficiency by DNA repair.

The importance of DNA repair is evident from the large investment that cells make in the enzymes that carry it out: several percent of the coding capacity of most genomes is devoted solely to DNA repair functions. The importance of DNA repair is also demonstrated by the increased rate of mutation that follows the inactivation of a DNA repair gene. Many DNA repair proteins and the genes that encode them—which we now know operate in a wide range of organisms,

MBOC7_ptr_ch05_253-320.indd 284 02/12/21 12:46 PM

DNA REPAIR 285

TABLE 5–2 Some Inherited Human Syndromes with Defects in DNA Repair			
Name of syndrome or responsible genes	Phenotype	Enzyme or process affected	
Msh2, Msh3, Msh6, Mlh1, Pms2	Colon cancer	Mismatch repair	
Polymerase proofreading- associated polyposis	Colon cancer	Proofreading by DNA polymerase ϵ	
Aicardi-Goutières syndrome	Encephalopathy, neurological dysfunction, genome instability	Removal of misincorporated ribonucleotides in DNA	
Xeroderma pigmentosum (XP) groups A-G	Skin cancer, UV sensitivity, neurological abnormalities	Nucleotide excision repair	
Cockayne syndrome	UV sensitivity, developmental abnormalities	Coupling of nucleotide excision repair to transcription	
XP variant	UV sensitivity, skin cancer	Translesion synthesis by DNA polymerase η	
Ataxia telangiectasia (AT)	Leukemia, lymphoma, γ-ray sensitivity, genome instability	ATM protein, a protein kinase activated by double-strand DNA breaks	
Seckel syndrome	Dwarfism, microcephaly	ATR protein, a protein kinase activated by single-strand DNA breaks	
Brca1	Breast and ovarian cancer	Repair by homologous recombination	
Brca2	Breast, ovarian, prostate, and pancreatic cancer	Repair by homologous recombination	
Ataxia-telangiectasia-like disorder (ATLD)	Leukemia, lymphoma, γ-ray sensitivity, genome instability	Mre11 protein, required for processing double-strand DNA breaks	
Werner syndrome	Premature aging, cancer at several sites, genome instability	Accessory 3'-exonuclease and DNA helicase used in repair	
Bloom syndrome	Cancer at several sites, stunted growth, genome instability	DNA helicase needed for recombination	
Fanconi anemia groups A-W	Congenital abnormalities, leukemia, genome instability	DNA interstrand cross-link repair	
46BR patient	Hypersensitivity to DNA-damaging agents, genome instability	DNA ligase I	

including humans—were originally identified in bacteria by the isolation and characterization of mutants that displayed an increased mutation rate or an increased sensitivity to DNA-damaging agents.

Studies of the consequences of a diminished capacity for DNA repair in humans have linked many human diseases with decreased repair (Table 5–2). Thus, we saw previously that defects in a human gene whose product normally functions to repair the mismatched base pairs resulting from DNA replication errors can lead to an inherited predisposition to cancers of the colon and some other organs, caused by an increased mutation rate. In another human disease, *xeroderma pigmentosum* (*XP*), the afflicted individuals have an extreme sensitivity to ultraviolet radiation because they are unable to repair the damage to DNA caused by this component of sunlight. This repair defect results in an increased mutation rate that leads to serious skin lesions and a greatly increased susceptibility to skin cancers. Finally, mutations in the *Brca1* and *Brca2* genes compromise a type of DNA repair known as *homologous recombination* and are a major cause of hereditary breast and ovarian cancers.

MBOC7_ptr_ch05_253-320.indd 285 02/12/21 12:46 PM

Without DNA Repair, Spontaneous DNA Damage Would Rapidly Change DNA Sequences

Although DNA is a highly stable material—as required for the storage of genetic information—it is a complex organic molecule that is susceptible, even under normal cell conditions, to spontaneous changes that would lead to mutations if left unrepaired (Figure 5–37 and see Table 5–3). For example, the DNA of each human cell loses about 18,000 purine bases (adenine and guanine) every day because their *N*-glycosyl linkages to deoxyribose break, a spontaneous hydrolysis reaction called *depurination*. Similarly, a spontaneous *deamination* of cytosine to uracil in

Figure 5–37 A summary of spontaneous alterations that require DNA repair.

The sites on each nucleotide modified

The sites on each nucleotide modified by spontaneous oxidative damage (red arrows), hydrolytic attack (blue arrows), and methylation (green arrows) are shown, with the width of each arrow indicating the relative frequency of each event (see Table 5–3). (After T. Lindahl, Nature 362:709–715, 1993.)

TABLE 5–3 Endogenous DNA Lesions Arising and Repaired in a Diploid Mammalian Cell in 24 Hours							
DNA lesion	Number repaired in 24 hr						
Hydrolysis							
Depurination	18,000						
Depyrimidination	600						
Cytosine deamination	100						
5-Methylcytosine deamination	10						
Oxidation							
8-oxoguanine	1500						
Ring-saturated pyrimidines (thymine glycol, cytosine hydrates)	2000						
Lipid peroxidation products (M1G, etheno-A, etheno-C)	1000						
Nonenzymatic methylation by S-adenosylmethionine							
7-Methylguanine	6000						
3-Methyladenine	1200						
Nonenzymatic methylation by nitrosated polyamines and peptides							
O ⁶ -Methylguanine	20–100

diverse forms of DNA damage. (From T. Lindahl and D.E. Barnes, Cold Spring Harb. Symp.

Quant. Biol. 65:127-133, 2000.)

MBOC7_ptr_ch05_253-320.indd 286 02/12/21 12:46 PM

DNA REPAIR 287

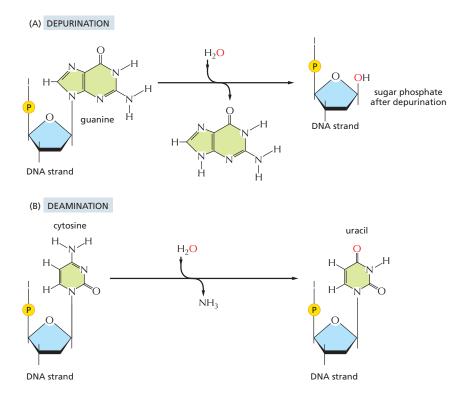

Figure 5–38 Depurination and deamination are the most frequent spontaneous chemical reactions known to create serious DNA damage in cells. (A) Depurination can remove guanine (or adenine) from DNA. (B) The major type of deamination reaction converts cytosine to uracil, which, as we have seen, is not normally found in DNA. However, deamination can occur on other bases as well. Both depurination and deamination take place on double-helical DNA, and neither reaction breaks the phosphodiester backbone.

DNA occurs at a rate of about 100 bases per cell per day (Figure 5–38). DNA bases are also occasionally damaged by encounters with reactive metabolites produced in the cell (for example, the high-energy methyl donor, *S*-adenosylmethionine) or by exposure to toxic chemicals in the environment. Likewise, ultraviolet radiation from the Sun can produce a covalent linkage between two adjacent pyrimidine bases in DNA to form, for example, thymine dimers (Figure 5–39). If left uncorrected, most of these changes would lead either to the deletion of one or more base pairs or to a base-pair substitution in the daughter DNA chain when the DNA is replicated (Figure 5–40). These mutations would then be propagated throughout all subsequent cell generations. Such a high rate of unrepaired random changes in the DNA sequence would have disastrous consequences, both in the germ line and in somatic tissues.

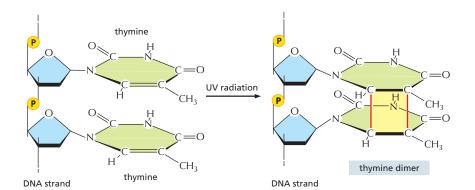

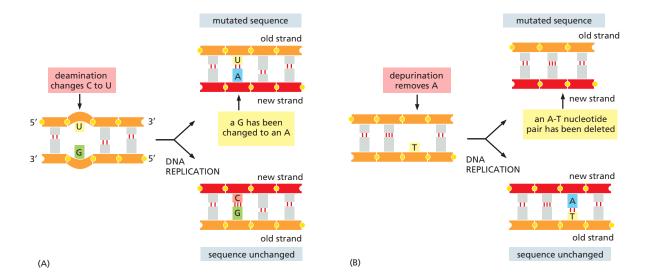

Figure 5–39 The ultraviolet radiation in sunlight can cause the formation of thymine dimers. Two adjacent thymine bases have become covalently attached to each other to form a thymine dimer. Skin cells that are exposed to sunlight are especially susceptible to this type of DNA damage. Dimers can also form between an adjacent thymine and cytosine.

MBOC7_ptr_ch05_253-320.indd 287 02/12/21 12:46 PM

The DNA Double Helix Is Readily Repaired

The double-helical structure of DNA is ideally suited for repair because it carries two separate copies of all the genetic information—one in each of its two strands. Thus, when one strand is damaged, the complementary strand retains an intact copy of the same information, and this copy is generally used as the template to restore the correct nucleotide sequences to the damaged strand.

An indication of the importance of a double-strand helix to the safe storage of genetic information is that all cells use it; only a few small viruses use single-stranded DNA or RNA as their genetic material. The types of repair processes described in this part of the chapter cannot operate on such nucleic acids, and once damaged, the chance of a permanent nucleotide change occurring in these single-strand genomes of viruses is thus very high. It seems that only tiny genomes (and therefore tiny targets for DNA damage) can have their genetic information successfully carried in any molecule other than a DNA double helix.

DNA Damage Can Be Removed by More Than One Pathway

Cells have multiple pathways to repair their DNA using different enzymes that act upon different kinds of lesions. Figure 5–41 shows two of the most common pathways. In both, the damage is excised, the original DNA sequence is restored by a high-fidelity DNA polymerase using the undamaged strand as its template, and the remaining break in the double helix is sealed by DNA ligase (see Figure 5–12).

The two pathways differ in the way in which they remove the damage from DNA. The first pathway, called **base excision repair**, involves a battery of enzymes called *DNA glycosylases*, each of which can recognize a specific type of altered base in DNA and catalyze its hydrolytic removal from the DNA backbone. There are many types of these enzymes, including those that remove deaminated C's, deaminated A's, different types of alkylated or oxidized bases, bases with opened rings, and bases in which a carbon–carbon double bond has been accidentally converted to a carbon–carbon single bond. How are altered bases detected in the double helix? A key step is an enzyme-mediated "flipping-out" of the altered nucleotide from the helix, which allows the DNA glycosylase to probe all faces of the base for damage (**Figure 5–42**). It is thought that these enzymes travel along DNA using base-flipping to evaluate the status of each base. Once an enzyme finds the damaged base that it recognizes, it removes that base from its sugar.

The "missing tooth" created by DNA glycosylase action is recognized by an enzyme called *AP endonuclease* (AP for *apurinic* or *apyrimidinic*, and *endo* to signify that the nuclease cleaves within the polynucleotide chain), which cuts the phosphodiester backbone, after which the resulting gap is repaired (see

Figure 5-40 Chemical modifications of nucleotides, if left unrepaired, produce mutations. (A) Deamination of cytosine, if uncorrected, results in the substitution of one base for another when the DNA is replicated. As shown in Figure 5-43, deamination of cytosine produces uracil. Uracil differs from cytosine in its basepairing properties and preferentially basepairs with adenine. The DNA replication machinery therefore inserts an adenine when it encounters a uracil on the template strand. (B) Depurination, if uncorrected, can lead to the loss of a nucleotide pair. When the replication machinery encounters a missing purine on the template strand, it can skip to the next complete nucleotide, as shown, thus producing a daughter DNA molecule that is missing one nucleotide pair. In other cases, the replication machinery places an incorrect nucleotide across from the missing base, again resulting in a mutation (not shown).

DNA REPAIR 289

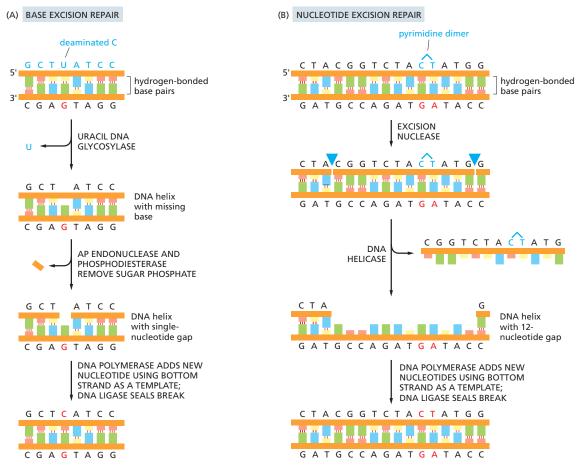

Figure 5–41 A comparison of two major DNA repair pathways. (A) Base excision repair. This pathway starts with a DNA glycosylase. In the example shown here, the enzyme uracil DNA glycosylase removes an accidentally deaminated cytosine in DNA. After the action of this glycosylase (or another DNA glycosylase that recognizes a different kind of damage), the sugar phosphate with the missing base is cut out by the sequential action of AP endonuclease and a phosphodiesterase. The gap of a single nucleotide is then filled by DNA polymerase and DNA ligase. The net result is that the U that was created by accidental deamination is restored to a C. The loss of a base can occur either from the actions of DNA glycosylases that recognize damaged bases or from spontaneous chemical reactions (see Figure 5–37). AP endonuclease is so named because it recognizes any site in the DNA helix that contains a deoxyribose sugar with a missing base; such sites can arise either by the loss of a purine (apurinic sites) or by the loss of a pyrimidine (apyrimidinic sites). (B) Nucleotide excision repair. In bacteria, after a multienzyme complex has recognized a lesion such as a pyrimidine dimer (see Figure 5–39), one cut is made on each side of the lesion, and an associated DNA helicase then removes the entire portion of the damaged strand. The excision repair machinery in bacteria operates as shown. In humans, once the damaged DNA is recognized, a helicase is recruited to locally unwind the DNA duplex. Next, the excision nuclease enters and cleaves on either side of the damage, leaving a gap of about 30 nucleotides that is subsequently filled in. The nucleotide excision repair machinery in both bacteria and humans can recognize and repair many different types of DNA damage.

Figure 5-41A). Depurination, which is by far the most frequent type of damage suffered by DNA, also leaves a deoxyribose sugar with a missing base. Depurinations are directly repaired beginning with AP endonuclease, following the bottom half of the pathway in Figure 5-41A.

The second major repair pathway is called **nucleotide excision repair**. This mechanism can repair the damage caused by almost any large change in the structure of the DNA double helix. Such "bulky lesions" include those created by the covalent reaction of DNA bases with large hydrocarbons (such as the carcinogen benzopyrene, found in tobacco smoke, coal tar, and diesel exhaust), as well as the various pyrimidine dimers (T-T, T-C, and C-C) caused by sunlight. In this pathway, a large multienzyme complex scans the DNA for a distortion in the double helix, rather than for a specific base change. Once it finds a lesion, it cleaves the phosphodiester backbone of the abnormal strand on both sides of

MBOC7_ptr_ch05_253-320.indd 289 02/12/21 12:46 PM

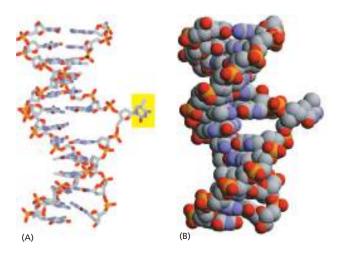

Figure 5–42 The recognition of an unusual nucleotide in DNA by base-flipping. The DNA glycosylase family of enzymes recognizes inappropriate bases in DNA in the conformation shown. Each of these enzymes cleaves the glycosyl bond that connects a particular recognized base (yellow) to the backbone sugar, removing it from the DNA. (A) Stick model of the DNA; (B) space-filling model.

the distortion, and a DNA helicase peels away the single-strand oligonucleotide containing the lesion. The large gap produced in the DNA helix is then repaired by DNA polymerase and DNA ligase (see Figure 5-41B).

An alternative to these base and nucleotide excision repair processes is the direct chemical reversal of DNA damage, and this strategy is selectively employed for the rapid removal of certain highly mutagenic or cytotoxic lesions. For example, the lesion O^6 -methylguanine has its methyl group removed by direct transfer to a cysteine residue in the repair protein itself. Because the repair protein is destroyed in the process, each molecule of it can only be used once. In another example, methyl groups in the lesions 1-methyladenine and 3-methylcytosine are "burned off" by an iron-dependent demethylase, with release of formaldehyde from the methylated DNA and regeneration of the native base.

Coupling Nucleotide Excision Repair to Transcription Ensures That the Cell's Most Important DNA Is Efficiently Repaired

All of a cell's DNA is under constant surveillance for damage, and the repair mechanisms we have described act on all parts of the genome. However, cells have a way of directing DNA repair to the DNA sequences that are most needed. They do this by linking RNA polymerase, the enzyme that transcribes DNA into RNA as the first step in gene expression, to the nucleotide excision repair pathway. As discussed above, this repair system can correct many different types of DNA damage. RNA polymerase stalls at DNA lesions and, through the use of coupling proteins, directs the excision repair machinery to those sites, thereby selectively repairing genes that are in current use by the cell. In bacteria, where genes are relatively short, the stalled RNA polymerase can be dissociated from the DNA; the DNA is repaired, and the gene is transcribed again from the beginning. In eukaryotes, where genes can be enormously long, a more complex reaction is used to "back up" the RNA polymerase, repair the damage, and then restart the polymerase.

The importance of transcription-coupled excision repair is seen in people with Cockayne syndrome, which is caused by a defect in this coupling. These individuals suffer from growth retardation, skeletal abnormalities, progressive neural retardation, and severe sensitivity to sunlight. Most of these problems are thought to arise from RNA polymerase molecules that become permanently stalled at sites of DNA damage that lie in important genes.

The Chemistry of the DNA Bases Facilitates Damage Detection

The DNA double helix is well suited for repair. As noted earlier, it contains a backup copy of all genetic information. Equally importantly, the nature of the four bases in DNA makes the distinction between undamaged and damaged

MBOC7_ptr_ch05_253-320.indd 290 02/12/21 12:46 PM

DNA REPAIR 291

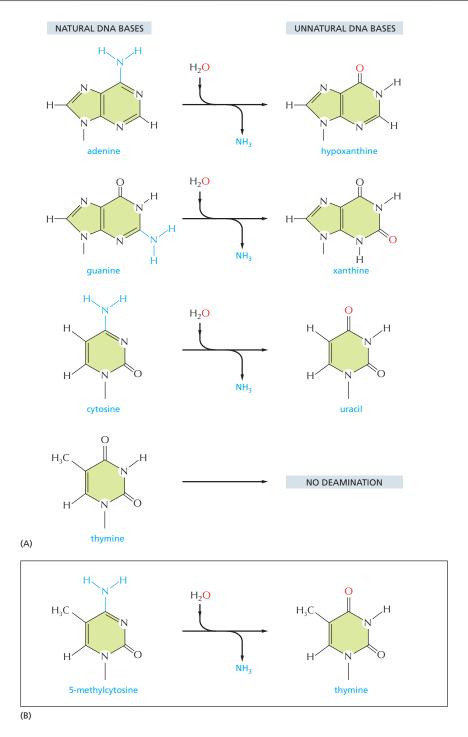

Figure 5-43 The deamination of DNA nucleotides. In each case, the oxygen atom that is added in this reaction with water is colored red. (A) The spontaneous deamination products of A and G are recognizable as unnatural when they occur in DNA and thus are readily found and repaired, as is the deamination of C to U; T has no amino group to remove. (B) About 3% of the C nucleotides in vertebrate DNAs are methylated to help in controlling gene expression (discussed in Chapter 7). When these 5-methyl C nucleotides are accidentally deaminated, they form the natural nucleotide T. This T will be paired with a G on the opposite strand, forming a mismatched base pair.

bases very clear. For example, every possible deamination event in DNA yields an "unnatural" base, which can be directly recognized and removed by a specific DNA glycosylase. Hypoxanthine, for example, is the simplest purine base capable of pairing specifically with C. But hypoxanthine is not used in DNA, presumably because it is the direct deamination product of A. Instead G, with a second amino group, pairs with C: G cannot form from A by spontaneous deamination, and its own deamination product (xanthine) is likewise unique (Figure 5–43).

MBOC7_ptr_ch05_253-320.indd 291 02/12/21 12:46 PM

As discussed in Chapter 6, RNA is thought, on an evolutionary time scale, to have served as the genetic material before DNA, and it seems likely that the genetic code was initially carried in the four nucleotides A, C, G, and U. This raises the question of why the U in RNA was replaced in DNA by T (which is 5-methyl U). We have seen that the spontaneous deamination of C converts it to U, but that this event is rendered relatively harmless by uracil DNA glycosylase. However, if DNA contained U as a natural base, the repair system would not be able to distinguish a deaminated C from a naturally occurring U.

A special situation occurs in vertebrate DNA, in which selected C nucleotides are methylated at specific CG sequences that are associated with inactive genes (discussed in Chapter 7). The accidental deamination of these methylated C nucleotides produces the natural nucleotide T (see Figure 5–43B) in a mismatched base pair with a G on the opposite DNA strand. To help in repairing deaminated methylated C nucleotides, a special DNA glycosylase recognizes a mismatched base pair involving T in the sequence T-G and removes the T. This DNA repair mechanism must be relatively ineffective, however, because methylated C nucleotides are exceptionally common sites for mutations in vertebrate DNA. It is striking that, even though only about 3% of the C nucleotides in human DNA are methylated, mutations in these methylated nucleotides account for about one-third of the single-base mutations that have been observed in inherited human diseases.

Special Translesion DNA Polymerases Are Used in Emergencies

If a cell's DNA suffers heavy damage, the repair mechanisms that we have discussed are often insufficient to cope with it. In these cases, a different strategy is called into play, one that entails some risk to the cell. The highly accurate replicative DNA polymerases stall when they encounter damaged DNA, and in emergencies cells employ versatile, but less accurate, backup polymerases, known as *translesion polymerases*, to replicate through the DNA damage.

Human cells contain seven different translesion polymerases, some of which can recognize a specific type of DNA damage and add the nucleotides required to restore the correct sequence. For example, one such polymerase adds two A's opposite a thymine dimer (see Figure 5–39). Others make only "good guesses," especially when the template base has been extensively damaged. These enzymes are not as accurate as the normal replicative polymerases even when they copy an undamaged DNA sequence. For one thing, they lack exonucleolytic proofreading activity; in addition, many are much less discriminating than the replicative polymerase in choosing which nucleotide to incorporate initially. Each such translesion polymerase is therefore given a chance to add only one or a few nucleotides before a high-fidelity replicative polymerase resumes DNA synthesis.

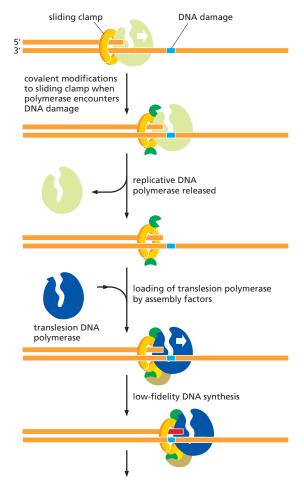

Despite their usefulness in allowing heavily damaged DNA to be replicated, these translesion polymerases do, as noted above, pose risks to the cell. They are probably responsible for most of the base-substitution and single-nucleotide deletion mutations that accumulate in genomes. Not only do they frequently produce mutations when copying damaged DNA, they probably also generate mutations—at a low level—on undamaged DNA. Clearly, it is important for the cell to tightly regulate these polymerases, activating them only at sites of DNA damage. Exactly how this happens for each translesion polymerase remains to be discovered, but a conceptual model is presented in Figure 5–44. The same principle applies to many of the DNA repair processes discussed in this chapter: because the enzymes that carry out these reactions are potentially dangerous to the genome, they must be brought into play only at the appropriate damaged sites.

Double-Strand Breaks Are Efficiently Repaired

An especially dangerous type of DNA damage occurs when both strands of the double helix are broken, leaving no intact template strand to enable accurate repair. Ionizing radiation, replication errors, oxidizing agents, and other

MBOC7_ptr_ch05_253-320.indd 292 02/12/21 12:46 PM

DNA REPAIR 293

removal of covalent modifications from clamp, reloading of replicative DNA polymerase, continuation of accurate DNA synthesis

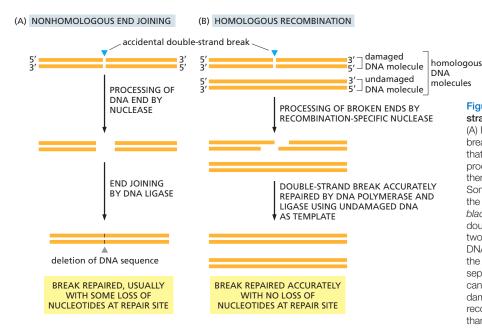

metabolites produced in the cell cause breaks of this type. If these lesions were left unrepaired, they would quickly lead to the breakdown of chromosomes into smaller fragments and to loss of genes when the cell divides. However, two distinct mechanisms have evolved to deal with this type of damage by restoring an intact double helix: *nonhomologous end joining* and *homologous recombination* (Figure 5–45).

The simplest to understand is **nonhomologous end joining**, in which the broken ends are processed to remove any damaged nucleotides and simply brought together and rejoined by DNA ligation, generally with the loss of nucleotides at the site of joining (**Figure 5–46**). This end-joining mechanism, which can be seen as a "quick and dirty" solution to the repair of double-strand breaks, is the predominant way of repairing these lesions in mammalian somatic cells. Although a change in the DNA sequence (a mutation) usually results at the site of breakage, so little of the mammalian genome is essential for life that this mechanism is apparently an acceptable solution to the problem of rejoining broken chromosomes. By the time a human reaches the age of 70, the typical somatic cell contains more than 2000 such "scars," distributed throughout its genome, representing places where DNA has been inaccurately repaired by nonhomologous end joining.

But nonhomologous end joining presents another danger: nonhomologous end joining can occasionally generate rearrangements in which one broken chromosome becomes covalently attached to another. This can result

Figure 5-44 How translesion DNA polymerases are recruited to damaged templates. According to this model, a replicative polymerase stalled at a site of DNA damage is recognized by the cell as needing rescue. Specialized enzymes covalently modify the sliding clamp (typically, it is ubiquitylated - see Figure 3-65), which releases the replicative DNA polymerase and, together with the damaged DNA, attracts a translesion polymerase specific to that type of damage. Once the damaged DNA is bypassed, the covalent modification of the clamp is removed, the translesion polymerase dissociates, and the highfidelity replicative polymerase is brought back into play.

MBOC7_ptr_ch05_253-320.indd 293 02/12/21 12:46 PM

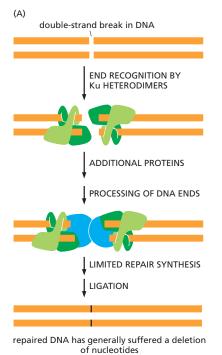

in chromosomes with two centromeres and chromosomes lacking centromeres altogether; both types of aberrant chromosomes are missegregated during cell division. As previously discussed, the specialized structure of telomeres prevents the natural ends of chromosomes from being mistaken for broken DNA and "repaired" in this way.

A much more accurate type of double-strand break repair is also possible (see Figure 5–45B). Here, a damaged DNA molecule is repaired using a second DNA double helix as a template, one with an identical (or nearly identical) DNA sequence. This reaction utilizes *homologous recombination*, a mechanism to be

Figure 5–45 Cells can repair doublestrand breaks in one of two ways.

(A) In nonhomologous end joining, the break is first "cleaned" by a nuclease that chews back the broken ends to produce flush ends. The flush ends are then stitched together by a DNA ligase. Some nucleotides are usually lost in the repair process, as indicated by the black lines in the repaired DNA. (B) If a double-strand break occurs in one of two duplicated DNA double helices after DNA replication has occurred, but before the chromosome copies have been separated, the undamaged double helix can be used as a template to repair the damaged double helix through homologous recombination. Although more complicated than nonhomologous end joining, this process accurately restores the original DNA sequence at the site of the break. Homologous recombination is described in detail in the next part of this chapter. Although nonhomologous end joining and homologous recombination are the two principal ways that cells repair double-strand breaks, additional mechanisms exist.

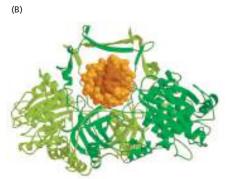

Figure 5–46 Nonhomologous end joining. (A) A central role is played by the Ku protein, a heterodimer that quickly grasps the broken chromosome ends. The additional proteins (shown in blue) are recruited to hold the broken ends together and remove any damaged nucleotides before the two DNA molecules are joined covalently by a specialized ligase that is dedicated to nonhomologous end joining. During this process, any single-strand gaps that arise are "filled in" by specialized repair polymerases. When DNA suffers double-strand breaks through ionizing radiation or chemical attack, the broken ends are often chemically damaged. Nonhomologous end joining is unusually versatile in being able to "clean up" just about any type of damaged end. (B) Three-dimensional structure of a Ku heterodimer bound to the end of a duplex DNA fragment. This Ku protein is also essential for V(D)J joining, a specific process through which antibody and T-cell receptor diversity is generated in developing B and T cells (discussed in Chapter 24). V(D)J joining and nonhomologous end joining share many mechanistic similarities, but the former relies on specific double-strand breaks that are produced deliberately by the cell. (From J. Walker, R. Corpina, and J. Goldberg, Nature 412:607–614, 2001. With permission from Springer Nature; PDB codes: 1JEQ, 1JEY.)

MBOC7_ptr_ch05_253-320.indd 294 02/12/21 12:46 PM

DNA REPAIR 295

described later in this chapter. Most organisms employ both nonhomologous end joining and homologous recombination to repair double-strand breaks in DNA. Nonhomologous end joining predominates in humans; homologous recombination is used only in the S and G_2 cell-cycle phases, when one newly replicated daughter molecule can act as a template to repair damage to the other daughter that remains nearby.

DNA Damage Delays Progression of the Cell Cycle

We have just seen that cells contain multiple enzyme systems that can recognize and repair many types of DNA damage (Movie 5.7). Because of the importance of maintaining intact, undamaged DNA from generation to generation, eukaryotic cells delay the progression of their cell cycle until DNA repair is complete. As discussed in detail in Chapter 17, the orderly progression of the cell cycle is stopped when damaged DNA is detected, and it restarts only when the damage has been repaired. In mammalian cells, the presence of DNA damage can block entry from G_1 phase into S phase, it can slow S phase once it has begun, and it can block the transition from G_2 phase to M phase. These delays facilitate DNA repair by providing the time needed for the repair to reach completion.

DNA damage also results in an increased synthesis of many DNA repair enzymes. This response depends on special signaling proteins that sense DNA damage and synthesize more of the DNA repair enzymes appropriate for the damage. The importance of this mechanism is revealed by the phenotype of humans who are born with defects in the gene that encodes the *ATM protein*. These individuals have the disease *ataxia telangiectasia* (*AT*), the symptoms of which include neurodegeneration, a predisposition to cancer, and genome instability. The ATM protein is a large protein kinase that generates the intracellular signals needed to halt the cell cycle in response to many types of spontaneous DNA damage (see Figure 17–60), and individuals with defects in this protein suffer from the effects of unrepaired DNA lesions.

Summary

Genetic information can be stored stably in DNA sequences only because a large set of DNA repair enzymes continually scans the DNA double helix and replaces any damaged nucleotides. Most types of DNA repair depend on the fact that a DNA molecule carries two copies of its genetic information—one copy on each of its two complementary strands. This allows an accidental lesion on one strand to be removed by a repair enzyme and a corrected strand then resynthesized by reference to the information in the undamaged strand.

Most of the damage to DNA bases is excised by one of two major DNA repair pathways. In base excision repair, the altered base is removed by a DNA glycosylase enzyme, followed by excision of the resulting sugar phosphate. In nucleotide excision repair, a small section of the DNA strand surrounding the damage is removed from the DNA double helix. In both cases, the gap left in the DNA helix is filled in by the sequential action of DNA polymerase and DNA ligase, using the undamaged DNA strand as the template. Some types of DNA damage can be repaired by a different strategy—the direct chemical reversal of the damage—which is carried out by specialized repair proteins. Usually, all such corrections are completed prior to DNA replication. But if not, a special class of inaccurate DNA polymerases, called translesion polymerases, is used to bypass the damage, allowing the cell to survive but sometimes creating permanent mutations at the sites of damage.

Other critical repair systems—based on either nonhomologous end joining or homologous recombination—are needed to reseal the accidental double-strand breaks that occasionally occur in the DNA helix. In most cells, an elevated level of DNA damage causes a delay in the cell cycle, which helps to ensure that the damage is repaired before the cell divides.

MBOC7_ptr_ch05_253-320.indd 295 02/12/21 12:46 PM

HOMOLOGOUS RECOMBINATION

In the preceding parts of this chapter, we discussed the mechanisms that allow the DNA sequences in cells to be maintained from generation to generation with very little change. In this part, we further explore a group of repair mechanisms that depend on a process called homologous recombination. The key feature of homologous recombination (also known as general recombination) is an exchange of DNA strands between a pair of homologous duplex DNA sequences. Such a strand exchange between two regions of double helix that are very similar or identical in nucleotide sequence allows one stretch of duplex DNA to restore lost or damaged information on a second stretch of duplex DNA. Because the DNA sequence information that is used to correct the damage can come from a separate DNA molecule, homologous recombination can repair many types of DNA damage. It makes possible, for example, the accurate repair of double-strand breaks, as mentioned previously (see Figure 5-45B). As pointed out earlier, these double-strand breaks can result from reactive chemicals or radiation (for example, that from radon gas that accumulates in some old basements). But more frequently they arise from DNA replication accidents—when forks become stalled or broken independently of any such external cause. Homologous recombination accurately corrects these accidents, and, because they occur during nearly every round of DNA replication, this repair pathway is essential for every proliferating cell. Homologous recombination can also repair other types of DNA damage (for example, covalent cross-links between the two strands of a DNA double helix), being perhaps the most versatile DNA repair mechanism available to the cell; this probably explains why its mechanism and the proteins that carry it out have been conserved in virtually all cells on Earth.

We shall also see that homologous recombination plays an additional role in sexually reproducing organisms. During meiosis, a key step in gamete (sperm and egg) production, it catalyzes the orderly exchange of blocks of genetic information between corresponding (homologous) maternal and paternal chromosomes. This creates new combinations of DNA sequences in the chromosomes that are passed to offspring, giving the next generation unique characteristics upon which natural selection can act.

Homologous Recombination Has Common Features in All Cells

The current view of homologous recombination as a critical DNA repair mechanism in all cells developed slowly from its original discovery as a key component in the specialized process of meiosis in plants and animals. The subsequent recognition that homologous recombination also occurs in unicellular organisms made it readily amenable to molecular analyses. Thus, much of what we know about the biochemistry of genetic recombination was derived from studies of bacteria, especially of E. coli and its viruses, as well as from experiments with simple eukaryotes such as yeasts. For these organisms with short generation times and relatively small genomes, it was possible to isolate a large set of mutants with defects in their recombination processes. The protein altered in each mutant was then identified and, ultimately, studied biochemically. Very close relatives of these proteins were subsequently found in more complex eukaryotes including flies, mice, and humans, and it is now possible to directly analyze homologous recombination in these species as well. As a result, we now know that the fundamental processes that catalyze homologous recombination are common to all cells.

DNA Base-pairing Guides Homologous Recombination

The hallmark of homologous recombination is that it takes place only between DNA duplexes that have extensive regions of sequence similarity (homology). Not surprisingly, base-pairing underlies this requirement: before undergoing homologous recombination, two DNA helices will "sample" each other's DNA sequence by testing the potential base-pairing between a single strand from one

MBOC7_ptr_ch05_253-320.indd 296 02/12/21 12:46 PM

DNA duplex and a complementary single strand from the other. Recombination is initiated when a match is found; this match need not be perfect, but it must be very close for homologous recombination to succeed. As we shall see, the process is carefully controlled and guided by a group of specialized proteins.

Homologous Recombination Can Flawlessly Repair Double-Strand Breaks in DNA

Unlike the nonhomologous end joining discussed earlier, homologous recombination repairs double-strand breaks accurately, without any loss or alteration of nucleotides at the site of repair. For homologous recombination to do this repair job, the damaged DNA must first be brought into proximity with a homologous but undamaged DNA double helix, which can then serve as a template for repair. For this reason, homologous recombination often occurs after DNA replication, when the two daughter DNA molecules lie close together and one can serve as a template for repair of the other.

One of the simplest pathways through which homologous recombination can repair double-strand breaks is shown in Figure 5–47. In essence, the broken DNA duplex and the template duplex carry out a "strand dance" so that one of the damaged strands can use the complementary strand of the intact DNA duplex

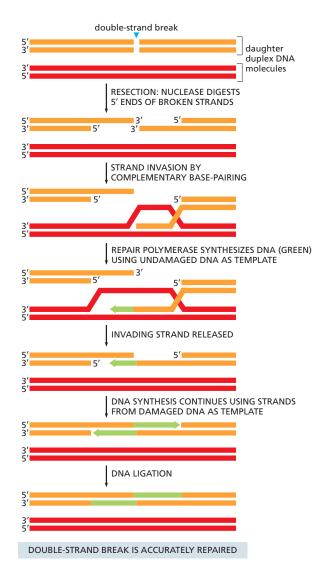

Figure 5-47 A mechanism that repairs double-strand breaks by homologous recombination. Homologous recombination can be regarded as a flexible series of reactions, with the exact pathway differing from one case to the next. The pathway shown here represents one of the major forms of recombinational double-strand break repair; however other, closely related pathways also exist. All share the first two steps-resection and strand invasionbut they diverge afterward. For example, recombinational repair of some doublestrand breaks proceeds through a double Holliday junction, a structure we discuss later in this chapter.

MBOC7_ptr_ch05_253-320.indd 297 02/12/21 12:46 PM

as a template for repair. Once the damaged and template DNA double helices are in proximity (as occurs, for example, after DNA replication), the ends of the broken DNA are chewed back, or "resected," by specialized nucleases to produce overhanging, single-strand 3' ends. The next step is **strand exchange** (also called *strand invasion*), during which one of the single-strand 3' ends from the damaged DNA molecule searches the template duplex for homologous sequences through base-pairing. Once stable base-pairing is established (which completes the *strand-exchange* step), an accurate DNA polymerase extends the invading strand using the information provided by the undamaged template molecule, thus restoring one of the damaged DNA strands. The last steps—strand displacement, further repair synthesis, and ligation—restore the two original DNA double helices and complete the repair process, as illustrated.

Homologous recombination resembles other DNA repair reactions in that a DNA polymerase utilizes a pristine template to restore damaged DNA. However, instead of using the partner strand as a template, as occurs in most DNA repair pathways, homologous recombination makes use of a complementary strand from a separate DNA duplex. In the following sections, we discuss the steps of homologous recombination in more detail with an emphasis on the proteins that guide this remarkable process.

Specialized Processing of Double-Strand Breaks Commits Repair to Homologous Recombination

Once a double-strand break occurs, nonhomologous end joining and homologous recombination compete to repair the damage. But the specialized nuclease that resects DNA ends to begin homologous recombination becomes highly active during S and G_2 (through its phosphorylation by cell-cycle-controlled kinases), and homologous recombination usually wins out at these times, allowing use of a newly replicated daughter DNA molecule as a template. The initiating nuclease (called the Mre11 complex in eukaryotes) chews back in the $5' \rightarrow 3'$ direction leaving protruding 3' ends on either side of the break that can be as long as several thousand nucleotides. Single-strand binding protein (the same one used at replication forks) then coats the exposed single strands, protecting them from other nucleases in the cell and ensuring that they remain free of intramolecular base-pairing. The formation of these protruding ends prevents nonhomologous end joining from occurring, and it commits the repair pathway to homologous recombination.

Strand Exchange Is Directed by the RecA/Rad51 Protein

Of all the steps of homologous recombination, strand invasion is the most difficult to imagine. How does the invading single strand rapidly sample a DNA duplex for a complementary sequence? Once the homology is found, how is the structure stabilized? And how is the inherent stability of the template double helix overcome to allow tests for base-pairing during this process?

The answers to these questions came from biochemical and structural studies of the main protein that carries out this feat, called **RecA** in *E. coli* and **Rad51** in virtually all eukaryotic organisms. A special group of accessory proteins loads a set of RecA/Rad51 monomers onto a protruding DNA single strand (such as that in Figure 5-47), forming a cooperatively bound filament that displaces the single-strand binding protein originally present. This orderly loading process produces a protein–DNA filament in which the DNA is held by RecA/Rad51 in an unusual conformation: groups of three consecutive nucleotides are positioned as though they were in a conventional DNA double helix, but, between adjacent triplets, the DNA backbone is untwisted and stretched out (**Figure 5-48**). This unusual protein–DNA structure then grasps a nearby duplex DNA molecule in a way that stretches it, destabilizing it and making it easy to pull the strands apart. The invading single strand then can sample the sequence of the duplex by conventional base-pairing to one of its strands. This sampling occurs in triplet

MBOC7_ptr_ch05_253-320.indd 298 02/12/21 12:46 PM

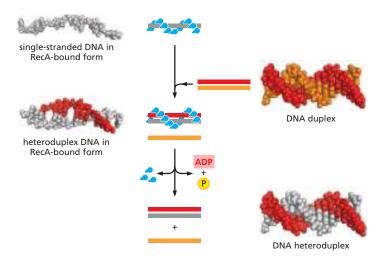

Figure 5–48 Strand invasion catalyzed by the RecA protein. Our understanding of this reaction is based in part on structures determined by x-ray diffraction studies of the bacterial RecA protein bound to single-stranded and double-stranded DNA. These DNA structures (illustrated with the RecA protein removed) are shown on the left side of the diagram. The reaction begins when ATP-bound RecA protein (blue) associates with a DNA single strand (typically a protruding 3' end as shown in Figure 5–47), holding it in an elongated form where groups of three bases are separated from each other by a stretched and twisted backbone. The RecA-bound single strand then binds to duplex DNA, destabilizing it to allow the single strand to sample its sequence through base-pairing, three bases at a time. If an extensive match is found, the structure is disassembled through ATP hydrolysis, resulting in protein dissociation and the exchange of one single strand of DNA for another, thereby forming a new heteroduplex from the complementary strands of two different DNA molecules. In the vast majority of cases, no match will be found in any one binding event, in which case the RecA-bound DNA single strand rapidly dissociates to begin a new search. (PDB code: 3CMX.)

nucleotide blocks, each of which is already in a "base-pair ready" conformation in the invading strand; when a good triplet match occurs, only then is the adjacent triplet sampled, and so on. In this way, mismatches very quickly cause dissociation, so that millions of possible pairings can be tested. Only an extended stretch of base-pairing (at least 15 nucleotides) can stabilize the invading strand, leading to the next steps in homologous recombination.

RecA/Rad51 is an ATPase, and the steps described above require that each monomer along the filament be in the ATP-bound state. However, the searching itself does not require ATP hydrolysis; instead, the process occurs by simple molecular collisions, allowing an enormous number of potential sequences to be rapidly sampled. Once stable base-pairing occurs and a strand-exchange reaction is completed, ATP hydrolysis is necessary to disassemble RecA from the complex of DNA molecules. At this point, repair DNA polymerases and DNA ligase, which we encountered earlier in this chapter, complete the repair process, as shown previously in Figure 5–47.

Homologous Recombination Can Rescue Broken and Stalled DNA Replication Forks

Although accurately repairing double-strand breaks is a crucial function of homologous recombination, it can also repair other types of damage. For example, some chemicals cross-link the two strands of DNA together by covalently joining nucleotides on opposite strands. A special set of enzymes unlinks the strands and cuts out the damaged bits on both strands. At this point, the damaged DNA has been converted to a double-strand break, which can be accurately repaired by homologous recombination, as discussed earlier. Similarly, proteins can become accidently covalently linked to DNA, and these sites can also be converted by nucleases into double-strand breaks, allowing repair by homologous

MBOC7_ptr_ch05_253-320.indd 299 02/12/21 12:46 PM

Figure 5–49 Repair of a broken replication fork by homologous recombination. When a moving replication fork encounters a single-strand break, it will collapse but can be repaired by homologous recombination. The process uses many of the same reactions shown in Figure 5–47 and proceeds through the same basic steps. *Green* strands represent the new DNA synthesis that takes place after the replication fork has broken. This pathway allows the fork to move past the break on the damaged template using the undamaged duplex as a template to synthesize DNA. (Adapted from M.M. Cox, *Proc. Natl. Acad. Sci. USA* 98:8173–8180, 2001. Copyright 2001 National Academy of Sciences, USA. With permission from National Academy of Sciences.)

recombination. But perhaps the most important role of homologous recombination is in rescuing broken or stalled DNA replication forks. Many types of events can cause a replication fork to stop, and here we consider two examples. The first arises from an accidental single-strand gap in the parent DNA helix that lies just ahead of a replication fork. When the fork reaches this lesion, it falls apart—resulting in one broken and one intact daughter chromosome. Because this is a "one-sided" double-strand break, it cannot be repaired by nonhomologous end joining, and homologous recombination becomes crucial. The broken fork can be accurately repaired using the same basic reactions we discussed earlier for the repair of double-strand breaks (Figure 5–49). With slight modifications, the set of reactions just depicted can accurately repair many different types of DNA damage, providing that an undamaged duplex DNA template is available.

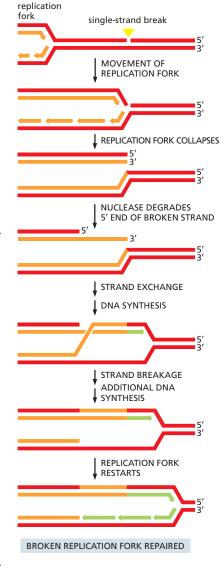

A different type of problem arises when a replication fork attempts to move through certain types of DNA damage that clogs up the replication machinery, stalling the fork. Because such damaged DNA often ends up deeply buried in the core of the replication fork, it cannot be easily repaired. To resolve this problem, the replication machine "backs up" through a series of strand-exchange reactions similar to those we have discussed (Figure 5–50). This maneuver allows one newly synthesized DNA strand to act as a template for synthesis of the other new strand, thereby bypassing the damaged template and allowing replication to proceed.

DNA Repair by Homologous Recombination Entails Risks to the Cell

Although homologous recombination neatly solves the problem of accurately repairing double-strand breaks and other types of DNA damage, it sometimes "repairs" damage using the wrong bit of the genome as the template. For example, sometimes a broken human chromosome is repaired using the homolog from the other parent instead of the sister chromatid as the template. Because maternal and paternal chromosomes differ in DNA sequence at many positions along their lengths, this type of repair can convert the sequence of the repaired DNA from the maternal to the paternal sequence or vice versa. The result of this type of errant recombination is a **loss of heterozygosity**. It can have severe consequences if the homolog used for repair contains a deleterious mutation, because the recombination event destroys the "good" copy. Loss of heterozygosity, although it happens rarely, is nonetheless a critical step in the formation of many cancers (discussed in Chapter 20).

Cells go to great lengths to minimize the risk of mishaps of these types; indeed, as we have seen, nearly every step of homologous recombination is carefully regulated. Recall that the first step (resection of the broken ends) is coordinated with the cell cycle: it occurs primarily in the S and G_2 phases of the cell cycle, favoring the use of a daughter duplex (either as a partially replicated chromosome or a fully replicated sister chromatid) as a template for repair (see Figure 5–47). The close proximity of the two daughter chromosomes disfavors the use of other genome sequences in the repair process.

The loading of RecA/Rad51 onto the processed DNA ends and the subsequent strand-exchange reaction are also tightly controlled by the cell, and a host of accessory proteins is needed to regulate these steps. There are many such proteins, and exactly how all of them coordinate and control homologous recombination remains a mystery, although we do understand how a few of them work, as described below. We also know that the enzymes that catalyze

MBOC7_ptr_ch05_253-320.indd 300 02/12/21 12:46 PM

Figure 5–50 Repair of a stalled replication fork by "fork reversal." This mechanism is brought into play when a replication fork stalls when it encounters certain types of damaged nucleotides. A specialized helicase (not shown) peels the newly synthesized DNA strands away from their parent templates, allowing them to form complementary base pairs with each other and backing up the replication fork. At this point two outcomes are possible. In the first, because the damaged DNA has been exposed, it can be repaired by conventional repair mechanisms, and the fork can be restarted. In the second, as shown, DNA synthesis can bypass the damage using newly synthesized daughter DNA (rather than the damaged parent strand) as the template. This scheme allows the replication fork to move through the DNA damage, which can be repaired at a later time. Although the initial steps of replication fork reversal are well understood, exactly how the fork restarts afterward remains a mystery.

recombinational repair are made at relatively high levels in eukaryotes and are dispersed throughout the nucleus in an inactive form. In response to DNA damage, they rapidly converge on the sites of DNA damage, become activated, and form "repair factories" where many lesions are apparently brought together and repaired (Figure 5–51). Formation of these factories probably results from many weak interactions between different repair proteins and between repair proteins and damaged DNA, producing the type of biomolecular condensates discussed in Chapter 3 (see Figure 3–77). The high local concentration of the appropriate proteins and their substrates within these condensates is thought to increase the speed and efficiency of the repair process.

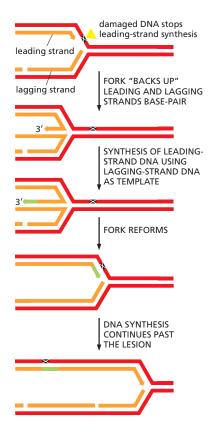

In Chapter 20, we shall see that both too much and too little homologous recombination can lead to cancer in humans, the former through repair using the "wrong" template (as described above) and the latter through an increased mutation rate caused by inefficient DNA repair. Clearly, a delicate balance has evolved that keeps this process in check on undamaged DNA, while still allowing it to act efficiently and rapidly on DNA lesions as soon as they arise.

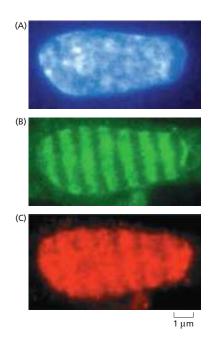

Not surprisingly, mutations in the components that carry out and regulate homologous recombination are responsible for several inherited forms of cancer. Two of these, the Brca1 and Brca2 proteins, were first discovered because mutations in their genes lead to a greatly increased frequency of breast cancer. Because these mutations cause inefficient repair by homologous recombination, accumulation of DNA damage can, in a small proportion of cells, give rise to a cancer. Brca1 regulates an early step in broken-end processing; without it, such ends are not processed correctly for homologous recombination and instead damaged molecules are shunted to the error-prone nonhomologous end-joining pathway (see Figure 5–45). After resection, Brca2 is needed to correctly load the Rad51 protein onto the protruding single-strand DNA ends in preparation for strand exchange.

Homologous Recombination Is Crucial for Meiosis

We have seen that homologous recombination can use a set of reactions—including broken-end resection, strand invasion, limited DNA synthesis, and ligation—to exchange DNA sequences between two double helices with the same nucleotide sequence and thereby repair damaged DNA. We now describe how homologous recombination is used to deliberately exchange material between two different chromosomes in order to generate DNA molecules that carry novel combinations of genes. This is a frequent and necessary part of meiosis, which occurs in sexually reproducing organisms such as fungi, plants, and animals.

Figure 5–51 Experiment demonstrating the rapid localization of repair proteins to DNA double-strand breaks. Human fibroblasts were x-irradiated to produce DNA double-strand breaks. Before the x-rays struck the cells, they were passed through a microscopic grid with x-ray-absorbing "bars" spaced 1 μ m apart. This produced a striped pattern of DNA damage, allowing a comparison of damaged and undamaged DNA in the same nucleus. (A) Total DNA in a fibroblast nucleus stained with the dye DAPI. (B) Sites of new DNA synthesis due to repair of DNA damage, indicated by incorporation of BrdU (a thymidine analog) and subsequent staining with fluorescently labeled antibodies to BrdU (green). (C) Localization of the Mre11 complex to damaged DNA as visualized by antibodies against the Mre11 subunit (red). Mre11 is the 5' \rightarrow 3' nuclease that produces the protruding single-strand DNA ends needed for strand invasion (see Figure 5–47). A, B, and C were processed 30 minutes after x-irradiation. MBOC7 ptr ch05 253-320.indd 301 02/12/21 12:46 PM

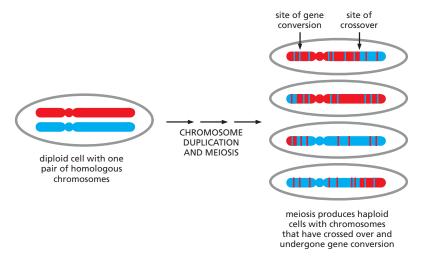

Figure 5–52 Chromosome crossing-over occurs in meiosis. Meiosis is the process by which a diploid cell gives rise to four haploid germ cells, as described in detail in Chapter 17. Meiosis produces germ cells in which the paternal and maternal genetic information (*red* and *blue*) has been reassorted through chromosome crossovers. In addition, many short regions of gene conversion occur, as indicated.

In meiosis, homologous recombination is an integral part of the process that allows chromosomes to be parceled out to germ cells (sperm and eggs in animals). We discuss the process of meiosis in detail in Chapter 17; here we discuss how homologous recombination during meiosis produces chromosome *crossing-over* and *gene conversion*, resulting in hybrid chromosomes that contain genetic information from both the maternal and paternal homologs (Figure 5–52). These mechanisms, at their core, closely resemble those used to repair double-strand breaks.

Meiotic Recombination Begins with a Programmed Double-Strand Break

Homologous recombination in meiosis starts with a bold stroke: a specialized Spo11 protein complex breaks both strands of the DNA double helix in one of the recombining chromosomes (Figure 5–53). After catalyzing this reaction, the protein complex remains covalently bound to the broken DNA, much like the DNA topoisomerase we encountered earlier in this chapter (see Figure 5–22). Many of the subsequent recombination reactions closely resemble those already described for the repair of double-strand breaks; indeed, some of the same proteins are used for both processes. For example, the Mre11 complex, which we encountered earlier, chews back the DNA ends, removing the proteins along with the DNA and leaving the protruding 3' single-strand ends needed for strand invasion.

However, several meiosis-specific proteins come into play and guide the reactions somewhat differently, resulting in the distinctive outcomes observed for meiosis. A key difference is that, in meiosis, recombination occurs preferentially between maternal and paternal chromosomal homologs (which are held closely together during meiosis), rather than between newly replicated, identical DNA duplexes as in double-strand break repair. In the sections that follow, we describe in more detail those aspects of homologous recombination that are especially important for meiosis.

Holliday Junctions Are Recognized by Enzymes That Drive Branch Migration

Of special importance in meiosis is an intermediate structure known as a **Holliday junction**, or *cross-strand exchange*, in which two homologous DNA helices that have paired are held together by the reciprocal exchange of two of the four strands

MBOC7_ptr_ch05_253-320.indd 302 02/12/21 12:46 PM

303

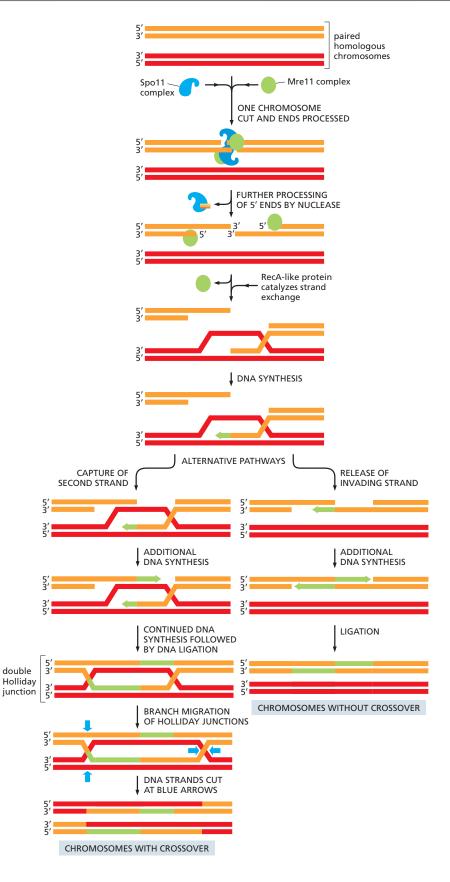

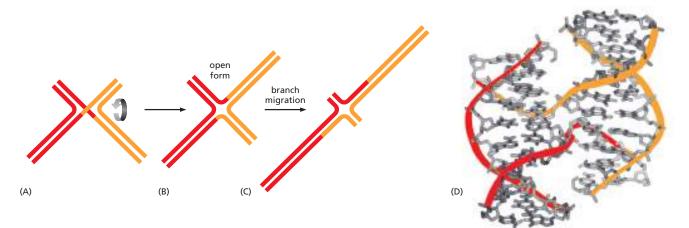

Figure 5-53 Homologous recombination during meiosis can generate chromosome crossovers. Once the Spo11 complex breaks the duplex DNA and the Mre11 complex processes the ends, homologous recombination in meiosis can proceed along alternative pathways (Movie 5.8). One (right side of figure) closely resembles the double-strand break repair reaction shown in Figure 5-47 and results in chromosomes that have been "repaired" without crossing over. The other (left side of figure) proceeds through a double Holliday junction and produces two chromosomes that have crossed over. During meiosis, the maternal and paternal chromosome homologs are held tightly together (see Figure 17-54), and both types of recombination occur between them.

MBOC7_ptr_ch05_253-320.indd 303 02/12/21 12:46 PM

present, one strand originating from each of the helices. This junction can be considered to contain two pairs of strands: one pair of crossing strands and one pair of noncrossing strands (**Figure 5-54A**). But by undergoing a series of rotational movements, it can isomerize to form an open, symmetrical structure in which both pairs of strands occupy equivalent positions (**Figure 5-54B and D**). A special set of recombination proteins that binds to this open isomer uses the energy of ATP hydrolysis to catalyze a reaction known as *branch migration* (**Figure 5-55**), which greatly expands the region of heteroduplex DNA that was initially created by a strand-exchange reaction (**Figure 5-54B and C**). In meiosis, heteroduplex regions often "migrate" thousands of nucleotides from the original site of the double-strand break. The step where this migration occurs is indicated in Figure 5-53. As shown in the figure, Holliday junctions are often produced in pairs, known as double Holliday junctions.

Homologous Recombination Produces Crossovers Between Maternal and Paternal Chromosomes During Meiosis

There are two basic outcomes of homologous recombination during meiosis, as shown previously in Figure 5–53 (Movie 5.8). In humans, approximately 90% of the double-strand breaks produced during meiosis are resolved as non-crossovers (right side of Figure 5–53). Here, the two original DNA duplexes separate from each other in a form unaltered except for a region of heteroduplex that formed near the site of the original double-strand break. As already noted, this set of reactions resembles that described earlier for the repair of double-strand breaks.

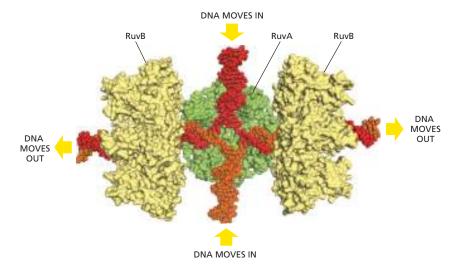

Figure 5-54 A Holliday junction. The initially formed structure (A) is usually drawn with two strands crossing, as in Figure 5-53. An isomerization of the Holliday junction (B) produces an open, symmetrical structure that is bound by specialized proteins. (C) These proteins "move" the Holliday junctions by a coordinated set of branch-migration reactions that involve the breaking and formation of base pairs (see Figure 5-55 and Movie 5.8). (D) Three-dimensional structure of the Holliday junction in the open form depicted in B. The Holliday junction is named for the scientist who first proposed its formation. (PDB code: 1DCW.)

Figure 5-55 Enzyme-catalyzed branch movement at a Holliday junction by branch migration. A tetramer of the RuvA protein (green) and two hexamers of the RuvB protein (yellow) bind to the open form of the junction. The RuvB protein, which resembles the hexameric helicases used in DNA replication (see Figure 5-14), uses the energy of ATP hydrolysis to spool DNA rapidly through the Holliday junction, extending the heteroduplex region as shown. The RuvA protein coordinates this movement, threading the DNA strands to avoid tangling. This example is from E. coli, but similar proteins function in meiosis in sexually reproducing organisms. (PDB codes: 1IXR, 1C7Y.)

MBOC7_ptr_ch05_253-320.indd 304 02/12/21 12:46 PM

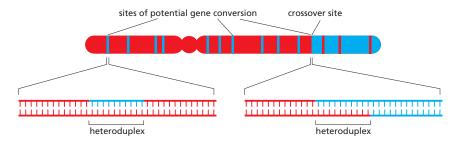

Figure 5–56 Heteroduplexes formed during meiosis. Heteroduplex DNA is present at sites of recombination that are resolved either as crossovers or noncrossovers. Because the DNA sequences of maternal and paternal chromosomes differ at many positions along their lengths, heteroduplexes often contain a small number of base-pair mismatches, and they are therefore potential sites of gene conversion (see Figure 5–57).

The other outcome is much more profound: a double Holliday junction is formed and is cleaved by specialized enzymes (*blue arrows* on the left side of Figure 5–53) to create a *crossover*. The two original portions of each chromosome upstream and downstream from the two Holliday junctions are thereby swapped, creating two chromosomes that are said to have "crossed over"—each containing a large number of both maternally inherited and paternally inherited genes.

How does the cell decide which double-strand breaks to resolve as cross-overs? The answer is not yet known, but we know the decision is not random. The relatively few crossovers that do form are distributed along chromosomes in such a way that a crossover in one position inhibits crossing-over in neighboring regions. Termed *crossover control*, this fascinating but poorly understood regulatory mechanism ensures the roughly even distribution of crossover points along chromosomes. It also ensures that each chromosome—no matter how small—undergoes at least one crossover event every meiosis. For many organisms, roughly two crossovers per chromosome occur during each meiosis, one on each arm. As discussed in detail in Chapter 17, these crossovers, in addition to producing novel DNA molecules, play an important mechanical role in the proper segregation of chromosomes during meiosis.

Whether a meiotic recombination event is resolved as a crossover or a non-crossover, the recombination machinery leaves behind a *heteroduplex region* where a strand with the DNA sequence of the paternal homolog is base-paired with a strand from the maternal homolog (**Figure 5–56**). These heteroduplex regions can tolerate a small percentage of mismatched base pairs, and because of branch migration, they often extend for thousands of nucleotide pairs. The many non-crossover events that occur in meiosis thereby produce scattered sites in the germ cells where short DNA sequences from one homolog have been pasted into the other homolog. Heteroduplex regions mark sites of potential *gene conversion*—where the four haploid chromosomes produced by meiosis contain three copies of a DNA sequence from one homolog and only one copy of this sequence from the other homolog, as explained next.

Homologous Recombination Often Results in Gene Conversion

In sexually reproducing organisms, it is a fundamental law of genetics that—aside from mitochondrial DNA, which is inherited only through the mother—each parent makes an equal genetic contribution to an offspring. One complete set of nuclear genes is inherited from the father and one complete set is inherited from the mother. Underlying this law is the accurate parceling out of chromosomes to the germ cells (eggs and sperm) that takes place during meiosis. Thus, when a diploid cell in a parent undergoes meiosis to produce four haploid germ cells, exactly half of the genes distributed among these four cells should be maternal (genes inherited from the mother of this parent) and the other half paternal (genes inherited from the father of this parent). In some organisms (fungi, for example), it is possible to recover and analyze all four of the haploid gametes produced from a single cell by meiosis. Studies in such organisms have revealed rare cases in which the parceling out of genes violates the standard genetic rules. Occasionally, for example, meiosis yields three copies of the maternal version of a gene and only one copy of the paternal version. Alternative versions of the same gene are called alleles, and it is the divergence from their expected distribution during

MBOC7_ptr_ch05_253-320.indd 305 02/12/21 12:46 PM

meiosis that is known as **gene conversion** (Movie 5.8). Genetic studies show that only small sections of DNA typically undergo gene conversion, and in many cases only a part of a gene is changed. How is this possible?

We have seen that both crossovers and non-crossovers produce heteroduplex regions of DNA. If the two strands that make up a heteroduplex region do not have identical nucleotide sequences, mismatched base pairs are formed, and these are often repaired by the cell's mismatch repair system (see Figure 5–20). However, unlike what happens after DNA replication, in meiosis the mismatch repair system randomly selects the strand to be used as a template, causing one allele to be lost and the other duplicated (Figure 5–57). Thus, gene conversion (the "conversion" of one allele to the other)—originally regarded as a mysterious deviation from the rules of genetics—can be seen as a straightforward consequence of the mechanisms of homologous recombination during meiosis.

Summary

Homologous recombination describes a flexible set of reactions resulting in the exchange of DNA sequences between a pair of identical or nearly identical duplex DNA molecules. Of special importance is a strand-exchange step whereby a single strand from one DNA duplex invades a second duplex and base-pairs with one strand while displacing the other. This reaction, catalyzed by the RecA/Rad51 family of proteins, can only occur if the invading strand can form a short stretch of consecutive nucleotide pairs with one of the strands of the duplex. This requirement ensures that homologous recombination occurs only between identical or very similar DNA sequences.

When used as a DNA repair mechanism, homologous recombination usually occurs between a damaged DNA molecule and its recently duplicated sister molecule, with the undamaged duplex acting as a template to repair the damaged copy flawlessly. In meiosis, homologous recombination is initiated by deliberate, carefully regulated double-strand breaks and occurs preferentially between the homologous chromosomes rather than the newly replicated sister chromatids. The outcome can be either two chromosomes that have crossed over (that is, chromosomes in which the DNA on either side of the site of DNA pairing originates from two different homologs) or two non-crossover chromosomes. In the latter case, the two chromosomes that result are identical to the original two homologs, except for relatively minor DNA sequence changes at the site of recombination.

TRANSPOSITION AND CONSERVATIVE SITE-SPECIFIC RECOMBINATION

We have seen that homologous recombination can result in the exchange of DNA sequences between chromosomes. However, the order of genes on the interacting chromosomes typically remains the same after homologous recombination, inasmuch as the recombining sequences must be very similar for the process to occur. In this part of the chapter, we describe two very different types of recombination—transposition and conservative site-specific recombination—that do not require substantial regions of DNA homology. These two types of recombination reactions can alter the gene order along a chromosome and introduce whole blocks of DNA sequence into the genome.

Transposition and conservative site-specific recombination are largely dedicated to moving a wide variety of specialized segments of DNA—collectively termed *mobile genetic elements*—from one position in a genome to another. We will see that mobile genetic elements can range in size from a few hundred to tens of thousands of nucleotide pairs, and each typically carries a unique set of genes. Often, one of these genes encodes a specialized enzyme that catalyzes the movement of only that element and its close relatives, thereby making this type of recombination possible.

Virtually all cells contain mobile genetic elements, known informally as "jumping genes." As explained in Chapter 4, over evolutionary time scales, they

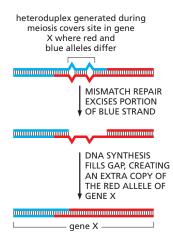

Figure 5-57 Gene conversion caused by mismatch correction. As shown in the preceding figure, heteroduplex DNA is formed at the sites of homologous recombination between maternal and paternal chromosomes. If the maternal and paternal DNA sequences are slightly different, the heteroduplex region will include some mismatched base pairs, which may then be corrected by the DNA mismatch repair machinery (see Figure 5-20). Because neither strand of DNA is newly synthesized, such repair can "erase" nucleotide sequences on either the paternal or the maternal strand. The consequence of this mismatch repair is gene conversion, detected as a deviation from the segregation of equal copies of maternal and paternal alleles that normally occurs in meiosis.

MBOC7_ptr_ch05_253-320.indd 306 02/12/21 12:46 PM

have had a profound effect on the shaping of modern genomes. For example, nearly half of the DNA in the human genome can be traced to these elements (see Figure 4–63). Over time, random mutation has altered their nucleotide sequences, and, as a result, only a few of the many copies of these elements in our DNA are still active and capable of movement. The remainder are molecular fossils whose existence provides striking clues to our evolutionary history.

Mobile genetic elements are often considered to be molecular parasites (they are also termed "selfish DNA") that persist because cells cannot get rid of them; they certainly have come close to overrunning our own genome. However, mobile DNA elements can provide benefits to the cell. For example, the genes they carry are sometimes advantageous to the host, as in the case of antibiotic resistance in bacterial cells, discussed later. The movement of mobile genetic elements also produces many of the genetic variants upon which evolution depends, because, in addition to moving themselves, mobile genetic elements occasionally rearrange neighboring sequences of the host genome. Thus, spontaneous mutations observed in bacteria, *Drosophila*, humans, and other organisms are often due to the random movement of mobile genetic elements. While many of these mutations will be deleterious to the organism, some will be advantageous and may spread throughout the population. It is almost certain that much of the variety of life we see around us originally arose from the movement of mobile genetic elements.

In this part of the chapter, we introduce mobile genetic elements and describe the mechanisms that enable them to move from place to place in a genome. As mentioned above, these elements move through a variety of different mechanisms that can be grouped into two broad categories, *transposition* and *conservative site-specific recombination*. We begin with transposition, by far the most predominant of these two processes.

Through Transposition, Mobile Genetic Elements Can Insert into Any DNA Sequence

Mobile elements that move by way of transposition are called **transposons**, or **transposable elements**. In transposition, a specific enzyme, usually encoded by the transposon itself and typically called a *transposase*, acts on specific DNA sequences at each end of the transposon, causing it to insert into a new DNA site. Most transposons are only modestly selective in choosing their target site, and they can therefore insert themselves into many different locations in a genome; in particular, there is no general requirement for sequence similarity between the ends of the element and the target sequence. Most transposons move only rarely. In bacteria, the rate is typically one transposition event once every 10^5 cell divisions, and significantly more frequent movement would probably destroy the host cell's genome. In plants and animals, the situation is different: it is common for progeny to carry tens to hundreds of new insertions relative to their parents. These high rates are tolerated, in part, because these genomes typically carry vast amounts of nonessential DNA sequences where most of the insertions are likely to occur.

On the basis of their structure and transposition mechanism, transposons can be grouped into three large classes: *DNA-only transposons, retroviral-like retrotransposons*, and *nonretroviral retrotransposons*. The differences among them are briefly outlined in **Table 5-4**, and each class will be discussed in turn.

DNA-only Transposons Can Move by a Cut-and-Paste Mechanism

DNA-only transposons, so named because they exist exclusively as DNA during their movement, predominate in bacteria, and they are largely responsible for the spread of antibiotic resistance in bacterial strains. When antibiotics such as penicillin and streptomycin first became widely available in the 1950s, most bacteria that caused human disease were susceptible to them. Now, the situation

MBOC7_ptr_ch05_253-320.indd 307 02/12/21 12:46 PM

TABLE 5-4 Three Major Classes of Transposable Elements								
Class description and structure	Specialized enzymes required for movement	Mode of movement	Examples					
DNA-only transposons								
Short inverted repeats at each end	Transposase	Moves as DNA, either by cut-and-paste or replicative pathways	P element (<i>Drosophila</i>), Ac-Ds (maize), Tn3 (<i>E. coli</i>), Tam3 (snapdragon), Helraiser (bat)					
Retroviral-like retrotransposons								
Directly repeated long terminal repeats (LTRs) at each end Reverse transcriptase all integrase		Moves via an RNA intermediate whose production is driven by a promoter in the LTR	Copia and Gypsy (<i>Drosophila</i>), Ty1 (yeast), HERVK (human), Bs1 (maize), EVADE (<i>Arabidopsis</i>					
Nonretroviral retrotransposons								
Poly A at 3' end of RNA transcript; 5' end is often truncated	Reverse transcriptase and endonuclease	Moves via an RNA intermediate that is often synthesized from a neighboring promoter	I element (<i>Drosophila</i>), L1 (human), Cin4 (maize), Karma (rice)					

These elements range in length from 1000 to about 12,000 nucleotide pairs. Each family contains many members, only a few of which are listed here. Some viruses can also move in and out of host-cell chromosomes by transpositional mechanisms. These viruses are related to the first two classes of transposons.

is different—antibiotics such as penicillin (and its modern derivatives) are no longer effective against many modern bacterial strains, including those causing gonorrhea and bacterial pneumonia. The spread of antibiotic resistance is due largely to genes that encode antibiotic-inactivating enzymes that are carried on transposons (Figure 5–58). Although these mobile elements can transpose only within cells that already carry them, they can be moved from one cell to another through other mechanisms known collectively as horizontal gene transfer (see Figure 1–18). Once introduced into a new cell, a transposon can insert itself into the genome and be faithfully passed on to all progeny cells through the normal processes of DNA replication and cell division.

DNA-only transposons can relocate from a donor site to a target site by *cut-and-paste transposition* (Figure 5-59). Here, the transposon is literally excised from one spot on a genome and inserted into another. This reaction produces a short duplication of the target DNA sequence at the insertion site; these direct repeat sequences that flank the transposon serve as convenient records of a prior transposition event. Such "signatures" often provide valuable clues in identifying transposons in genome sequences.

When a cut-and-paste DNA-only transposon is excised from its original location, it leaves behind a "hole" in the chromosome. This lesion can be perfectly healed by recombinational double-strand break repair, provided that the chromosome has recently been replicated so that an identical copy of the damaged host sequence is available. Alternatively, a nonhomologous end-joining reaction can reseal the break; in this case, the DNA sequence that originally flanked the transposon is often altered, producing a mutation at the chromosomal site from which the transposon was excised (see Figure 5–45).

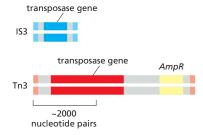

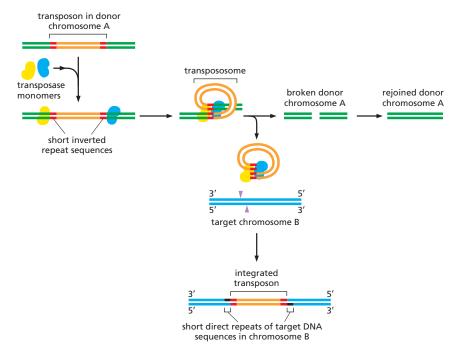

Figure 5–58 Transposons often code for the components they need for transposition. Shown here are two types of bacterial DNA-only transposons. Each carries a gene that encodes a transposase (dark blue and red)—the enzyme that catalyzes the element's movement—as well as short DNA sequences (light blue and pink) that are recognized by the matching transposase. The short sequences (two in each transposon) are usually arranged so that one is an inverted repeat of the other.

Some transposons carry additional genes (yellow) that encode enzymes that inactivate antibiotics such as ampicillin (AmpR). The spread of these transposons is a serious problem in medicine, as it has allowed many disease-causing bacteria to become resistant to the antibiotics developed in the twentieth century.

MBOC7_ptr_ch05_253-320.indd 308 02/12/21 12:46 PM

Remarkably, the same mechanism used to excise cut-and-paste transposons from DNA has been found to operate in the developing immune system of vertebrates, catalyzing the DNA rearrangements that produce antibody and T-cell receptor diversity. Known as V(D)J recombination, this process will be discussed in Chapter 24. Found only in vertebrates, V(D)J recombination is a relatively recent evolutionary novelty, but its mechanism was probably derived from the much more ancient cut-and-paste transposons.

Some DNA-only Transposons Move by Replicating Themselves

Although cut-and-paste transposition is common, especially in bacteria, there are other ways that DNA-only transposons can move. These involve replicating the transposon and moving the copy to a new position on the genome, leaving the original transposon intact and in its original position. There are several different ways this can occur and we discuss only one here, which is characteristic of a large class of DNA-only transposons known as *helitrons*. Found in all branches of life, these transposons are especially common in plants and animals where they can compose several percent of genomes. They carry a gene for an unusual type of transposase, one that functions as both a sequence-specific nuclease and as a helicase, thereby directing the movement of the transposon (Figure 5–60).

Because of the mechanism behind their movement, helitrons often transfer bits of the genome, along with themselves, to new positions. For this reason, they are thought to be especially important in reshuffling genomic information to produce variant organisms subject to natural selection over evolutionary time scales.

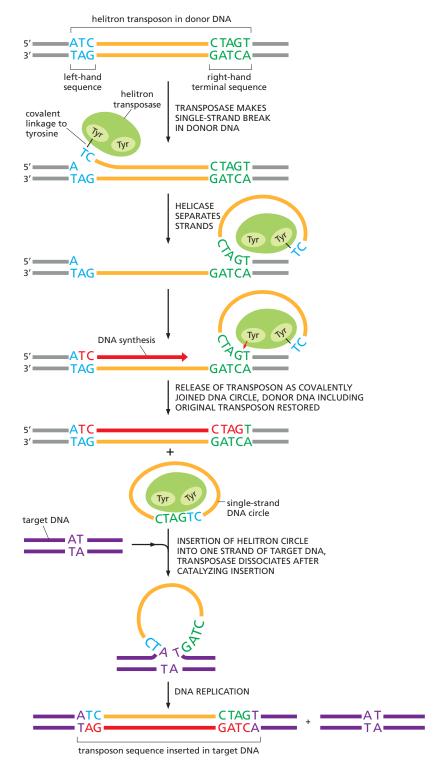

Some Viruses Use a Transposition Mechanism to Move Themselves into Host-Cell Chromosomes

Certain viruses are considered mobile genetic elements because they use transposition mechanisms to integrate their genomes into that of their host cell. However, unlike transposons, the nucleotide sequences that form these viruses encode proteins that package their genetic information into virus particles that can leave the original host cell to infect other cells. As discussed in Chapter 1, most viruses probably evolved from transposable elements through the capture

Figure 5-59 Cut-and-paste

transposition. DNA-only transposons can be recognized in chromosomes by the inverted repeat DNA sequences (red) present at their ends. These sequences. which can be as short as 20 nucleotides. are all that is necessary for the DNA between them to be transposed by the particular transposase enzyme associated with the element. The cut-and-paste movement of a DNA-only transposable element from one chromosomal site to another begins when the transposase enzyme brings the two inverted DNA sequences together, forming a DNA loop. Insertion into the target chromosome, also catalyzed by the transposase, occurs at a random site through the creation of staggered breaks in the target chromosome (purple arrowheads). After the transposition reaction, the single-strand gaps created by the staggered breaks are repaired by DNA polymerase and ligase (black). As a result, the insertion site is marked by a short direct repeat of the target DNA sequence, as shown. Although the break in the donor chromosome (green) is repaired, this process often alters the DNA sequence, causing a mutation at the original site of the excised transposable element (not shown).

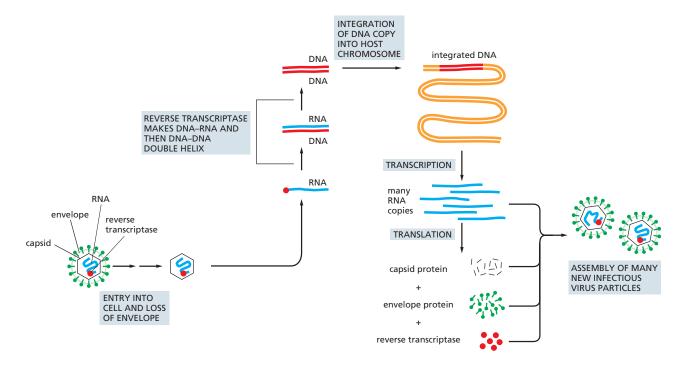

MBOC7_ptr_ch05_253-320.indd 309 02/12/21 12:46 PM

of genes from their host cells. Although originally serving some other purpose in the cell, such captured genes, after a long process of mutation and selection, now code for the structural proteins of viruses, allowing them to escape the cell. Viruses are among the most numerous biological entities on Earth, and we discuss them in more detail in Chapter 23. The viruses that insert themselves into host chromosomes generally do so by employing one of the first two mechanisms

Figure 5-60 Mechanism of transposition by helitrons, a type of DNA-only transposon. Several models have been proposed for the movement of these recently discovered transposons, and one is shown here. This model is based on studies of a helitron found in bats, called Helraiser. The process begins when the transposase (green) makes a single-strand break at one end of the transposon (blue) and, with the aid of a helicase, "peels back" the single strand. A second transposasemediated reaction releases the transposon in the form of single-stranded DNA, which can move to new positions in the host genome. The transposase (which travels with the single-stranded DNA) can then catalyze the covalent insertion of the transposon into a new location in the host DNA. Transposition by helitrons often moves adjacent host genome sequences along with them. This occurs when, in the third step, the transposase skips over its own CTAGT sequence and cleaves its host DNA downstream at a similar DNA sequence. According to the model, this skipping produces a single-strand DNA circle that includes both helitron and host DNA, and both are inserted into target DNA.

MBOC7_ptr_ch05_253-320.indd 310 02/12/21 12:46 PM

listed in Table 5–4; namely, by behaving like DNA-only transposons or like retroviral-like retrotransposons. Indeed, much of our knowledge of these mechanisms has come from studies of particular viruses that employ them.

Transposition has a key role in the life cycle of many viruses. Most notable are the **retroviruses**, which include the human AIDS virus, HIV. Outside the cell, a retrovirus exists as a single-strand RNA genome packed into a protein shell, or *capsid*, along with a virus-encoded **reverse transcriptase** enzyme. During the infection process, the viral RNA enters a cell and is converted to a double-strand DNA molecule by the action of this crucial enzyme, which is able to polymerize DNA on either an RNA or a DNA template (**Figure 5–61**). The term *retrovirus* refers to the virus's ability to reverse the usual flow of genetic information, which normally is from DNA to RNA (see Figure 1–4).

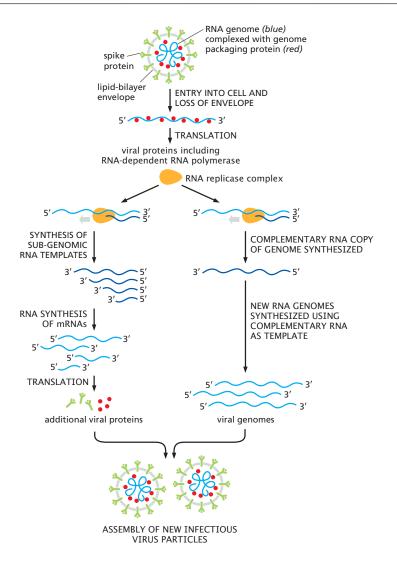

Once the reverse transcriptase has produced a double-strand DNA molecule, specific sequences near its two ends are recognized by a virus-encoded transposase called *integrase*. Integrase then inserts the viral DNA into the chromosome by a mechanism similar to that used by the cut-and-paste DNA-only transposons (see Figure 5–59).

Some RNA Viruses Replicate and Express Their Genomes Without Using DNA as an Intermediate

Retroviruses are not the only viruses that carry their genomes in the form of RNA. Other viruses also have single-strand RNA genomes, but, unlike retroviruses, many replicate and express their genomes without ever using DNA; that is, they are *RNA-only viruses*. For example, SARS-CoV-2, the coronavirus underlying the COVID-19 pandemic, replicates its single-strand RNA genome using a special, viral-encoded *RNA-dependent RNA polymerase*. Upon entering a cell, the viral genome is directly translated by ribosomes as though it were an mRNA molecule, producing many different viral-encoded proteins, including the RNA-dependent RNA polymerase. (We discuss mRNA and the process of translation in detail in Chapter 6.) The polymerase assembles with several other viral proteins and a few host proteins to form the complete *replicase complex*. This specialized replicase, which does not require a primer to begin synthesis, starts at the 3' end of the viral genome and makes a complementary RNA copy of the entire genome

Figure 5-61 The life cycle of a retrovirus. The retrovirus genome consists of an RNA molecule (blue) that is typically between 7000 and 12,000 nucleotides in length. It is packaged inside a virus-encoded protein capsid, which is surrounded by a lipid-based envelope that contains virus-encoded envelope proteins (green). Inside an infected cell, the enzyme reverse transcriptase (red circle) first makes a DNA copy of the viral RNA molecule and then a second DNA strand, generating a doublestrand DNA copy of the RNA genome. The integration of this DNA double helix into the host chromosome is then catalyzed by a virus-encoded integrase enzyme. This integration is required for the synthesis of new viral RNA molecules by the hostcell RNA polymerase, the enzyme that transcribes DNA into RNA (discussed in Chapter 6). As indicated, this viral RNA is then used by host-cell machinery to produce the capsid, envelope, and reverse transcriptase proteins needed to form new virus particles.

MBOC7_ptr_ch05_253-320.indd 311 02/12/21 12:46 PM

(Figure 5-62). Using this complementary copy as a template, the replicase then synthesizes new genomes, which are then packaged with newly synthesized viral proteins into complete virus particles. The whole process of viral replication takes about 10 hours, and a single infected cell can produce as many as 1000 new virus particles, which can spread to other cells within the same host or move in aerosols to new hosts. Because coronaviruses do not use DNA, all steps of viral replication can take place outside the nucleus. In the case of SARS-CoV-2, viral replication occurs in the cytoplasm inside double-membrane compartments that are commandeered by the virus from the endoplasmic reticulum, an organelle described in detail in Chapter 12. These virus-induced compartments are believed to protect the virus from the cell's many antiviral defenses (see pp. 1337–1338) during viral replication and assembly.

Several features of coronaviruses distinguish them from other RNA-only viruses such as those that cause influenza or polio. Perhaps the most unusual is the ability of coronavirus replicase complexes to proofread as they copy their RNA genomes. This proofreading occurs in much the same way that we saw for DNA polymerases earlier in the chapter: An incorrectly added nucleotide is excised by a 3'-to-5' exonuclease carried in the replicase complex, giving the replicase another chance to add the correct nucleotide. This feature means that coronaviruses do not mutate as rapidly as most other RNA viruses, which lack proofreading ability. As discussed in Chapter 23, the relatively high mutation rate of influenza

Figure 5-62 Simplified view of the coronavirus life cycle as exemplified by SARS-CoV-2. The viral genome, a singlestrand RNA molecule of approximately 30,000 nucleotides, is packaged throughout its length with an RNA-binding protein (red) and enclosed by a lipid bilayer containing the viral spike protein. (The appearance of spike proteins, emanating from the lipid envelope, is responsible for the "corona" moniker.) As described in Chapter 23, the spike proteins bind to a receptor on the surface of susceptible cells and direct the fusion of the viral envelope with the outer cell membrane, releasing the viral genome into the cytoplasm. The genome is then directly translated into protein. Single-strand RNA viruses of this type are called [+] strand viruses, denoting the ability of their genomes to be immediately translated by the host-cell machinery. In contrast, the genomes of [-] strand viruses must first be used as templates to make complementary RNA strands that are then translated (see Table 23-1).

Among the first proteins made by coronaviruses are those that form the RNA-dependent RNA polymerase, which is responsible for producing new viral genomes by synthesizing RNA using RNA as a template. The replicase complex (which includes the polymerase and several other loosely associated proteins) first synthesizes complete noncoding copies of the viral genome. These complementary copies in turn serve as templates for the replicase complex to synthesize new genomes. The replicase also makes a series of shorter coding RNAs, which are needed to produce additional viral proteins including the spike. Once new viral genomes and proteins have been synthesized, new virus particles are assembled and exit the cell. Although only a few viral proteins are shown in the diagram, the virus codes for at least 27 different proteins: some of these organize the double-membrane structures in which the virus replicates, while others inhibit various immune system responses to the infection.

MBOC7_ptr_ch05_253-320.indd 312 02/12/21 12:46 PM

virus helps explain why new vaccines are needed every year, and this may not always be the case for coronaviruses.

The proofreading also has other important implications. As discussed earlier in this chapter, the lower the mutation rate, the greater the number of essential proteins that a genome can maintain. Proofreading allows coronaviruses to have a larger genome than is typical for RNA viruses; for example, compare the 30,000 nucleotides of the SARS-CoV-2 genome (coding for at least 27 proteins) to the 13,500 nucleotides of the influenza virus (coding for about 10 proteins). Proofreading also affects the development of antiviral drugs. Viral replicases are attractive targets for such drugs, in part because similar enzymes do not exist in uninfected host cells, reducing the chance of side effects. Drugs of this type (for example, remdesivir) are typically nucleoside triphosphate analogs that "fool" the RNA replicase into adding them to growing RNA chains. Once incorporated, the analogs—which have improper 3' ends—poison further chain elongation (see Figure 8-42). Coronavirus proofreading can excise many of these analogs and thereby reduce their potency. A related strategy (exemplified by molnupiravir) employs nucleoside triphosphate analogs that are incorporated into RNA by the viral replicase, escape proofreading, but base pair incorrectly in the next round of replication, thereby introducing a lethal number of mutations.

Another striking feature of coronaviruses is the way in which they make many different proteins from a genome carried on a single RNA molecule. As described earlier, the viral genome, once it enters a cell, is treated like an mRNA molecule and translated into protein. We shall see in the next chapter, however, that most eukaryotic mRNAs can code for only a single protein. Coronavirus production of many different proteins from a single RNA genome requires a series of unusual steps, some of which appear unique to coronaviruses. We shall discuss the general topics of mRNA translation and its regulation in Chapters 6 and 7. But first, we return to our discussion of transposons, some of which closely resemble viruses in the way they move from place to place in their host genomes.

Retroviral-like Retrotransposons Resemble Retroviruses, but Cannot Move from Cell to Cell

A large family of transposons called retroviral-like retrotransposons (see Table 5-4) move themselves in and out of chromosomes by a mechanism similar to that used by retroviruses. These elements are present in organisms as diverse as yeasts, flies, and mammals; unlike viruses, they have no intrinsic ability to leave their resident cell but are passed along to all descendants of that cell through the normal processes of DNA replication and cell division. The first step in their transposition is the transcription of the entire transposon, producing an RNA copy of the element that is typically several thousand nucleotides long. This transcript, which is translated as a messenger RNA by the host cell, encodes a reverse transcriptase enzyme. This enzyme makes a double-strand DNA copy of the RNA molecule via an RNA-DNA hybrid intermediate, precisely mirroring the early stages of infection by a retrovirus (see Figure 5-61). Like a retrovirus, the linear, double-strand DNA molecule then integrates into a site on the chromosome using an integrase enzyme that is also encoded by the element. The structure and mechanisms of these integrases closely resemble those of the transposases of DNA-only transposons.

A Large Fraction of the Human Genome Is Composed of Nonretroviral Retrotransposons

A significant fraction of many vertebrate chromosomes is made up of repeated DNA sequences. In human chromosomes, these repeats are mostly mutated and truncated versions of **nonretroviral retrotransposons**, the third major type of transposon (see Table 5–4). Although most of these transposons in the human genome are immobile, a few retain the ability to move. Movements of the *L1 element* (sometimes referred to as a LINE, or long interspersed nuclear element)

MBOC7_ptr_ch05_253-320.indd 313 02/12/21 12:46 PM

have been identified, some of which result in human disease; for example, a particular type of hemophilia results from an L1 insertion into the gene encoding the blood-clotting protein Factor VIII (see Figure 6–25).

Nonretroviral retrotransposons are found in many organisms and move via a distinct mechanism that requires a complex of an endonuclease and a reverse transcriptase. As illustrated in **Figure 5–63**, the RNA and reverse transcriptase have a much more direct role in the recombination event than they do in the retroviral-like retrotransposons described above.

Inspection of the human genome sequence reveals that the bulk of nonretroviral retrotransposons—for example, the many copies of the Alu element, a member of the SINE (short interspersed nuclear element) family—do not carry their own endonuclease or reverse transcriptase genes. Nonetheless, they have successfully amplified themselves to become major constituents of our genome, presumably by pirating enzymes encoded by active LI elements. Together the LINEs and SINEs make up more than 30% of the human genome (see Figure 4–62); there are 500,000 copies of the former and more than a million of the latter.

Different Transposable Elements Predominate in Different Organisms

We have described several types of transposable elements: (1) DNA-only transposons, the movement of which is based on DNA breaking and joining reactions; (2) retroviral-like retrotransposons, which also move via DNA breakage and joining, but where RNA has a key role as a template to generate the DNA recombination substrate; and (3) nonretroviral retrotransposons, in which an RNA copy of the element is central to the incorporation of the element into the target DNA, acting as a direct template for a DNA target-primed reverse transcription event.

Intriguingly, different types of transposons predominate in different organisms. For example, the vast majority of bacterial transposons are DNA-only types, with a few related to the nonretroviral retrotransposons also present. In yeasts, the main mobile elements are retroviral-like retrotransposons. In *Drosophila*, DNA-only, retroviral, and nonretroviral transposons are all found. Finally, the human genome contains all three types of transposon, but as discussed below, their evolutionary histories are strikingly different.

Genome Sequences Reveal the Approximate Times at Which Transposable Elements Have Moved

The nucleotide sequence of the human genome provides a rich fossil record of the activity of transposons over evolutionary time spans. By carefully comparing the nucleotide sequences of the approximately 3 million transposable element remnants in the human genome, it has been possible to broadly reconstruct the movements of transposons in our ancestors' genomes over the past several hundred million years. For example, the cut-and-paste DNA-only transposons appear to have been very active well before the divergence of humans and Old World monkeys (25-35 million years ago), but because they gradually accumulated inactivating mutations, they have been dormant in the human lineage since that time. Likewise, although our genome is littered with relics of retroviral-like retrotransposons, none appear to be active today. Only a single family of retroviral-like retrotransposons is believed to have transposed in the human genome since the divergence of human and chimpanzee approximately 6 million years ago. The nonretroviral retrotransposons are also ancient, but in contrast to other types, some are still moving in our genome, as mentioned previously. For example, it is estimated that de novo movement of an Alu element occurs once in every 100-200 human births. This movement of nonretroviral retrotransposons is responsible for a small but significant fraction of new human mutations—perhaps two mutations out of every thousand.

The situation in mice is significantly different. Although the mouse and human genomes contain roughly the same density of the three types of transposons, both

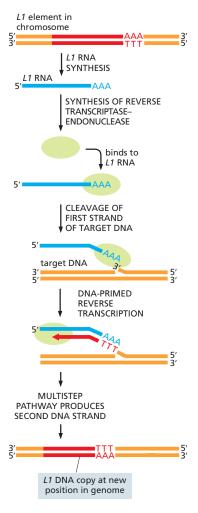

Figure 5–63 Transposition by a nonretroviral retrotransposon.

Transposition of the L1 element (red) begins when an endonuclease that is part of a complex with the L1 reverse transcriptase (green) bound to the 3' end of L1 RNA (blue) nicks the target DNA at the point at which insertion will occur. This cleavage produces a 3'-OH DNA end in the target DNA, which is then used as a primer for the reverse transcription step shown. This generates a single-strand DNA copy of the element that is directly linked to the target DNA. In subsequent reactions, further processing of the single-strand DNA copy results in the generation of a new double-strand DNA copy of the L1 element that is inserted at the site of the initial nick.

types of retrotransposons are still actively transposing in the mouse genome, being responsible for approximately 10% of new mutations.

Although we are only beginning to understand how the movements of transposons have shaped the genomes of present-day mammals, it has been proposed that bursts in transposition activity could have been responsible for critical speciation events during the radiation of the mammalian lineages from a common ancestor, a process that began approximately 170 million years ago. At present, we can only wonder how many of our uniquely human qualities have been derived from the past activity of the mobile genetic elements whose remnants are found scattered throughout our chromosomes.

Conservative Site-specific Recombination Can Reversibly Rearrange DNA

A different kind of recombination mechanism, known as *conservative site-specific recombination*, rearranges other types of mobile DNA elements. In this pathway, breakage and joining occur at two special sites, one on each participating DNA molecule, with the recombination event being carried out by a specialized enzyme that breaks and rejoins the two DNA double helices at these specific sequences. The same enzyme system that joins two DNA molecules can often take them apart again, precisely restoring the sequence of the two original DNA molecules (**Figure 5–64A**). Alternatively, with a different orientation of these two sequences in a chromosome, conservative site-specific recombination produces a DNA inversion (**Figure 5–64B**).

The conservative site-specific recombination pathway illustrated in Figure 5–64A is often used by bacterial DNA viruses to move their genomes in and out of the genomes of their host cells. When integrated into its host genome, the viral DNA is replicated along with the host DNA and is faithfully passed on to all descendant cells. If the host cell suffers damage (for example, by UV irradiation), the virus can reverse the site-specific recombination reaction, excise its genome, and package it into a virus particle. In this way, many viruses can replicate themselves passively as a component of the host genome, but can also "leave the sinking ship" by excising their genomes and packaging them in a protective coat until a new, healthy host cell is encountered.

Several features distinguish conservative site-specific recombination from transposition. First, conservative site-specific recombination requires specialized

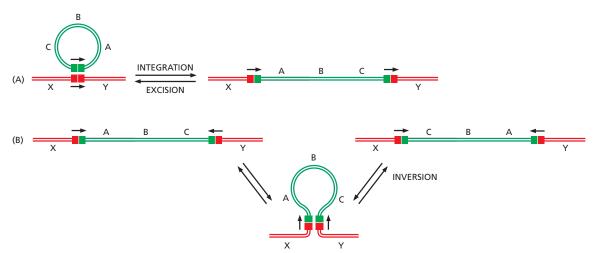

Figure 5–64 Two types of DNA rearrangement produced by conservative site-specific recombination. The only difference between the reactions in A and B is the relative orientation of the two short DNA sites (indicated by *arrows*) at which a site-specific recombination event occurs. (A) Through an integration reaction, a circular DNA molecule can become incorporated into a second DNA molecule; by the reverse reaction (excision), it can exit to re-form the original DNA circle. Many bacterial viruses move in and out of their host chromosomes in this way. (B) Conservative site-specific recombination can also invert a specific segment of DNA in a chromosome. A well-studied example of DNA inversion through site-specific recombination occurs in the bacterium *Salmonella enterica* serovar Typhimurium, as we discuss in the next section.

MBOC7_ptr_ch05_253-320.indd 315 02/12/21 12:46 PM

DNA sequences on both the donor and recipient DNA (hence the term "site-specific"). These sequences contain recognition sites for the particular recombinase that will catalyze the rearrangement. In contrast, transposition requires only that the transposon bears a specialized sequence; for most transposons, the recipient DNA can be of nearly any sequence. Second, the reaction mechanisms are fundamentally different. The recombinases that catalyze conservative site-specific recombination resemble topoisomerases in the sense that they form transient high-energy covalent bonds with the DNA and use this energy to complete all the DNA rearrangements without the need for new DNA synthesis (see Figure 5–22). Thus, all the phosphate bonds that are broken during a recombination event are restored upon its completion (hence the term "conservative"). Transposition, in contrast, typically leaves gaps in the DNA that must be repaired by DNA polymerases.

Conservative Site-specific Recombination Can Be Used to Turn Genes On or Off

Many bacteria use conservative site-specific recombination to control the expression of particular genes. A well-studied example occurs in *Salmonella* bacteria, an organism that is a major cause of food poisoning in humans. Known as **phase variation**, the switch in gene expression results from the occasional inversion of a specific 1000-nucleotide-pair piece of DNA, brought about by a conservative site-specific recombinase encoded in the *Salmonella* genome. This change alters the expression of the cell-surface protein flagellin, for which the bacterium has two different genes. The DNA inversion changes the orientation of a promoter (a DNA sequence that directs transcription of a gene) that is located within the inverted DNA segment. With the promoter in one orientation, the bacteria synthesize one type of flagellin; with the promoter in the other orientation, they synthesize the other type (**Figure 5–65**).

The recombination reaction is reversible, allowing bacterial populations to switch back and forth between the two types of flagellin. Inversions occur only rarely, and because such changes in the genome will be copied faithfully during all subsequent replication cycles, entire clones of bacteria will have one type of flagellin or the other.

Phase variation helps protect the bacterial population against the immune response of its vertebrate host. If the host makes antibodies against one type of flagellin, a few bacteria whose flagellin has been altered by gene inversion will still be able to survive and multiply.

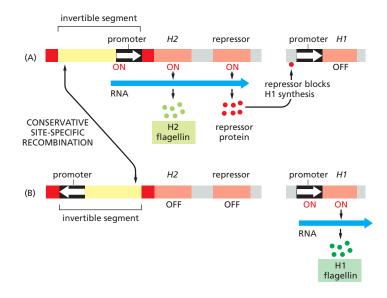

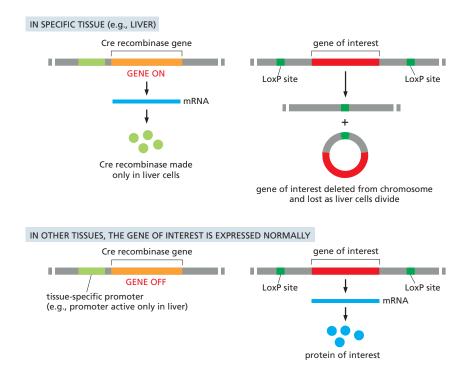

Figure 5-65 Switching gene expression by DNA inversion in bacteria. Which one of the two flagellin genes in a Salmonella bacterium is used to produce its flagellum is controlled by a conservative site-specific recombination event that inverts a small DNA segment containing a promoter. (A) In one orientation, the promoter activates transcription of the H2 flagellin gene along with the transcription of a repressor protein that blocks the expression of the H1 flagellin gene. Promoters and repressors are described in detail in Chapter 7; here we note simply that a promoter is needed to express a gene and that a repressor blocks this from happening. (B) When the promoter is inverted, it no longer turns on H2 or the repressor, and the H1 gene, which is thereby released from repression, is expressed instead. The inversion reaction requires specific DNA sequences (red) and a recombinase enzyme that is encoded in the invertible DNA segment. Because this conservative site-specific recombination mechanism is activated only rarely (about once in every 105 cell divisions), the production of one or the other type of flagellin tends to be faithfully inherited in each clone of cells.

MBOC7_ptr_ch05_253-320.indd 316 02/12/21 12:46 PM

Bacterial Conservative Site-specific Recombinases Have Become Powerful Tools for Cell and Developmental Biologists

Like many of the mechanisms used by cells and viruses, site-specific recombination has been put to work by scientists to aid in the study of a wide variety of problems. To decipher the roles of specific genes in complex multicellular organisms, genetic engineering techniques are used to produce worms, flies, and mice carrying both a gene encoding a site-specific recombination enzyme and a carefully designed target DNA that includes a gene of interest flanked by DNA sites recognized by the recombination enzyme. At an appropriate time, the gene encoding the enzyme can be activated to rearrange the target DNA sequence. Such a rearrangement is widely used to delete a specific gene in a particular tissue of a multicellular organism (Figure 5-66). This strategy is particularly useful when the gene of interest plays a key role in the early development of many tissues, and a complete deletion of the gene from the germ line would cause death very early in development. The same strategy can also be used to artificially express any specific gene in a tissue of interest; here, the triggered deletion joins a strong transcriptional promoter to the gene of interest. With this tool one can in principle determine the influence of any protein in any desired tissue of an intact animal.

Summary

The genomes of nearly all organisms contain mobile genetic elements that can move from one position in the genome to another by either transposition or conservative site-specific recombination. In most cases, this movement is random and happens at a very low frequency. There are three classes of transposons: the DNA-only transposons, the retroviral-like retrotransposons, and the nonretroviral retrotransposons. The first two classes have close relatives among the viruses, including the human retrovirus that causes AIDS, HIV. Although mobile genetic elements can be viewed as parasites, many of the new arrangements of DNA sequences that their recombination events produce have been important for creating the genetic variation required for the evolution of cells and organisms.

Figure 5–66 How a conservative sitespecific recombination enzyme from bacteria is used to delete a specific gene from a particular mouse tissue.

This approach requires the insertion of two specially engineered DNA molecules into the animal's germ line. The first contains the gene for a recombinase (in this case, the Cre recombinase from the bacteriophage P1) under the control of a tissue-specific promoter that ensures the recombinase is expressed only in that tissue. The second DNA molecule contains the gene of interest, flanked by the DNA sequences of the recognition sites for the recombinase (in this case, LoxP sites). The mouse has been engineered to contain only this copy of the gene of interest. Therefore, if the recombinase is expressed only in the liver, the gene of interest will be deleted there, and only there. As described in Chapter 7, many tissue-specific promoters are known; moreover, many of these promoters are active only at specific times in development. Thus, this method makes it possible to study the effects of deleting any gene of interest at specific times during the development of each tissue. For this reason, it is a powerful tool for scientists investigating the role of individual genes in animal and plant development.

MBOC7_ptr_ch05_253-320.indd 317 02/12/21 12:46 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **5–1** The majority of cells in your body have exactly the same nucleotide sequence in their genomes.
- **5–2** In a replication bubble, the same parent DNA strand serves as the template strand for leading-strand synthesis at one replication fork and as the template for lagging-strand synthesis at the other fork.
- **5–3** In *E. coli*, where the replication fork travels at 500 nucleotide pairs per second, the DNA ahead of the fork—in the absence of topoisomerase—would have to rotate at nearly 3000 revolutions per minute.
- 5–4 When bidirectional replication forks from adjacent origins meet, a leading strand always runs into a lagging strand.
- 5–5 DNA repair mechanisms all depend on the cell having two homologous chromosomes.

Discuss the following problems.

5–6 To determine the reproducibility of mutation frequency measurements, you do the following experiment. You inoculate each of 10 cultures with a single *E. coli* bacterium, allow the cultures to grow until each contains 10^6 cells, and then measure the number of cells in each culture that carry a mutation in your gene of interest. You were so surprised by the initial results that you repeated the experiment to confirm them. Both sets of results display the same extreme variability, as shown in Table Q5–1. Assuming that the rate of mutation is constant, why do you suppose there is so much variation in the frequencies of mutant cells in different cultures?

TABLE Q5-1 Frequencies of mutant cells in multiple cultures (Problem 5-6)										
	Culture (mutant cells/10 ⁶ cells)									
Experiment	1	2	3	4	5	6	7	8	9	10
1	4	0	257	1	2	32	0	0	2	1
2	128	0	1	4	0	0	66	5	0	2

- 5–7 Discuss the following statement: "Primase is a sloppy enzyme that makes many mistakes. Eventually, the RNA primers it makes are replaced with DNA made by a polymerase with higher fidelity. This is wasteful. It would be more energy-efficient if a DNA polymerase made an accurate copy in the first place."
- **5–8** If DNA polymerase requires a perfectly paired primer in order to add the next nucleotide, how is it that any mismatched nucleotides "escape" this requirement and become substrates for mismatch repair enzymes?
- **5–9** DNA repair enzymes preferentially repair mismatched bases on the newly synthesized DNA strand,

using the old DNA strand as a template. If mismatches were instead repaired without regard for which strand served as template, would mismatch repair reduce replication errors? Would such a mismatch repair system result in fewer mutations, more mutations, or the same number of mutations as there would have been without any repair at all? Explain your answers.

The laboratory you joined is studying the life cycle of an animal virus that uses circular, double-stranded DNA as its genome. Your project is to define the location of the origin(s) of replication and to determine whether replication proceeds in one or both directions away from an origin (unidirectional or bidirectional replication). To accomplish your goal, you broke open cells infected with the virus, isolated replicating viral genomes, cleaved them with a restriction nuclease that cuts the genome at only one site to produce a linear molecule from the circle, and examined the resulting molecules in the electron microscope. Some of the molecules you observed are illustrated schematically in Figure Q5-1. (Note that it is impossible to distinguish the orientation of one DNA molecule relative to another in the electron microscope because they land on the electron microscope grid in random orientations.)

You must present your conclusions to the rest of the lab tomorrow. How will you answer the two questions your advisor posed for you? Is there a single, unique origin of replication or several origins? Is replication unidirectional or bidirectional?

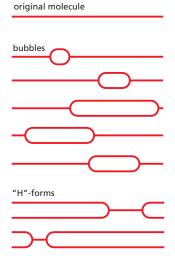

Figure Q5–1 Parent and replicating forms of an animal virus genome (Problem 5–10).

5–11 You are investigating DNA synthesis in tissue-culture cells, using ³H-thymidine to radioactively label the replication forks. By breaking open the cells in a way that allows some of the DNA strands to be stretched out, very long DNA strands can be isolated intact and examined. You overlay the DNA with a photographic emulsion, and expose it for 3–6 months, a procedure known as autoradiography. Because the emulsion is sensitive to radioactive emissions, the ³H-labeled DNA shows up as tracks of silver grains. Because the stretching collapses replication bubbles, the daughter duplexes lie side by side and cannot be distinguished from each other.

MBOC7_ptr_ch05_253-320.indd 318 02/12/21 12:46 PM

PROBLEMS 319

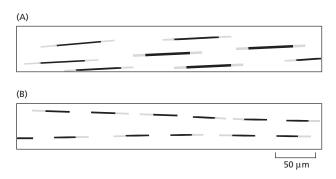

Figure Q5–2 Autoradiographic investigation of DNA replication in cultured cells (Problem 5–11). (A) Addition of ³H-labeled thymidine immediately after release from the arrest. (B) Addition of ³H-labeled thymidine 30 minutes after release from the arrest.

You treat the cells to arrest them at the beginning of S phase. In the first experiment, you release the arrest and add ³H-thymidine immediately. After 30 minutes, you wash the cells and change the medium so that the total concentration of thymidine is the same as it was, but only one-third of it is radioactive. After an additional 15 minutes, you prepare DNA for autoradiography. The results of this experiment are shown in Figure Q5–2A. In the second experiment, you release the arrest and wait 30 minutes before adding ³H-thymidine. After 30 minutes in the presence of ³H-thymidine, you once again change the medium to reduce the concentration of radioactive thymidine and incubate the cells for an additional 15 minutes. The results of the second experiment are shown in Figure Q5–2B.

- A. Explain why, in both experiments, some regions of the tracks are dense with silver grains (dark), whereas others are less dense (light).
- **B.** In the first experiment, each track has a central dark section with light sections at each end. In the second experiment, the dark section of each track has a light section at only one end. Explain the reason for this difference.
- C. Estimate the rate of fork movement (μ m/min) in these experiments. Do the estimates from the two experiments agree? Can you use this information to gauge how long it would take to replicate the entire genome?
- **5–12** If you compare the frequency of the 16 possible dinucleotide sequences in the *E. coli* and human genomes, there are no striking differences except for one dinucleotide, 5′-CG-3′. The frequency of CG dinucleotides in the human genome is significantly lower than in *E. coli* and significantly lower than expected by chance. Why do you suppose that CG dinucleotides are underrepresented in the human genome?
- 5–13 With age, somatic cells are thought to accumulate genomic "scars" as a result of the inaccurate repair of double-strand breaks by nonhomologous end joining (NHEJ). Estimates based on the frequency of breaks in primary human fibroblasts suggest that by age 70, each human somatic cell may carry some 2000 NHEJ-induced mutations due to inaccurate repair. If these mutations were distributed randomly around the genome, how many protein-coding genes would you expect to be affected? Would

you expect cell function to be compromised? Why or why not? (Assume that 2% of the genome—1.5% protein-coding and 0.5% regulatory—is crucial information.)

5–14 Draw a schematic diagram of the double Holliday junction that would result from strand invasion by both ends of the broken duplex into the intact homologous duplex shown in **Figure Q5–3**. Label the left end of each strand in the Holliday junction 5' or 3' so that the relationship to the parent and recombinant duplexes is clear. Indicate how DNA synthesis would be used to fill in any single-strand gaps in your double Holliday junction.

Figure Q5–3 A broken duplex with single-strand tails ready to invade an intact homologous duplex (Problem 5–14).

5–15 In addition to correcting DNA mismatches, the mismatch repair system acts to discourage homologous recombination between DNA duplexes that are only moderately similar in sequence. Why would recombination between moderately similar sequences pose a problem for human cells?

5–16 Cre recombinase is a site-specific enzyme that catalyzes recombination between two LoxP DNA sites. Cre recombinase pairs two LoxP sites in the same orientation, breaks both duplexes at the same point in each LoxP site, and joins the ends with new partners so that each LoxP site is regenerated, as shown schematically in **Figure Q5–4A**. On the basis of this mechanism, predict the arrangement of sequences that will be generated by Cre-mediated site-specific recombination for each of the two DNAs shown in **Figure Q5–4B**.

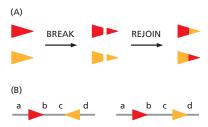

Figure Q5–4 Cre recombinase—mediated site-specific recombination (Problem 5–16). (A) Schematic representation of Cre/LoxP site-specific recombination. The LoxP sequences in the DNA are represented by triangles that are colored differently so that the site-specific recombination event can be followed more readily. In reality their DNA sequences are identical. (B) DNA substrates containing two arrangements of LoxP sites.

5–17 It is thought that a self-correcting polymerase cannot start chains *de novo* because the initial nucleotides will be weakly paired, thus subject to removal by an efficient proofreading exonuclease. This argument implies the converse: an enzyme that starts chains anew cannot be efficient at self-correction. Remarkably, SARS-CoV-2 encodes an RNA replicase complex that is able to do both: using RNA as a template, it starts strands *de novo* and removes errors with an efficient 3'-to-5' proofreading exonuclease. How might this be possible?

How Cells Read the Genome: From DNA to Protein

CHAPTER

6

Since the structure of DNA was discovered in the early 1950s, progress in cell and molecular biology has been astounding. We now know the complete genome sequences for thousands of different organisms, revealing fascinating details of their biochemistry as well as important clues as to how these organisms evolved. Complete genome sequences have also been obtained for hundreds of thousands of individual humans, as well as for a few of our now-extinct relatives, such as the Neanderthals. Knowing the maximum amount of information that is required to produce a complex organism like ourselves puts constraints on the biochemical and structural features of cells and makes it clear that biology is not infinitely complex.

As discussed in Chapter 1, most of the genetic information carried by DNA specifies the sequence of amino acids in proteins. But this DNA does not direct the synthesis of proteins directly, instead producing RNA as an intermediary. When the cell needs a particular protein, the nucleotide sequence of the appropriate portion of the DNA molecule in a chromosome is first copied into RNA (a process called *transcription*). These RNA copies of segments of the DNA sequence are then used to direct the synthesis of the protein (a process called *translation*). The genetic information in cells thereby flows from DNA to RNA to protein. All cells, from bacteria to humans, express their genetic information in this way—a principle so fundamental that it is termed the *central dogma* of molecular biology (Figure 6–1).

Despite this universality, there are important variations between organisms in the way information flows from DNA to protein. Most notable, the RNA transcripts in eukaryotic cells are subject to a series of processing steps in the nucleus, including *RNA splicing*, before they are permitted to exit from the nucleus and be translated into protein. As we discuss in this chapter, these processing steps can critically change the "meaning" of an RNA molecule, and they are therefore crucial for understanding how eukaryotic cells read their genome.

Although we shall focus in this chapter on the production of the proteins encoded by the genome, for some genes RNA is the final product. Like proteins, some of these RNAs fold into precise three-dimensional structures that have structural and catalytic roles in the cell. Although the functions of many non-coding RNAs are not yet known, some have been studied in great detail and are discussed in this and the following chapter.

One might have expected that the information present in genomes would be arranged in an orderly fashion, resembling a dictionary or a telephone directory. But it turns out that the genomes of most multicellular organisms are surprisingly disorderly, reflecting their chaotic evolutionary histories. The genes in these organisms largely consist of a long string of alternating short exons and long introns, as discussed in Chapter 4 (see Figure 4–15D). Moreover, small bits of DNA sequence that code for protein are interspersed with large blocks of seemingly meaningless DNA. Some sections of the genome contain many genes and others lack genes altogether. Proteins that work closely with one another in the cell usually have their genes located on different chromosomes, and adjacent genes typically encode proteins that have little to do with each other in the cell. Decoding genomes is therefore no simple matter. Even with the aid of powerful

IN THIS CHAPTER

From DNA to RNA

From RNA to Protein

The RNA World and the Origins of Life

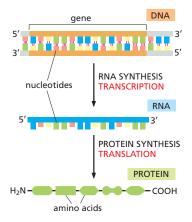

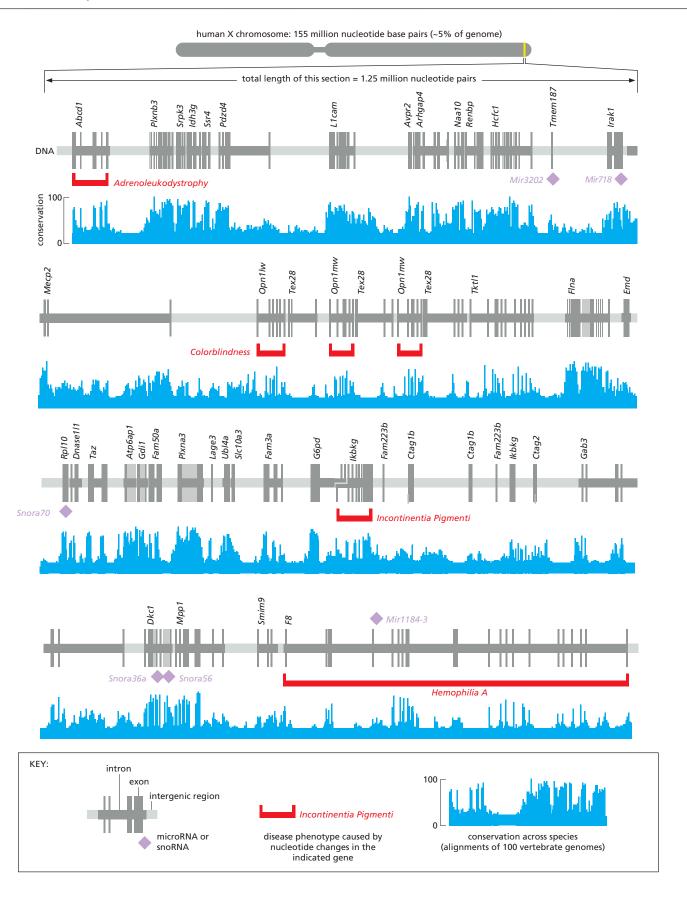

Figure 6-1 Genetic information directs the synthesis of proteins. The flow of genetic information from DNA to RNA (transcription) and from RNA to protein (translation) occurs in all living cells. As we saw in Chapter 5, DNA can also be copied—or replicated—to produce new DNA molecules.

MBOC7_ptr_ch06_321-396.indd 321 02/12/21 2:16 PM

MBOC7_ptr_ch06_321-396.indd 322 02/12/21 2:16 PM

Figure 6–2 Schematic depiction of a small portion of the human X chromosome. As summarized in the key, the known protein-coding genes (starting with *Abcd1* and ending with *F8*) are marked by a *dark gray* central line, with their coding regions (exons) indicated by *dark gray* bars that extend above and below this line. Noncoding RNAs with known functions are indicated by *purple diamonds*. The *blue* histogram indicates the extent to which portions of the human genome are conserved with other vertebrate species. It is likely that additional genes, currently unrecognized, also lie within this portion of the human genome.

Genes whose mutation causes an inherited human condition are indicated by *red brackets*. The *Abcd1* gene codes for a protein that imports fatty acids into the peroxisome; mutations in the gene cause demyelination of nerves, which can result in cognition and movement disorders. *Incontinentia pigmenti* is a disease of the skin, hair, nails, teeth, and eyes. *Hemophilia A* is a bleeding disorder caused by mutations in the Factor VIII gene, which codes for a blood-clotting protein (see Figure 6–25B). Because males have only a single copy of the X chromosome, most of the conditions shown here affect only males; females that inherit one of these defective genes are often asymptomatic because a functional protein is made from their other X chromosome. (Courtesy of Alex Williams, data obtained from the University of California, Genome Browser, http://genome.ucsc.edu.)

computers, it is difficult for researchers, in the absence of direct experimental evidence, to locate definitively the beginning and end of genes, much less to decipher when and where each gene is expressed in the life of the organism. Yet the cells in our body do this automatically, thousands of times a second.

The problems that cells face in decoding genomes can be appreciated by considering a tiny portion of the human genome (Figure 6–2). The region illustrated represents less than 1/2000 of our genome and includes at least 48 genes that encode proteins plus 6 genes for noncoding RNAs. When we consider the entire human genome, we can only marvel at the capacity of our cells to rapidly and accurately handle such large amounts of information.

In this chapter, we explain how cells decode and use the information in their genomes. Much has been learned about how the genetic instructions written in an alphabet of just four "letters"—the four different nucleotides in DNA—direct the formation of a bacterium, a fruit fly, or a human. Nevertheless, we still have a great deal to discover about how the information stored in an organism's genome produces even the simplest unicellular bacterium with about 500 genes, let alone how it directs the development of a human with approximately 25,000 genes. An enormous amount of ignorance remains; many fascinating challenges therefore await the next generation of cell biologists.

FROM DNA TO RNA

Transcription and translation are the means by which cells read out, or express, the genetic instructions in their genes. Because many identical RNA copies can be made from the same gene, and each RNA molecule can direct the synthesis of many identical protein molecules, cells can synthesize a large amount of protein from a single gene when necessary. Importantly, genes can be transcribed and translated with different efficiencies, allowing the cell to make vast quantities of some proteins and tiny amounts of others (Figure 6–3). Moreover, as we see in the next chapter, a cell can change (or regulate) the expression of each of

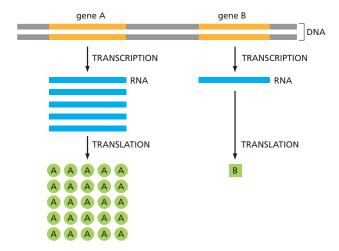

Figure 6–3 Genes can be expressed with different efficiencies. In this example, gene A is transcribed much more efficiently than gene B, and each RNA molecule that it produces is also translated more frequently. This causes the amount of protein A in the cell to be much greater than that of protein B. In this and later figures, the portions of DNA that are transcribed are shown in *orange*.

MBOC7_ptr_ch06_321-396.indd 323 02/12/21 2:16 PM

its genes according to its needs—commonly by controlling the production of its RNA—and many genes will not be expressed at all in some cells.

One of the central problems in producing proteins from the information carried in genomes is that most steps depend on conventional nucleic acid base-pairing, which on its own has only modest specificity. In many contexts, a correct base pair is only 10–100 times more thermodynamically stable than an incorrect base pair, so that most steps of gene expression rely on mechanisms that both improve the specificity of the base-pairing and correct the many mistakes that arise. A central theme of this chapter, therefore, is the way cells deal with the fundamentally inaccurate base-pairing process that lies at the heart of the mechanisms that they use to read their genome.

RNA Molecules Are Single-Stranded

The first step a cell takes in reading out its genetic instructions is to copy a particular portion of its DNA nucleotide sequence—a gene—into an RNA nucleotide sequence (Figure 6–4). The information in RNA, although copied into another chemical form, is still written in essentially the same language as it is in DNA—the language of a nucleotide sequence. Hence the name given to producing RNA molecules on DNA is *transcription*.

Like DNA, RNA is a linear polymer made of four different types of nucleotide subunits linked together by phosphodiester bonds (see Figure 6-4). It differs from DNA chemically in two respects: (1) the nucleotides in RNA are *ribonucleotides*—that is, they contain the sugar ribose (hence the name *ribonucleic* acid) rather than deoxyribose; (2) although, like DNA, RNA contains the bases adenine (A), guanine (G), and cytosine (C), it contains the base uracil (U) instead of the thymine (T) in DNA (Figure 6-5). Because U, like T, can base-pair by hydrogen-bonding with A (Figure 6-6), the complementary base-pairing properties described for DNA in Chapters 4 and 5 apply also to RNA (in RNA, G pairs with C, and A pairs with U).

Although these chemical differences are slight, DNA and RNA differ quite dramatically in overall structure. Whereas DNA always occurs in cells as a double-strand helix, RNA is single-stranded. An RNA chain can therefore fold up into a particular shape, just as a polypeptide chain folds up to form the final shape of a protein (Figure 6–7). As we see later in this chapter, the ability to fold into complex three-dimensional shapes allows some RNA molecules to have precise structural and catalytic functions.

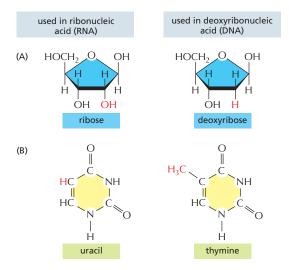

Figure 6–5 The chemical structure of RNA. (A) RNA contains the sugar ribose, which differs from deoxyribose, the sugar used in DNA, by the presence of an additional –OH group. (B) RNA contains the base uracil, which differs from thymine, the equivalent base in DNA, by the absence of a –CH₃ group.

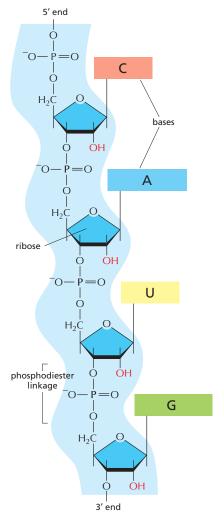

Figure 6–4 A short length of RNA. The phosphodiester chemical linkage between nucleotides in RNA is the same as that in DNA.

MBOC7_ptr_ch06_321-396.indd 324 02/12/21 2:16 PM

Transcription Produces RNA Complementary to One Strand of DNA

The RNA in a cell is made by **DNA transcription**, a process that has certain similarities to the process of DNA replication discussed in Chapter 5. Transcription begins with the opening and unwinding of a small portion of the DNA double helix to expose the bases on each DNA strand. One of the two strands of the DNA double helix then acts as a template for the synthesis of an RNA molecule. As in DNA replication, the nucleotide sequence of the RNA chain is determined by the complementary base-pairing between incoming nucleotides and the DNA template. When a good match is made (A with T, U with A, G with C, and C with G), the incoming ribonucleotide is covalently linked to the growing RNA chain in an enzymatically catalyzed reaction. The RNA chain produced by transcription—the *transcript*—is therefore elongated one nucleotide at a time, and it has a nucleotide sequence that is exactly complementary to the strand of DNA used as the template (**Figure 6–8**).

Transcription, however, differs from DNA replication in several crucial ways. Unlike a newly formed DNA strand, the RNA strand does not remain hydrogenbonded to the DNA template strand. Instead, just behind the region where the ribonucleotides are being added, the RNA chain is displaced and the DNA helix re-forms. Thus, the RNA molecules produced by transcription are released from the DNA template as single strands. In addition, because they are copied from only a limited region of the DNA, RNA molecules are much shorter than DNA molecules. A DNA molecule in a human chromosome can be up to 250 million nucleotide-pairs long; in contrast, most RNAs are no more than a few thousand nucleotides long, and many are considerably shorter.

H C C W H Wadenine N C C N Adenine S' sugar-phosphate backbone

Figure 6–6 Uracil base pairs with adenine. The absence of a methyl group in U has no effect on base-pairing; thus, U-A base pairs closely resemble T-A base pairs (see Figure 4–5).

RNA Polymerases Carry Out DNA Transcription

The enzymes that perform transcription are called **RNA polymerases**. Like the DNA polymerase that catalyzes DNA replication (discussed in Chapter 5), RNA polymerases catalyze the formation of the phosphodiester bonds that link the nucleotides together to form a linear chain. The RNA polymerase moves stepwise

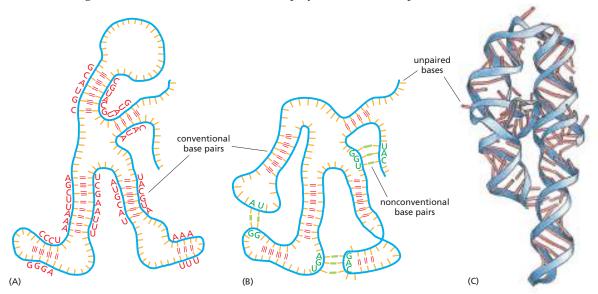

Figure 6–7 RNA can fold into specific structures. RNA is largely single-stranded, but it often contains short stretches of nucleotides that can form conventional base pairs with complementary sequences found elsewhere on the same molecule. These interactions, along with additional "nonconventional" base-pair interactions (for example, A-G), allow an RNA molecule to fold into a three-dimensional structure that is determined by its sequence of nucleotides (Movie 6.1). (A) Diagram of a folded RNA structure showing only conventional (G-C and A-U) base-pair interactions (red). (B) Formation of nonconventional (green) base-pair interactions folds the hypothetical structure shown in A even further. (C) Structure of an actual RNA molecule, in this case one that catalyzes its own splicing (see pp. 347–348). Each conventional base-pair interaction is indicated by a "rung" in the double helix. Bases in other configurations are indicated by broken rungs.

MBOC7_ptr_ch06_321-396.indd 325 02/12/21 2:16 PM

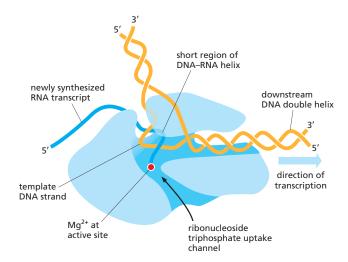

along the DNA, unwinding the DNA helix just ahead of its active site for polymerization to expose a new region of the template strand for complementary base-pairing. In this way, the growing RNA chain is extended by one nucleotide at a time in the 5'-to-3' direction (Figure 6-9). The substrates are ribonucleoside triphosphates (ATP, CTP, UTP, and GTP); as in DNA replication, the hydrolysis of high-energy bonds provides the energy needed to drive the reaction forward (see Figure 5-4 and Movie 6.2).

The almost immediate separation of the RNA strand from the DNA as it is synthesized means that many RNA copies can be made from the same gene in a relatively short time, with the synthesis of additional RNA molecules being started before the previous RNA molecules are completed (Figure 6-10). When RNA polymerase molecules follow hard on each other's heels in this way, each moving at speeds up to 50 nucleotides per second, more than a thousand transcripts can be synthesized in an hour from a single gene.

Although RNA polymerase catalyzes essentially the same chemical reaction as DNA polymerase, there are some important differences between the activities of the two enzymes. First, and most obviously, RNA polymerase catalyzes the linkage of ribonucleotides, not deoxyribonucleotides. Second, unlike the DNA polymerases involved in DNA replication (see pp. 259–260), RNA polymerases can start an RNA chain without a primer. This difference is thought possible because transcription need not be as accurate as DNA replication (see Table 5–1, p. 260). RNA polymerases make about one mistake for every 10⁴ nucleotides copied into RNA (compared with an error rate for direct copying and proofreading by DNA polymerase of about one in 10⁷ nucleotides), and the consequences of an error in RNA transcription are much less significant as RNA does not permanently store genetic information in cells. Finally, unlike DNA polymerases, which make their products in segments that are later stitched together, RNA polymerases are processive; that is, the same RNA polymerase that begins an RNA molecule must finish it without dissociating from the DNA template.

Although not nearly as accurate as the DNA polymerases that replicate DNA, RNA polymerases nonetheless have a modest proofreading mechanism. If an incorrect ribonucleotide is added to the growing RNA chain, the polymerase can back up, and the active site of the enzyme can perform an excision reaction that resembles the reverse of the polymerization reaction, except that a water molecule replaces the pyrophosphate and a nucleoside monophosphate is released.

Given that DNA and RNA polymerases both carry out template-dependent nucleotide polymerization, it might be expected that the two types of enzymes would be structurally related. However, x-ray crystallographic studies reveal that, other than containing a critical ${\rm Mg}^{2+}$ ion at the catalytic site, the two enzymes are quite different. Template-dependent nucleotide-polymerizing enzymes seem to have arisen at least twice during the early evolution of cells. One lineage led to the

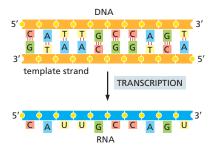

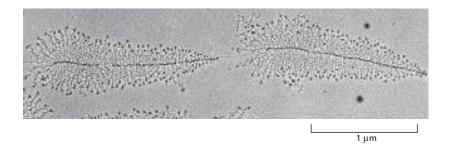

Figure 6–8 DNA transcription produces a single-strand RNA molecule that is complementary to one strand of the DNA double helix. Note that the sequence of bases in the RNA molecule produced is the same as the sequence of bases in the non-template DNA strand, except that a U replaces every T base in the DNA.

Figure 6-9 DNA is transcribed by the enzyme RNA polymerase. The RNA polymerase (pale blue) moves stepwise along the DNA, unwinding the DNA helix at its active site indicated by the Mg2-(red), which is required for catalysis. As it progresses, the polymerase adds nucleotides one by one to the RNA chain at the polymerization site, using an exposed DNA strand as a template. The RNA transcript is thus a complementary copy of one of the two DNA strands. A short region of DNA-RNA helix (approximately nine nucleotide pairs in length) is formed only transiently, and a "window" of DNA-RNA helix therefore moves along the DNA with the polymerase as the DNA double helix re-forms behind it. The incoming nucleotides are in the form of ribonucleoside triphosphates (ATP, UTP, CTP, and GTP), and the energy stored in their phosphate-phosphate bonds provides the driving force for the polymerization reaction. The figure, based on an x-ray crystallographic structure, shows a cutaway view of the polymerase: the part facing the viewer has been sliced away to reveal the interior (Movie 6.3), (Adapted from P. Cramer et al., Science 288:640-649, 2000. PDB code: 1HQM.)

MBOC7_ptr_ch06_321-396.indd 326 02/12/21 2:16 PM

modern DNA polymerases and reverse transcriptases discussed in Chapter 5, as well as to a few RNA polymerases from viruses. The other lineage formed all of the RNA polymerases that we discuss in this chapter.

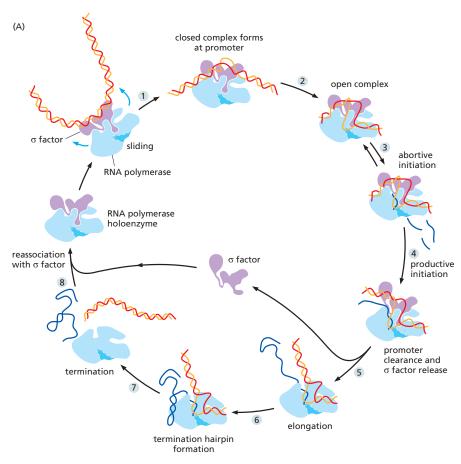

Cells Produce Different Categories of RNA Molecules

The majority of genes carried in a cell's DNA specify the amino acid sequence of proteins, and the RNAs that are copied from these genes (which ultimately direct the synthesis of proteins) are called messenger RNA (mRNA) molecules. The final product of other genes is the RNA molecule itself. These RNAs are known as noncoding RNAs, because they do not code for protein. In a well-studied, single-celled eukaryote, the yeast Saccharomyces cerevisiae, more than 1200 genes (about 15% of the total) produce RNA as their final product. Humans produce about 5000 different noncoding RNAs. These RNAs, like proteins, serve as enzymatic, structural, and regulatory components for a wide variety of processes in the cell. In Chapter 5, we encountered one of them as the template RNA carried by the enzyme telomerase. We shall see in this chapter that ribosomal RNA (rRNA) molecules form the core of ribosomes, that transfer RNA (tRNA) molecules serve as the adaptors that select amino acids and hold them in place on a ribosome for incorporation into protein, and that small nuclear RNA (snRNA) molecules direct the splicing of pre-mRNA to form mRNA. In Chapter 7, we shall see that microRNA (miRNA) molecules and small interfering RNA (siRNA) molecules serve as key regulators of eukaryotic gene expression, and that piwi-interacting RNAs (piRNAs) protect animal germ lines from transposons; we also discuss the long noncoding RNAs (lncRNAs), a diverse set of RNAs, many of whose functions are just being discovered (Table 6-1).

Figure 6-10 Transcription of two genes as observed under the electron microscope. The micrograph shows many molecules of RNA polymerase simultaneously transcribing each of two adjacent genes. Molecules of RNA polymerase are visible as a series of dots along the DNA with the newly synthesized transcripts (fine threads) attached to them. The RNA molecules (ribosomal RNAs; rRNAs) shown in this example are not translated into protein but are instead used directly as components of ribosomes, the machines on which translation takes place. The particles at the 5' end (the free end) of each rRNA transcript are believed to reflect the beginnings of ribosome assembly. From the relative lengths of the newly synthesized transcripts, it can be deduced that the RNA polymerase molecules are transcribing from right to left. (Courtesy of Ulrich Scheer.)

TABLE 6-1 Principal Types of RNAs Produced in Cells			
Type of RNA	Function		
mRNAs	Messenger RNAs, code for proteins		
rRNAs	Ribosomal RNAs, form the basic structure of the ribosome and catalyze protein synthesis		
tRNAs	Transfer RNAs, central to protein synthesis as the adaptors between mRNA and amino acids		
Telomerase RNA	Serves as the template for the telomerase enzyme that extends the ends of chromosomes		
snRNAs	Small nuclear RNAs, function in a variety of nuclear processes, including the splicing of pre-mRNA		
snoRNAs	Small nucleolar RNAs, help to process and chemically modify rRNAs		
IncRNAs	Long noncoding RNAs, not all of which appear to have a function; some serve as scaffolds and regulate diverse cell processes, including X-chromosome inactivation		
miRNAs	MicroRNAs, regulate gene expression by blocking translation of specific mRNAs and causing their degradation		
siRNAs	Small interfering RNAs, turn off gene expression by directing the degradation of selective mRNAs and helping to establish repressive chromatin structures		
piRNAs	Piwi-interacting RNAs, bind to piwi proteins and protect the germ line from transposable elements		

MBOC7_ptr_ch06_321-396.indd 327 02/12/21 2:16 PM

Each transcribed segment of DNA is called a *transcription unit*. In eukaryotes, a transcription unit typically carries the information of just one gene, and therefore codes for either a single RNA molecule or a single protein (or group of related proteins if the initial RNA transcript is spliced in more than one way to produce different mRNAs). In bacteria, a set of adjacent genes is often transcribed as a unit; the resulting mRNA molecule therefore carries the information for producing several distinct proteins.

Overall, RNA makes up a few percent of a cell's dry weight, whereas proteins compose about 50%. Most of the RNA in cells is rRNA; mRNA composes only 3–5% of the total RNA in a typical mammalian cell. The mRNA population is made up of tens of thousands of different species, and there are on average only 10–15 molecules of each species of mRNA present in each cell.

Signals Encoded in DNA Tell RNA Polymerase Where to Start and Stop

To transcribe a gene accurately, RNA polymerase must recognize where on the genome to start and where to finish. The way in which RNA polymerases perform these tasks differs somewhat between bacteria and eukaryotes. Because the processes in bacteria are simpler, we discuss them first.

The initiation of transcription is an especially important step in gene expression because it is the main point at which the cell regulates which proteins are to be produced and at what rate. The bacterial RNA polymerase core enzyme is a multisubunit complex that synthesizes RNA using the DNA template as a guide. An additional subunit called sigma (σ) factor associates with the core enzyme and assists it in reading the signals in the DNA that tell it where to begin transcribing (Figure 6–11). Together, σ factor and the core enzyme are known as the

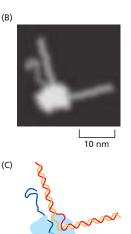

Figure 6-11 The transcription cycle of bacterial RNA polymerase. (A) In step 1, the RNA polymerase holoenzyme (polymerase core enzyme plus σ factor) assembles and then, by sliding, locates a promoter DNA sequence (see Figure 6-12). The polymerase opens (unwinds) the DNA at the position at which transcription is to begin (step 2) and begins transcribing (step 3). This initial RNA synthesis (abortive initiation) is relatively inefficient as short, unproductive transcripts are often released. However, once RNA polymerase has managed to synthesize about 10 nucleotides of RNA, it breaks its interactions with the promoter DNA (step 4) and eventually releases σ factor—as the polymerase tightens around the DNA and shifts to the elongation mode of RNA synthesis, moving along the DNA (step 5). During the elongation mode, transcription is highly processive, with the polymerase leaving the DNA template and releasing the newly transcribed RNA only when it encounters a termination signal (steps 6 and 7). Termination signals are typically encoded in DNA, and many function by forming an RNA hairpin-like structure that destabilizes the polymerase's hold on the RNA

In bacteria, all RNA molecules are synthesized by a single type of RNA polymerase, and the cycle depicted in the figure therefore applies to the production of mRNAs as well as structural and catalytic RNAs. (B) Two-dimensional image of an elongating bacterial RNA polymerase, as determined by atomic force microscopy. (C) Interpretation of the image in B. (Adapted from K.M. Herbert et al., *Annu. Rev. Biochem.* 77:149–176, 2008. With permission from Annual Reviews.)

MBOC7_ptr_ch06_321-396.indd 328 02/12/21 2:16 PM

RNA polymerase holoenzyme; this complex adheres only weakly to DNA when the two collide, and a holoenzyme typically slides rapidly along the long bacterial DNA molecule and then dissociates. However, when the polymerase holoenzyme slides into a special sequence of nucleotides indicating the starting point for RNA synthesis called a **promoter**, the polymerase binds tightly because its σ factor makes specific contacts with the edges of bases exposed on the outside of the DNA double helix (step 1 in Figure 6–11A).

The tightly bound RNA polymerase holoenzyme at a promoter opens up the double helix to expose a short stretch of nucleotides on each strand (step 2 in Figure 6–11A). The region of unpaired DNA (about 10 nucleotides) is called the *transcription bubble*, and it is stabilized by the binding of σ factor to the unpaired bases on one of the exposed strands. The other exposed DNA strand then acts as a template for complementary base-pairing with incoming ribonucleotides, two of which are joined together by the polymerase to begin an RNA chain (step 3 in Figure 6–11A).

The first 10 or so nucleotides of RNA are synthesized using a "scrunching" mechanism, in which RNA polymerase remains bound to the promoter and pulls the upstream DNA into its active site, thereby expanding the transcription bubble. This process creates considerable stress, and the short RNAs are often released, thereby relieving the stress and forcing the polymerase, which remains in place, to begin synthesis over again. Eventually this process of *abortive initiation* is overcome, and the stress generated by scrunching helps the core enzyme to break free of its interactions with the promoter DNA (step 4 in Figure 6–11A) and discard the σ factor (step 5 in Figure 6–11A).

At this point, the polymerase begins to move down the DNA, synthesizing RNA in a stepwise fashion: the polymerase moves forward one base pair for every nucleotide added. During this process, the transcription bubble continually expands at the front of the polymerase and contracts at its rear. Chain elongation continues (at a speed of approximately 50 nucleotides per second for bacterial RNA polymerases) until the enzyme encounters a second signal, the terminator (step 6 in Figure 6–11A), where the polymerase halts and releases both the newly made RNA molecule and the DNA template (step 7 in Figure 6–11A). The free polymerase core enzyme then reassociates with a free σ factor to form a holoenzyme that can begin the process of transcription again (step 8 in Figure 6–11A).

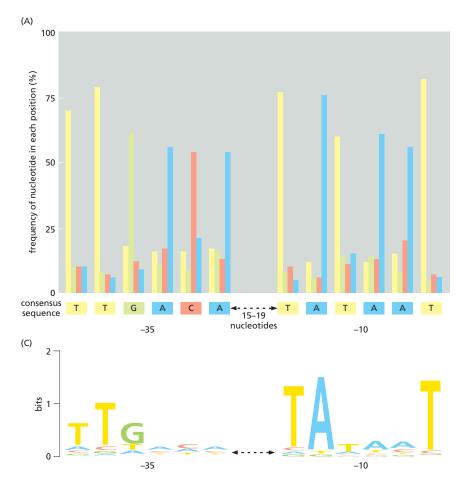

The process of transcription initiation is complicated and requires that the RNA polymerase holoenzyme and the DNA undergo a series of conformational changes, first opening the DNA double helix at promoters and subsequently tightening the enzyme around the DNA and RNA so that it does not dissociate before it has finished transcribing a gene. If an RNA polymerase does dissociate prematurely, it must start over again at the promoter.

How do the termination signals in the DNA stop the elongating polymerase? For most bacterial genes, a termination signal consists of a string of A-T nucleotide pairs preceded by a twofold symmetric DNA sequence, which, when transcribed into RNA, folds into a "hairpin" structure through Watson–Crick base-pairing (see Figure 6–92). As the polymerase transcribes across a terminator, the formation of the hairpin helps release the RNA transcript, which is held in place by relatively weak A-T and U-A base pairs (step 7 in Figure 6–11A). As we shall see, the folding of RNA into specific structures affects many steps in decoding the genome.

Bacterial Transcription Start and Stop Signals Are Heterogeneous in Nucleotide Sequence

As we have just seen, the processes of transcription initiation and termination involve a complicated series of structural transitions in protein, DNA, and RNA molecules. The signals encoded in DNA that specify these transitions are often difficult for researchers to recognize. Indeed, a comparison of many different bacterial promoters reveals a surprising degree of variation. Nevertheless, they all contain related sequences, reflecting aspects of the DNA that are recognized

MBOC7_ptr_ch06_321-396.indd 329 02/12/21 2:16 PM

directly by the σ factor. These common features are often summarized in the form of a *consensus sequence* (Figure 6-12). A **consensus nucleotide sequence** is derived by comparing many sequences with the same basic function and tallying up the most common nucleotides found at each position. It therefore serves as a summary or "average" of a large number of individual nucleotide sequences. A more accurate way of displaying the range of DNA sequences recognized by a protein is through the use of a *sequence logo*, which reveals the relative frequencies of each nucleotide at each position (Figure 6-12C).

The DNA sequences of individual bacterial promoters differ in ways that determine their strength, that is, the number of initiation events per unit time. Evolutionary processes have fine-tuned each to initiate as often as necessary and have thereby created a wide spectrum of promoter strengths. Promoters for genes that code for abundant proteins are much stronger than those associated with genes that encode rare proteins, and the nucleotide sequences of their promoters are responsible for these differences.

Like bacterial promoters, transcription terminators also have a wide range of sequences, with the potential to form a simple hairpin RNA structure being the most important common feature. Because an almost unlimited number of nucleotide sequences have this potential, terminator sequences are even more heterogeneous than promoter sequences.

We have discussed bacterial promoters and terminators in some detail to illustrate an important point regarding the analysis of genome sequences. Although we know a great deal about bacterial promoters and terminators and can construct "average" sequences that summarize their most salient features, their variation in nucleotide sequence makes it difficult to definitively locate them simply by

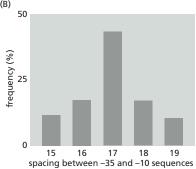

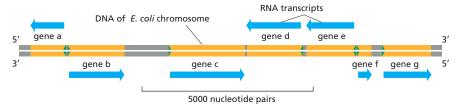

Figure 6-12 Consensus nucleotide sequence and sequence logo for the major class of Escherichia coli promoters. (A) On the basis of a comparison of 300 promoters, the frequencies of each of the four nucleotides at each position in the promoter are given. The consensus sequence, shown directly below the histogram, reflects the most common nucleotide found at each position in the collection of promoters. These promoters are characterized by two hexameric DNA sequences—the -35 sequence and the -10 sequence. named for their approximate location relative to the start point of transcription (designated +1). The sequence of nucleotides between the -35 and -10 hexamers shows little similarity among promoters but the spacing matters. For convenience, the nucleotide sequence of a single strand of DNA is shown; in reality, promoters are double-stranded DNA. The nucleotides shown in the figure are recognized by σ factor, a subunit of the RNA polymerase holoenzyme. (B) The distribution of spacing between the -35 and -10 hexamers found in E. coli promoters. (C) A sequence logo displaying the same information as in panel A. Here, the height of each letter is proportional to the frequency at which that base occurs at that position across a wide variety of promoter sequences. The total height of all the letters at each position is proportional to the information content (expressed in bits) at that position. For example, the total information content of a position that can tolerate several different bases is small (see the last three bases of the -35 sequences) but statistically greater than random.

MBOC7_ptr_ch06_321-396.indd 330 02/12/21 2:16 PM

analysis of the nucleotide sequence of a genome. It is even more difficult to locate analogous sequences in eukaryotic genomes, due in part to the excess DNA carried in these genomes. Often we need additional information, some of it from direct experimentation, to locate and accurately interpret the short DNA signals in genomes.

As shown in Figure 6-12, promoter sequences are asymmetric, ensuring that RNA polymerase can bind in only one orientation. Because the polymerase can synthesize RNA only in the 5'-to-3' direction, the promoter orientation specifies the strand to be used as a template. Genome sequences reveal that the DNA strand that is used as the template for RNA synthesis varies from gene to gene, depending on the orientation of the promoter (Figure 6-13).

Having considered transcription in bacteria, we now turn to the situation in eukaryotes, where the synthesis of RNA molecules is a much more elaborate affair.

Transcription Initiation in Eukaryotes Requires Many Proteins

In contrast to bacteria, which contain a single type of RNA polymerase, eukaryotic nuclei have three: RNA polymerase I, RNA polymerase II, and RNA polymerase III. The three polymerases are structurally similar to one another and share some common subunits, but they transcribe different categories of genes (Table 6-2). RNA polymerases I and III transcribe the genes encoding transfer RNA, ribosomal RNA, and various small RNAs. RNA polymerase II transcribes most genes, including all those that encode proteins, and our subsequent discussion therefore focuses on this enzyme.

Eukaryotic RNA polymerase II has many structural similarities to bacterial RNA polymerase (Figure 6–14). But there are several important differences in the way in which the bacterial and eukaryotic enzymes function, two of which concern us immediately.

- 1. While bacterial RNA polymerase requires only a single transcription-initiation factor (σ) to begin transcription, eukaryotic RNA polymerases require many such factors, collectively called the *general transcription factors*.
- 2. Eukaryotic transcription initiation must take place on DNA that is packaged into nucleosomes and higher-order forms of chromatin structure (described in Chapter 4), features that are absent from bacterial chromosomes.

TABLE 6-2 The Three RNA Polymerases in Eukaryotic Cells				
Type of polymerase	Genes transcribed			
RNA polymerase I	5.8S, 18S, and 28S rRNA genes			
RNA polymerase II	All protein-coding genes, plus snoRNA genes, miRNA genes, siRNA genes, lncRNA genes, and most snRNA genes			
RNA polymerase III	tRNA genes, 5S rRNA genes, some snRNA genes, and genes for other small RNAs			
The rRNAs were named according to their "S" values, which refer to their rate of sedimentation in an ultracentrifuge. The larger the S value, the larger the rRNA.				

Figure 6-13 Directions of transcription along a short portion of a bacterial chromosome. Some genes are transcribed using one DNA strand as a template, while others are transcribed using the other DNA strand. The direction of transcription is determined by the orientation of the promoter at the beginning of each gene (green arrowheads). This diagram shows approximately 0.2% (9000 base pairs) of the E. coli chromosome. The genes transcribed from left to right use the bottom DNA strand as the template; those transcribed from right to left use the top strand as the template. DNA that is not transcribed is indicated in gray.

MBOC7_ptr_ch06_321-396.indd 331 02/12/21 2:16 PM

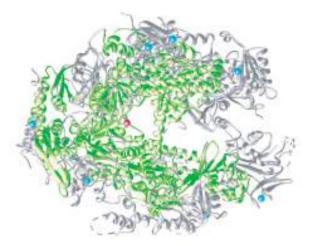

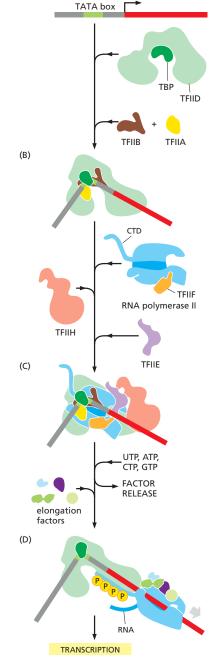

Figure 6–14 Structural similarity between a bacterial RNA polymerase and a eukaryotic RNA polymerase II. Regions of the two RNA polymerases that have similar structures are indicated in *green*. The eukaryotic polymerase is larger than the bacterial enzyme (12 subunits instead of 5), and some of the additional regions are shown in *gray*. The *red sphere* represents the Mg atom present at the active site, where polymerization takes place, while the *blue spheres* denote Zn atoms that serve as structural components. The RNA polymerases in all modern-day cells (bacteria, archaea, and eukaryotes) are closely related, indicating that the basic features of the enzyme were in place before the divergence of the three major branches of life. (Courtesy of P. Cramer and R. Kornberg.)

To Initiate Transcription, RNA Polymerase II Requires a Set of General Transcription Factors

The **general transcription factors** help to position eukaryotic RNA polymerase correctly at the promoter, aid in pulling apart the two strands of DNA to allow transcription to begin, and release RNA polymerase from the promoter to start its elongation mode. The proteins are "general" because they are needed at nearly all promoters used by RNA polymerase II. They consist of a set of interacting proteins denoted arbitrarily as TFIIA, TFIIB, and so on (TFII standing for transcription factor for polymerase II). In a broad sense, the eukaryotic general transcription factors carry out functions that are equivalent to those of the σ factor in bacteria.

Figure 6-15 illustrates how the general transcription factors assemble at promoters used by RNA polymerase II, and **Table 6-3** summarizes their activities. The assembly process begins when TFIID binds to a short double-helical DNA sequence primarily composed of T and A nucleotides. For this reason, this sequence is known as the TATA sequence, or **TATA box**, and the subunit of TFIID that recognizes it is called TBP (for TATA-binding protein). The TATA box is typically located about 30 nucleotides upstream from the transcription start site. It is not the only DNA sequence that signals the start of transcription (**Figure 6-16**), but for many polymerase II promoters it is the most important. The binding of

Figure 6–15 Initiation of transcription of a eukaryotic gene by RNA polymerase II. To begin transcription, RNA polymerase requires several general transcription factors. (A) Many promoters contain a DNA sequence called the TATA box, which, in humans, is located about 30 nucleotides away from the site at which transcription is initiated. (B) Through its subunit TBP, TFIID recognizes and binds the TATA box, which then enables the adjacent binding of TFIIB and TFIIA. (C) The RNA polymerase and the rest of the general transcription factors assemble at the promoter. (D) TFIIH then uses energy from ATP hydrolysis to pry apart the DNA double helix at the transcription start point, locally exposing the template strand. TFIIH also phosphorylates the long C-terminal polypeptide tail of RNA polymerase II, also called the C-terminal domain (CTD). This causes the polymerase to be released from the general factors and begin the elongation phase of transcription. For most genes, TFIID remains bound at the promoter whereas most of the other general transcription factors are released when the polymerase begins transcribing.

start of transcription

MBOC7_ptr_ch06_321-396.indd 332 02/12/21 2:16 PM

TABLE 6-3 The General Transcription Factors Needed for Transcription Initiation by Eukaryotic RNA Polymerase II				
Name	Number of subunits	Roles in transition initiation		
TFIID	12	Recognizes TATA box and other DNA sequences near the transcription start point		
TFIIB	1	Recognizes BRE element in promoters; accurately positions RNA polymerase at the start site of transcription		
TFIIA	2	Not required in all promoters; stabilizes binding of TFIID		
TFIIF	3	Stabilizes RNA polymerase interaction with TFIIB; helps attract TFIIE and TFIIH		
TFIIE	2	Attracts and regulates TFIIH		
TFIIH	10	Unwinds DNA at the transcription start point, phosphorylates Ser5 of the RNA polymerase C-terminal domain (CTD); releases RNA polymerase from the promoter		
TFIID is composed of TBP and 11 additional subunits called TAFs (TBP-associated factors).				

TFIID causes a large distortion in the DNA of the TATA box (Figure 6–17). This distortion is thought to serve as a physical landmark for the location of an active promoter in the midst of a very large genome, and it brings DNA sequences on both sides of the distortion closer together to allow for subsequent protein assembly steps. The additional general transcription factors then assemble, along with RNA polymerase II, to form a complete *transcription initiation complex* (see Figure 6–15). The most complicated of the general transcription factors is TFIIH (shown in *pink*). Consisting of 10 subunits, it is nearly as large as RNA polymerase II itself and, as we shall see shortly, performs several enzymatic steps needed for the initiation of transcription.

After forming a transcription initiation complex on the promoter DNA, RNA polymerase II must gain access to the template strand at the transcription start point. TFIIH makes this step possible by hydrolyzing ATP and pulling apart the DNA strands at the start site, thereby exposing the template strand. Next, RNA polymerase II, like the bacterial polymerase, remains at the promoter synthesizing short lengths of RNA until it undergoes a series of conformational changes that allow it to move away from the promoter and enter the elongation phase of transcription. A key step in this transition is the addition of phosphate groups to the "tail" of the RNA polymerase (known as the CTD, or C-terminal domain). In

element	consensus sequence	general transcription factor
BRE	G/C G/C G/A C G C C	TFIIB
TATA	T A T A A/T A A/T	TBP subunit of TFIID

DPE	A/G G A/T C G T G	TFIID

Figure 6–16 Consensus sequences found in the vicinity of eukaryotic RNA polymerase II start points. The name given to each consensus sequence (first column) and the general transcription factor that recognizes it (last column) are indicated. N indicates any nucleotide, and two nucleotides separated by a slash indicate an equal probability of either nucleotide at the indicated position. In reality, each consensus sequence is a shorthand representation of a histogram similar to that of Figure 6–12.

For most RNA polymerase II transcription start points, only two or three of the four sequences are present. For example, many polymerase II promoters have a TATA box sequence, but those that do not typically have a "strong" INR sequence. Although most of the DNA sequences that influence transcription initiation are located upstream of the transcription start point, a few, such as the DPE shown in the figure, are located within the transcribed region.

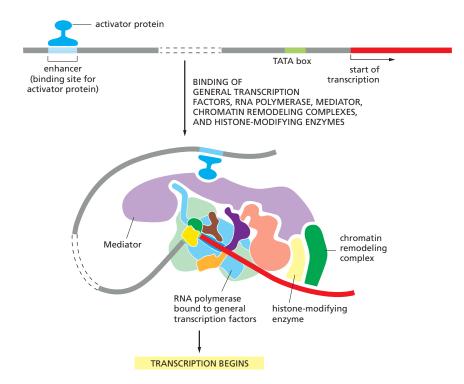

MBOC7_ptr_ch06_321-396.indd 333 02/12/21 2:16 PM

humans, the CTD consists of 52 tandem repeats of a seven-amino-acid sequence, which extend from the RNA polymerase core structure. During transcription initiation, the serines located at the fifth position in each repeat sequence (Ser5) are phosphorylated by TFIIH, which contains a protein kinase in one of its subunits. Triggered by these phosphorylations, the polymerase disengages from the cluster of general transcription factors (see Figure 6–15D). During this process, it undergoes a series of conformational changes that tighten its interaction with DNA, and it acquires new proteins that allow it to transcribe for long distances, in some cases for many hours, without dissociating from DNA.

Once the polymerase II has begun elongating the RNA transcript, most of the general transcription factors are released from the DNA so that they are available to initiate another round of transcription with a new RNA polymerase molecule. As we see shortly, the phosphorylation of the tail of RNA polymerase II has an additional function: it causes components of the RNA-processing machinery to load onto the polymerase and thereby be positioned to modify the newly transcribed RNA as it emerges from the polymerase.

In Eukaryotes, Transcription Initiation Also Requires Activator, Mediator, and Chromatin-modifying Proteins

The model for transcription initiation just described is based on experiments performed *in vitro* using purified proteins and DNA. However, as discussed in Chapter 4, DNA in eukaryotic cells is packaged into nucleosomes, which are further arranged in higher-order chromatin structures. As a result, transcription initiation in a eukaryotic cell is more complex and requires more proteins than it does on purified DNA. First, regulatory proteins known as *transcriptional activators* must bind to specific sequences in DNA (called *enhancers*) to help attract the general transcription factors and RNA polymerase II to the start point of transcription (**Figure 6–18**). We discuss the role of these activators in Chapter 7, because they are one of the main ways in which cells regulate expression of their genes. Here we simply note that their presence on DNA is required for transcription initiation in a eukaryotic cell. Second, eukaryotic transcription initiation *in vivo* requires the presence of a large protein complex known as *Mediator*, which

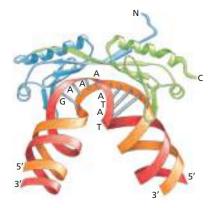

Figure 6–17 Three-dimensional structure of TBP (TATA-binding protein) bound to DNA. The TBP is the subunit of the general transcription factor TFIID that is responsible for recognizing and binding the TATA box sequence in the DNA. The unique DNA bending caused by TBP—kinks in the double helix separated by partly unwound DNA—is thought to serve as a landmark that helps to attract the other general transcription factors (Movie 6.4). TBP is a single polypeptide chain that is folded into two very similar domains (blue and green). (Adapted from J.L. Kim et al., Nature 365:520–527, 1993.)

Figure 6–18 Transcription initiation by RNA polymerase II in a eukaryotic cell.

Transcription initiation in vivo requires the presence of transcription activator proteins. As described in Chapter 7, these proteins bind to short, specific sequences in DNA that are located in regulatory regions called enhancers. Although only one activator is shown here (in blue), a typical eukaryotic gene utilizes many DNA-bound transcription activator proteins, which act together to determine that gene's rate and pattern of transcription across different cell types. Often acting from a distance of many thousand nucleotide pairs along DNA (indicated by the dashes), these proteins help RNA polymerase, the general transcription factors, and Mediator all to assemble at the promoter. In addition, ATP-dependent chromatin remodeling complexes and histone-modifying enzymes are needed at most genes. One of the main roles of Mediator is to coordinate the assembly of all these proteins at the promoter so that transcription can begin. As discussed in Chapter 4, the "default" state of eukaryotic DNA is to be packaged into nucleosomes and higher-order chromatin structures; for simplicity, these are not shown in this figure.

MBOC7_ptr_ch06_321-396.indd 334 02/12/21 2:16 PM

allows the activator proteins to communicate properly with the polymerase II and with the general transcription factors. Mediator also correctly positions TFIIH near the tail of RNA polymerase, facilitating phosphorylation of the tail and the consequent release of the polymerase from the promoter to begin synthesizing RNA. Finally, transcription initiation in a eukaryotic cell typically requires the recruitment of chromatin-modifying enzymes, including chromatin remodeling complexes and histone-modifying enzymes. As discussed in Chapter 4, both types of enzymes can increase access to the DNA in chromatin, and by doing so they facilitate the assembly of the transcription initiation machinery onto DNA.

To summarize, as illustrated schematically in Figure 6-18, many proteins (well over 100 individual subunits) must assemble at the start point of transcription to initiate transcription in a eukaryotic cell. We shall return to some of these proteins—especially transcription activator proteins, chromatin remodeling complexes, and histone-modifying enzymes—in the following chapter, where we discuss how eukaryotic cells regulate the process of transcription initiation.

Transcription Elongation in Eukaryotes Requires Accessory Proteins

Once RNA polymerase has initiated transcription, it moves jerkily, pausing at some DNA sequences and rapidly transcribing through others. Elongating RNA polymerases, both bacterial and eukaryotic, are associated with a series of *elongation factors*, proteins that decrease the likelihood that RNA polymerase will dissociate before it reaches the end of a gene. These factors typically associate with RNA polymerase shortly after initiation, and they help the polymerase move both through nucleosomes (**Figure 6–19**) and through the wide variety of different DNA sequences that are found in genes.

We will see in the next chapter that, like the process of transcription initiation, transcription elongation can be regulated by the cell; more specifically, we will see that at many human genes, RNA polymerase pauses shortly after it initiates transcription. This pause can last from several seconds to many hours, and the cell controls the duration of this pause as part of gene regulatory processes.

As RNA polymerase II moves along a gene, some of the enzymes bound to it modify the histones, leaving behind a record of where the polymerase has been. Although it is not clear exactly how the cell uses this information, it may aid in transcribing a gene over and over again once it has become active for the first time.

Transcription Creates Superhelical Tension

Nucleosomes are not the only impediment to elongating RNA polymerases, and in this section, we describe an entirely different type of barrier, one that applies to both bacterial and eukaryotic polymerases. To introduce this issue, we need first to consider a subtle property inherent in the DNA double helix called DNA supercoiling. **DNA supercoiling** is the name given to a conformation that DNA

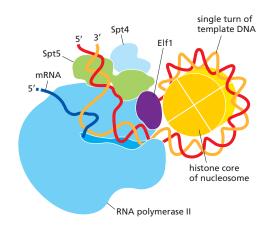

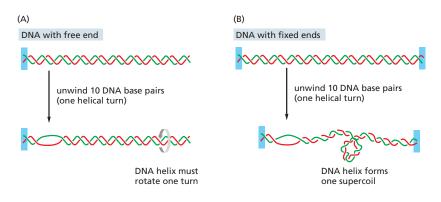

Figure 6-19 Structure of an RNA polymerase II transcribing through a nucleosome. In the structure diagrammed here, which was determined by cryoelectron microscopy, the polymerase has moved about halfway through the DNA of the nucleosome, leaving only one of the two loops of duplex DNA still bound to the histone core. The polymerase is shown in blue, associated with three elongation factors (Spt4, Spt5, and Elf1) that help the polymerase transcribe through nucleosomes. These factors act in several ways: they form a wedge to pry the DNA away from the histone core as the polymerase moves forward; they directly destabilize histone-DNA interactions by pushing a positively charged surface ahead of the RNA polymerase; and they reduce the intrinsic "stickiness" of RNA polymerase for nucleosomes. In addition to these factors, eukaryotic transcription is typically aided by ATP-dependent chromatin remodeling complexes that seek out and rescue the occasional stalled polymerase, as well as by histone chaperones that can partially disassemble nucleosomes in front of a moving RNA polymerase and reassemble them behind. (Based on PDB code 6IR9.)

MBOC7_ptr_ch06_321-396.indd 335 02/12/21 2:16 PM

can adopt in response to superhelical tension. Alternatively, the creation of loops or coils in a double-helical DNA molecule will produce such tension.

Figure 6-20 illustrates why. There are approximately 10 nucleotide pairs for every helical turn in a DNA double helix. Imagine a helix whose two ends are fixed with respect to each other (as they are in a DNA circle, such as a bacterial chromosome, or in a tightly clamped loop, as can exist in eukaryotic chromosomes). In this case, one large DNA supercoil will form to compensate for each 10 nucleotide pairs that are opened (unwound). The formation of this supercoil is energetically favorable because it restores a normal helical twist to the base-paired regions that remain, which would otherwise become overwound because of the fixed ends.

RNA polymerase creates superhelical tension as it moves along a stretch of DNA that is anchored at its ends. As illustrated in Figure 6–20C, if the polymerase is not free to rotate rapidly (and such rotation is unlikely given the size of RNA polymerases and their attached transcripts), a moving polymerase will generate positive superhelical tension in the DNA in front of it and negative helical tension

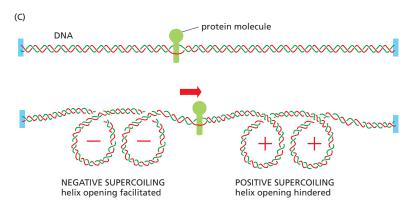

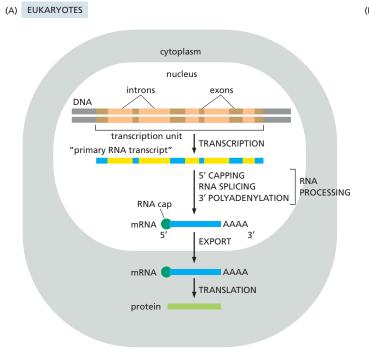

Figure 6-20 Superhelical tension in DNA causes DNA supercoiling. (A) For a DNA molecule with one free end (or a break in one strand that serves as a swivel), the DNA double helix rotates by one turn for every 10 nucleotide pairs opened. (B) If rotation is prevented, superhelical tension is introduced into the DNA by helix opening. In the example shown, the DNA helix contains 10 helical turns, one of which is opened. One way of accommodating the tension created would be to increase the helical twist from 10 to 11 nucleotide pairs per turn in the double helix that remains. The DNA helix, however, resists such a deformation in a springlike fashion, preferring to relieve the superhelical tension by bending into supercoiled loops. As a result, one DNA supercoil forms in the DNA double helix for every 10 nucleotide pairs opened. The supercoil formed in this case is a positive supercoil. (C) Supercoiling of DNA is induced by a protein tracking through the DNA double helix. The two ends of the DNA shown here are unable to rotate freely relative to each other, and the protein molecule is assumed also to be prevented from rotating freely as it moves. Under these conditions, the movement of the protein causes an excess of helical turns to accumulate in the DNA helix ahead of the protein (inducing positive supercoils) and a deficit of helical turns to arise in the DNA behind the protein (inducing negative supercoils), as shown. Because locally pulling apart the two strands of the double helix relieves the tension from negative supercoils, it is easier to do behind the moving protein than ahead of it.

MBOC7_ptr_ch06_321-396.indd 336 02/12/21 2:16 PM

behind it. If this tension is not relieved, the polymerase will grind to a halt because further unwinding requires more energy than the transcription process can provide. For eukaryotes, the mild buildup of tension is thought to provide a bonus: the positive superhelical tension ahead of the polymerase facilitates the partial unwrapping of the DNA in nucleosomes, inasmuch as the release of DNA from the histone core helps to relax this tension. The tension can also be relieved by DNA topoisomerase enzymes, as we saw in the previous chapter for the similar kind of tension generated by DNA polymerases during DNA replication (see Figure 5–21).

In bacteria (but not eukaryotes), a specialized topoisomerase called *DNA gyrase* uses the energy of ATP hydrolysis to pump supercoils continually into the DNA, thereby maintaining the DNA under constant tension. These are *negative supercoils*, having the opposite handedness from the *positive supercoils* that form when a region of DNA helix opens (see Figure 6–20B). Whenever a region of helix opens, it removes these negative supercoils from bacterial DNA, reducing the superhelical tension. DNA gyrase therefore makes the opening of the DNA helix in bacteria energetically favorable compared with helix opening in DNA that is not supercoiled. For this reason, it facilitates those genetic processes in bacteria, such as the initiation of transcription by bacterial RNA polymerase, that require helix opening (see Figure 6–11).

Transcription Elongation in Eukaryotes Is Tightly Coupled to RNA Processing

We saw earlier that bacterial mRNAs are synthesized by the RNA polymerase starting and stopping at specific spots on the genome. The situation in eukaryotes is substantially different. In particular, transcription is only the first of several steps needed to produce a mature mRNA molecule. Other critical steps are the covalent modification of the ends of the RNA and the removal of *intron sequences* that are discarded from the middle of the RNA transcript by the process of *RNA splicing* (Figure 6-21). As we shall see, RNA splicing not only joins together different portions of an RNA transcript to eliminate the intron sequences; it also provides eukaryotes with the ability to synthesize several related but different proteins from the same gene.

(B) BACTERIA

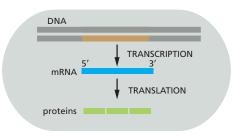

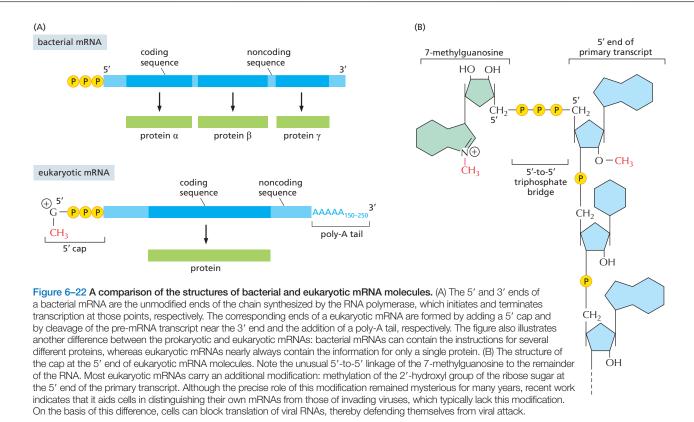

Figure 6-21 Comparison of the steps leading from gene to protein in eukaryotes and bacteria. The final amount of a protein in the cell depends on the efficiency of each step and on the rates of degradation of the RNA and protein molecules. (A) In eukaryotic cells, the mRNA molecule resulting from transcription contains both coding (exon) and noncoding (intron) sequences. Before it can be translated into protein, the two ends of the RNA are modified, the introns are removed by an enzymatically catalyzed RNA splicing reaction, and the resulting mRNA is transported from the nucleus to the cytoplasm. For convenience, the steps in this figure are depicted as occurring one at a time; in reality, many occur concurrently. For example, the RNA cap is added and splicing begins before transcription has been completed. Because of the coupling between transcription and RNA processing, intact primary transcripts—the full-length RNAs that would, in theory, be produced if no processing had occurred—are found only rarely. (B) In bacteria, the production of mRNA is much simpler. The 5' end of an mRNA molecule is produced by the initiation of transcription, and the 3' end is produced by the termination of transcription. Because bacteria lack a nucleus, transcription and translation take place in a common compartment, and the translation of a bacterial mRNA often begins before its synthesis has been completed. As indicated, a single bacterial mRNA typically produces several different proteins, another feature that distinguishes eukarvotes from bacteria.

MBOC7_ptr_ch06_321-396.indd 337 02/12/21 2:16 PM

Both ends of eukaryotic mRNAs are modified: by *capping* on the 5' end and by *polyadenylation* of the 3' end (**Figure 6-22**). These special ends allow the cell to assess whether both ends of an mRNA molecule are present (and if the message is therefore intact) before it exports the RNA from the nucleus and translates it into protein.

A simple mechanism has evolved to couple all of the above RNA-processing steps to transcription elongation. As discussed previously, a key step in transcription initiation by RNA polymerase II is the phosphorylation of the RNA polymerase II tail, also called the CTD (C-terminal domain). This phosphorylation, which proceeds gradually as the RNA polymerase initiates transcription and moves along the DNA, not only helps to dissociate the RNA polymerase II from other proteins present at the start point of transcription but also allows a new set of proteins to associate with the RNA polymerase tail, which function in transcription elongation and RNA processing, as we discuss in the following sections. Some of the processing proteins are thought to "hop" from the polymerase tail onto the nascent RNA molecule to begin their processing reactions as soon as this RNA emerges from the RNA polymerase. Thus, we can view RNA polymerase II in its elongation mode as an RNA factory that not only moves along the DNA synthesizing an RNA molecule but also processes the RNA that it produces (Figure 6-23). Fully extended, the CTD is nearly 10 times longer than the remainder of the RNA polymerase. As a flexible protein domain, it serves as a scaffold or tether, holding a variety of proteins close by so that they can rapidly act when needed. This scaffolding strategy, which greatly speeds up the overall rate of a series of consecutive reactions, is one that is commonly utilized in the cell (see Figure 3-76).

RNA Capping Is the First Modification of Eukaryotic Pre-mRNAs

As soon as RNA polymerase II has produced about 20 nucleotides of RNA, the 5' end of the new RNA molecule is modified by addition of a cap that consists of a modified guanine nucleotide (see Figure 6-22B). Three enzymes, acting in

MBOC7_ptr_ch06_321-396.indd 338 02/12/21 2:16 PM

Figure 6–23 Eukaryotic RNA polymerase II as an RNA synthesis and processing machine. As the polymerase transcribes DNA into RNA, it carries RNA-processing proteins on its tail that are transferred to the nascent RNA at the appropriate time. The tail contains 52 tandem repeats of a seven-amino-acid sequence, and there are two serines in each repeat. The capping proteins first bind to the RNA polymerase tail when it is phosphorylated on Ser5 of the heptad repeats late in the process of transcription intitation (see Figure 6–15). This strategy ensures that the RNA molecule is efficiently capped as soon as its 5′ end emerges from the RNA polymerase. As the polymerase continues transcribing, its tail is extensively phosphorylated on the Ser2 positions by a kinase associated with the elongating polymerase and is eventually dephosphorylated at Ser5 positions. These further modifications attract splicing and 3′-end processing proteins to the moving polymerase, positioning them to act on the newly synthesized RNA as it emerges from the RNA polymerase. There are many RNA-processing enzymes, and not all travel with the polymerase. In RNA splicing, for example, the tail carries only a few critical components; once bound to an emerging RNA molecule, they serve as a nucleation site for the remaining components.

When RNA polymerase II finishes transcribing a gene, it is released from DNA, and protein phosphatases remove the phosphates on its tail so that it can reinitiate transcription. Only the fully dephosphorylated form of RNA polymerase II is competent to begin RNA synthesis at a promoter.

succession, perform the capping reaction: a phosphatase removes a phosphate from the triphosphate left at the 5' end of the nascent RNA molecule, a guanyl transferase adds a GMP in a reverse linkage (5'-to-5' instead of 5'-to-3') to the 5' diphosphate just produced, and a methyl transferase adds a methyl group to the guanosine (**Figure 6-24**). Because all three enzymes bind to the RNA polymerase tail phosphorylated at the Ser5 position—the modification added by TFIIH during transcription initiation—they are poised to modify the 5' end of the nascent transcript as soon as it emerges from the polymerase.

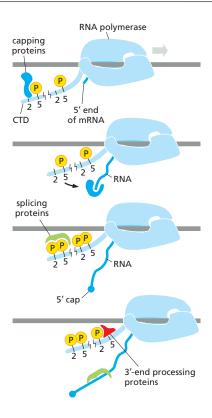

The 7-methylguanosine cap signifies the 5' end of eukaryotic mRNAs, and this landmark helps the cell to distinguish mRNAs from the other types of RNA molecules present in the cell. For example, RNA polymerases I and III produce uncapped RNAs during transcription, in part because these polymerases lack a CTD. In the nucleus, the cap binds a protein complex called CBC (cap-binding complex), which, as we discuss in subsequent sections, helps a future mRNA to be further processed and exported. The 5' cap also has an important role in the translation of mRNAs in the cytosol, as we discuss later in the chapter.

Although the vast majority of eukaryotic mRNAs possess a 7-methylguanosine cap at their 5' ends, an alternative type of cap is found on some mRNAs, specifically a nicotinamide adenine dinucleotide phosphate (NADP⁺). We saw earlier in Chapter 2 that NADP⁺ is an important cofactor for many biochemical reactions, and it is added to certain mRNAs by RNA polymerase itself as the first nucleotide when a new mRNA molecule chain is begun. The role of this particular type of mRNA cap is not known with certainty, but one hypothesis holds that it provides a way for the cell to link the expression of some of its genes to its overall metabolic "health."

RNA Splicing Removes Intron Sequences from Newly Transcribed Pre-mRNAs

As discussed in Chapter 4, the protein-coding sequences of eukaryotic genes are typically interrupted by noncoding intervening sequences (introns). Discovered in 1977, this feature of eukaryotic genes came as a surprise to scientists, who had been, until that time, familiar only with bacterial genes, which consist of a continuous stretch of coding DNA that is directly transcribed into mRNA. In marked contrast, eukaryotic genes were found to be broken up into small pieces of coding sequence (*expressed sequences*, or **exons**) interspersed with much longer

Figure 6–24 The reactions that cap the 5' end of each RNA molecule synthesized by RNA polymerase II. The final cap contains a novel 5'-to-5' linkage between the positively charged 7-methylguanosine residue and the 5' end of the RNA transcript (see Figure 6–22B). The letter N represents any one of the four ribonucleotides, although the nucleotide that starts an RNA chain is usually a purine (an A or a G). (After A.J. Shatkin, *Bioessays* 7:275–277, 1987. intervening sequences, or **introns**; thus, the coding portion of a eukaryotic gene is often only a small fraction of the length of the gene (**Figure 6–25**).

Both intron and exon sequences are transcribed into RNA. The intron sequences are removed from the newly synthesized RNA through the process of RNA splicing. The vast majority of RNA splicing that takes place in cells functions in the production of mRNA, and our discussion of splicing focuses on this so-called precursor-mRNA (or pre-mRNA) splicing. Only after 5'- and 3'-end processing and splicing have taken place is an RNA transcript called an mRNA molecule.

Each splicing event removes one intron, proceeding through two sequential phosphoryl-transfer reactions known as transesterifications; these join two exons together while removing the intron between them as a "lariat" (Figure 6–26). The machinery that catalyzes pre-mRNA splicing is complex, consisting of five additional RNA molecules and several hundred proteins, and it hydrolyzes many ATP molecules per splicing event. This complexity ensures that splicing is accurate, while at the same time being flexible enough to deal with the enormous variety of introns found in a typical eukaryotic cell. On average, there are 11 introns in each of the approximately 20,000 human protein-coding genes, so the cell devotes considerable resources to this step in gene expression.

Although it seems wasteful to first produce and then remove large numbers of introns from an RNA transcript, this process provides an advantage to the cell. In many organisms, the transcript of a given gene can be spliced in more than one way, and this allows the same gene to produce a set of different but related proteins (Figure 6–27). It has been proposed that 95% of human gene transcripts are spliced in more than one way, but this is almost certainly an overestimate: many

Figure 6–25 Structure of two human genes showing the arrangement of exons and introns. (A) The relatively small β -globin gene, which encodes a subunit of the oxygen-carrying protein hemoglobin, contains 3 exons (see also Figure 4–9). (B) The much larger Factor VIII gene contains 26 exons; it codes for a protein (Factor VIII) that functions in the blood-clotting pathway. The most prevalent form of hemophilia results from mutations in this gene.

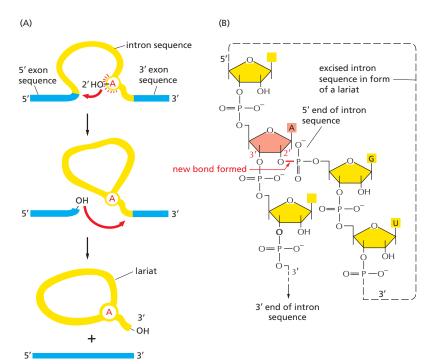

Figure 6-26 The pre-mRNA splicing reaction. (A) In the first step, a specific adenine nucleotide in the intron sequence (indicated in red) attacks the 5' splice site and cuts the sugar-phosphate backbone of the RNA at this point. The cut 5' end of the intron becomes covalently linked to the adenine nucleotide, as shown in detail in (B), thereby creating a loop in the RNA molecule. The released free 3'-OH end of the exon sequence then reacts with the start of the next exon sequence, joining the two exons together and releasing the intron sequence in the shape of a lariat. The two exon sequences thereby become joined into a continuous coding sequence. The released intron sequence is discarded. eventually being broken down into single nucleotides, which are recycled.

MBOC7_ptr_ch06_321-396.indd 340 02/12/21 2:16 PM

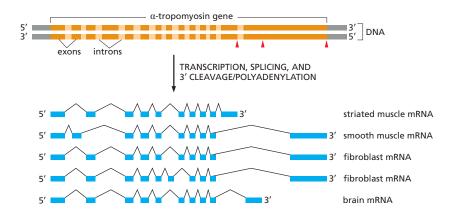

Figure 6-27 Alternative splicing of the α -tropomyosin gene from rat. $\alpha ext{-Tropomyosin}$ is a coiled-coil protein (see Figure 3-8) involved in the regulation of contraction in muscle cells. Its initial RNA transcript can be spliced in different ways, as indicated in the figure, to produce distinct mRNAs, which then give rise to variant proteins. Some of the splicing patterns are specific for certain types of cells. For example, the α -tropomyosin made in striated muscle is different from that made from the same gene in smooth muscle. The arrowheads in the top part of the figure mark the sites where cleavage and poly-A addition form the 3' ends of the mature mRNAs.

of the splicing products that can be detected are the results of splicing errors and do not produce functional proteins. Nonetheless, *alternative splicing* is a key feature of gene expression in many organisms, and we shall return to this subject later, after we describe the cellular machinery that performs the basic reaction.

Nucleotide Sequences Signal Where Splicing Occurs

The mechanism of pre-mRNA splicing shown in Figure 6–26 requires that the splicing machinery recognize three portions of the precursor RNA molecule: the 5' splice site, the 3' splice site, and the branch point in the intron sequence that forms the base of the excised lariat. Not surprisingly, each site has a consensus nucleotide sequence that is similar from intron to intron and provides the cell with cues for where splicing is to take place (Figure 6–28). These consensus sequences are relatively short and can accommodate extensive sequence variability, and as we shall see shortly, the cell uses additional types of information to ultimately choose exactly where, on each RNA molecule, splicing is to take place.

RNA Splicing Is Performed by the Spliceosome

Unlike the other steps in mRNA production we have discussed, key steps in RNA splicing are performed by RNA molecules rather than proteins. Specialized RNA molecules recognize the nucleotide sequences that specify where splicing is to occur and also form the active site that catalyzes the chemistry of splicing. These RNA molecules are relatively short (less than 200 nucleotides each), and there are five of them, U1, U2, U4, U5, and U6. Known as snRNAs (small nuclear RNAs), each is complexed with at least seven protein subunits to form an *snRNP* (small nuclear ribonucleoprotein). These snRNPs form the core of the spliceosome, the large assembly of RNA and protein molecules that performs pre-mRNA splicing in the cell. Recognition of the 5' splice junction, the branch-point site, and the 3' splice junction is performed through base-pairing between the snRNAs and RNA sequences in the pre-mRNA substrate.

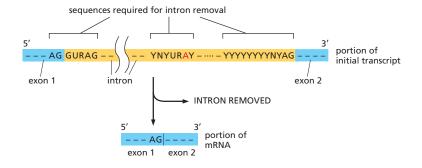

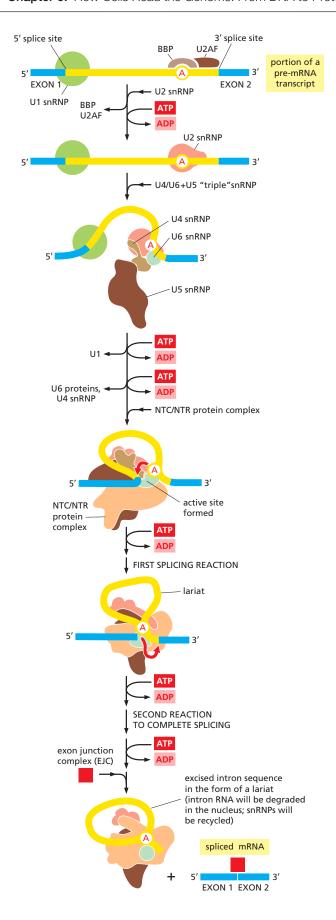

Figure 6-28 The consensus nucleotide sequences in an RNA molecule that signal the beginning and the end of most introns in humans. The three blocks of nucleotide sequences shown are required to remove an intron sequence Here A, G, U, and C are the standard RNA nucleotides; R stands for a purine (A or G); and Y stands for a pyrimidine (C or U). The A highlighted in red forms the branch point of the lariat produced by splicing (see Figure 6-26). Only the GU at the start of the intron and the AG at its end are invariant nucleotides in the splicing consensus sequences. Several different nucleotides can occupy the remaining positions, although the indicated nucleotides are preferred. Although the distances along the RNA between the three splicing consensus sequences are highly variable, the distance between the branch point and 3' splice junction is typically much shorter than the distance between the 5' splice junction and the branch point.

MBOC7_ptr_ch06_321-396.indd 341 02/12/21 2:16 PM

The U1 snRNP forms base pairs with the 5' splice junction. BBP (branch-point binding protein) recognizes the branch-point site and binds cooperatively with U2AF, which recognizes the polypyrimidine tract and the 3' splice junction (see Figure 6–28).

The U2 snRNP displaces BBP and U2AF and forms base pairs with the branch-point site consensus sequence.

The U4/U6+U5 "triple" snRNP enters the reaction. In this triple snRNP, the U4 and U6 snRNAs are held firmly together by base-pair interactions. Subsequent rearrangements break apart the U4/U6 base pairs, allowing U6 to displace U1 at the 5' splice junction and ejecting the U4 snRNP and some of the proteins of the U6 snRNP.

Addition of the NTC/NTR protein complex positions the snRNPs to form the active site of the spliceosome and brings the branch point in proximity to the 5' splice site.

Lariat formed. Additional rearrangements bring the two exon segments together and place them in the active site.

Spliced RNA is released. Spliceosome components recycled using ATP hydrolysis to "reset" them.

MBOC7_ptr_ch06_321-396.indd 342 02/12/21 2:16 PM

Figure 6–29 The pre-mRNA splicing mechanism. RNA splicing is catalyzed by an assembly of snRNPs (shown as colored shapes) plus other proteins (most of which are not shown), which together constitute the spliceosome. The spliceosome recognizes the splicing signals on a pre-mRNA molecule, brings the two ends of the intron together, and forms the active site that catalyzes the two covalent bond-making and -breaking steps required (see Figure 6–26A and Movie 6.5). As shown, nearly every step is accompanied by hydrolysis of a molecule of ATP, which prevents the reaction from stalling or moving backwards and, as discussed below, increases the accuracy of splicing. Although only six molecules of ATP are shown in this simplified diagram, some steps require more than one, and a total of eight ATPs are consumed in each splicing reaction. As indicated in the last step, a set of proteins called the exon junction complex (EJC) is retained on the spliced mRNA molecule; its subsequent role will be discussed shortly.

The spliceosome is a complex and dynamic machine. When studied *in vitro*, a few components of the spliceosome assemble on pre-mRNA and, as the splicing reaction proceeds, new components enter and those that have already performed their tasks are jettisoned (Figure 6-29). However, many scientists believe that, inside the cell, the spliceosome is a preexisting, loose assembly of all the components—capturing, splicing, and releasing RNA as a coordinated unit, and undergoing extensive rearrangements each time a splice is made.

The Spliceosome Uses ATP Hydrolysis to Produce a Complex Series of RNA–RNA Rearrangements

There are many unusual features of the splicing reaction compared to the typical catalytic processes in the cell introduced in Chapter 2. First, splicing seems grossly inefficient, requiring more than a hundred proteins, five RNA molecules, and the hydrolysis of eight molecules of ATP to produce a single splice. Many genes require multiple splicing events to produce a single functional mRNA molecule (more than 20 in the example in Figure 6–25B), and the process seems inordinately complex. Second, each splicing reaction requires that the catalytic site for the reaction be assembled *de novo* on each pre-mRNA molecule through a complex, multistep process. Third, as mentioned earlier, the catalytic site of the spliceosome (which catalyzes both steps of the splicing reaction) is formed by RNA molecules (the snRNAs) rather than by proteins (Figure 6–30), with the proteins required to correctly position these RNAs. In the final section of this chapter, we describe the structure and chemical properties of RNA molecules that allow them to act as catalysts, as well as the proposal that the RNA-based reaction mechanisms that exist today are "leftovers" from ancient, RNA-only biological systems.

How might we rationalize the unusual biochemical complexity of splicing compared to other steps in gene expression? As we discuss shortly, pre-mRNA splicing has evolved from a much simpler, purely RNA-based process, and its complexity may in part be an example of what some evolutionary biologists term "runaway bureaucracies," accruing more and more parts over time that are now required for the process without necessarily making it any better. We do know, however, that some of the complexity of pre-mRNA splicing provides advantages. Even though ATP hydrolysis is not required for the splicing reaction per se, the numerous ATP hydrolysis steps keep the reaction from stalling or running backwards and, as we will see shortly, they also increase the accuracy of pre-mRNA splicing.

Most of the spliceosome proteins that hydrolyze ATP use the released energy to break existing RNA-RNA interactions to allow the formation of new ones. These RNA-RNA rearrangements allow the splicing signals on the pre-mRNA to be examined several times during the course of splicing. For example, the U1 snRNP initially recognizes the 5' splice site through conventional base-pairing; as splicing proceeds, these base pairs are broken (using the energy of ATP hydrolysis) and U1 is replaced by U6 (see Figure 6–30A and B). Likewise, the branch point is "examined" twice, the first time by the branch-point binding protein and the second time by the U2 snRNP (see Figure 6–29). In this way, the spliceosome checks and rechecks the splicing signals before the active site for the two transesterification reactions forms (see Figure 6–30C), thereby increasing overall accuracy.

Note that both catalytic steps of the splicing reaction occur in the same active site (the second reaction is almost the reverse of the first). ATP-mediated

MBOC7_ptr_ch06_321-396.indd 343 02/12/21 2:16 PM

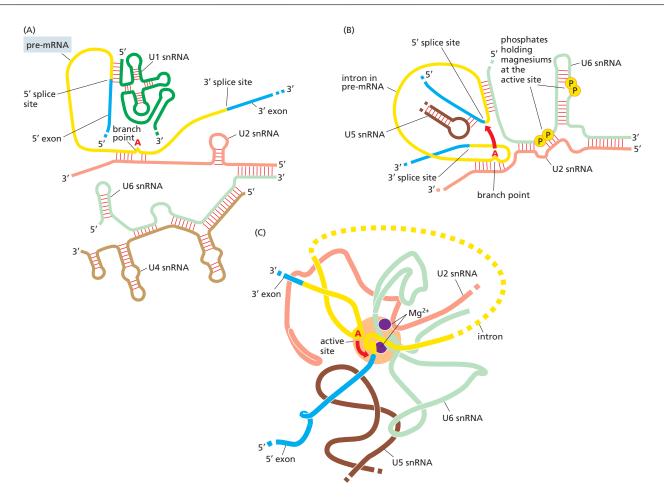

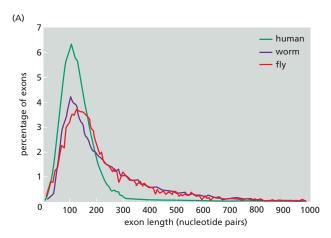

Figure 6–30 An example of an ATP hydrolysis–driven RNA–RNA rearrangement that occurs during splicing. Schematic diagram of the arrangement of RNA molecules before (A) and after (B) the active site has been formed for the two phosphoryl-transfer reactions. This rearrangement also brings the branch point and the 5' splice site together in preparation for the first reaction. The active site (which grasps the two magnesium ions needed for the chemistry of the reactions) is formed by U2 and U6. Several sequential ATP-dependent rearrangement steps are needed to convert the configuration in A to that in B. (C) The actual structure, determined by cryo-electron microscopy, of the RNA-based catalytic core of the spliceosome that was schematically illustrated in B. For simplicity, the proteins that surround the RNAs are not shown, even though their conformations are known. High-resolution structures have also been determined for most of the other spliceosome intermediates. (B, adapted from M.E. Wilkinson, C. Charenton, and K. Nagai, *Annu. Rev. Biochem.* 89:359–398, 2020. With permission from Annual Reviews.)

rearrangements are required between the two reactions to properly reposition the pre-mRNA for the second reaction, helping to ensure that splicing accidents occur only rarely.

A general process associated with ATP hydrolysis, called *kinetic proofreading*, further increases spliceosome accuracy. Because an incorrect, "off-target" base-pairing interaction will be weaker than the correct one, incorrect interactions will dissociate more rapidly than correct ones. Each ATP-mediated rearrangement of the spliceosome takes a finite amount of time, and this time delay will favor the correct choice, because off-target interactions will often dissociate during this time window, giving the correct interaction multiple chances to form. Such kinetic proofreading is used throughout biology. For example, we saw in Chapter 5 that the initial selection of the correct nucleotides by DNA polymerase during DNA replication takes advantage of this principle. We will discuss it in more detail later in the chapter when we describe translation by the ribosome.

Once the splicing chemistry is completed, the snRNPs remain bound to the excised lariat. The disassembly of these snRNPs from the lariat (and from

MBOC7_ptr_ch06_321-396.indd 344 02/12/21 2:16 PM

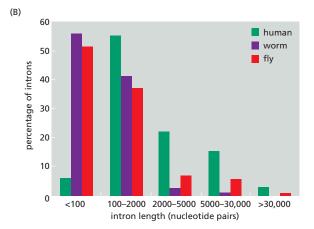

Figure 6–31 Variation in intron and exon lengths in the human, worm, and fly genomes. (A) Size distribution of exons. (B) Size distribution of introns. Reproduced with permission of SNCSC.)

each other) requires another series of ATP-driven RNA-RNA rearrangements, thereby returning the snRNAs to their original configuration to be used again in a new reaction.

As splicing is completed, the spliceosome directs a set of proteins to bind to the mRNA near the position formerly occupied by the intron. Called the *exon junction complex (EJC)*, these proteins mark the site of a successful splicing event, and, as we shall see later in this chapter, they influence the subsequent fate of the mRNA.

Other Properties of Pre-mRNA and Its Synthesis Help to Explain the Choice of Proper Splice Sites

As shown in Figure 6-31, intron sequences vary enormously in size; some are more than 100,000 nucleotides long. One might therefore expect frequent splicing mistakes—including exon skipping and the mistaken use of "cryptic" splice sites (Figure 6-32). To minimize these problems the fidelity mechanisms built into the spliceosome are supplemented by two additional strategies that further increase the accuracy of splicing. The first is a simple consequence of splicing being coupled to transcription (Figure 6-33). As transcription proceeds, the phosphorylated tail of RNA polymerase carries several components that stimulate formation of the spliceosome (see Figure 6-23), and these components are transferred directly from the polymerase to the RNA as the RNA emerges from the polymerase. This strategy helps the cell to keep track of introns and exons; for example, the snRNPs that assemble at a 5' splice site are initially presented only with the single 3' splice site that emerges next from the polymerase, inasmuch as the potential sites further downstream have not yet been synthesized. The coordination of transcription with splicing is thus important for preventing inappropriate exon skipping.

Another mechanism, called *exon definition*, also helps cells choose the appropriate splice sites. Exon size tends to be much more uniform than intron size,

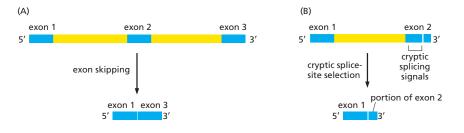

Figure 6–32 Two types of potential splicing errors. (A) Exon skipping.
(B) Cryptic splice-site selection. Cryptic splicing signals are nucleotide sequences of RNA that closely resemble true splicing signals and are sometimes mistakenly used by the spliceosome.

MBOC7_ptr_ch06_321-396.indd 345 02/12/21 2:17 PM

averaging about 150 nucleotide pairs across a wide variety of eukaryotic organisms (see Figure 6-31). Through exon definition, the splicing machinery seeks out the relatively homogeneously sized exon sequences rather than the intron sequences. It does this in the following way: as RNA synthesis proceeds, a group of additional components (most notably SR proteins, so-named because each contains a domain rich in serines and arginines) assemble on exon sequences and help to mark off each 3' and 5' splice site, starting at the 5' end of the RNA (Figure 6-34). These proteins, in turn, recruit the U1 snRNP, which marks the one exon boundary, and U2AF, which, along with BBP, specifies the other. By marking out the exons in this way and thereby taking advantage of the relatively uniform size of exons, the cell increases the accuracy with which it deposits the initial splicing components on the nascent RNA and thereby avoids "near miss" splice sites. To further aid the cell in marking off exons and distinguishing them from introns, some SR proteins bind tightly to specific RNA sequences, often termed splicing enhancers, that are preferentially found in exons. Because several different codons specify most amino acids, it is possible for a splicing enhancer to evolve without a change in the amino acid sequence coded by the exon.

Both the marking of exon and intron boundaries and the assembly of the spliceosome begin on an RNA molecule while it is still being elongated by RNA polymerase (see Figure 6–33). However, because the actual chemistry of splicing can be delayed, intron sequences are not necessarily removed from a pre-mRNA molecule in the order in which they occur along the RNA chain.

RNA Splicing Has Remarkable Plasticity

We have seen that the choice of splice sites depends on such features of the premRNA transcript as the strength of the three signals on the RNA recognized by

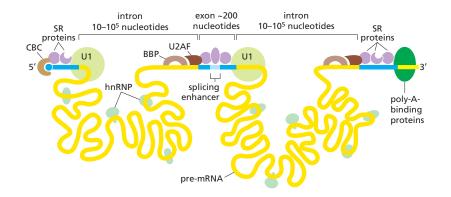

Figure 6-34 The exon definition hypothesis. SR proteins bind to each exon sequence in the pre-mRNA and thereby help to guide the snRNPs to the proper intron-exon boundaries. This demarcation of exons by the SR proteins occurs co-transcriptionally, beginning at the CBC (cap-binding complex) at the 5' end. It has also been proposed that a group of proteins known as the heterogeneous nuclear ribonucleoproteins (hnRNPs) preferentially associates with intron sequences, further helping the spliceosome distinguish introns from exons. (Adapted from R. Reed, Curr. Opin. Cell Biol. 12:340–345, 2000. With permission from Elsevier.)

MBOC7_ptr_ch06_321-396.indd 346 02/12/21 2:17 PM

the splicing machinery (the 5' and 3' splice junctions and the branch point), the co-transcriptional assembly of the spliceosome, and the "bookkeeping" that underlies exon definition. We do not know exactly how accurate splicing normally is because, as we see later, there are several quality-control systems that rapidly destroy mRNAs whose splicing goes awry. However, we do know that, compared with other steps in gene expression, splicing is unusually flexible.

Thus, for example, a mutation in a nucleotide sequence critical for splicing of a particular intron does not necessarily prevent splicing of that intron altogether. Instead, the mutation typically creates a new pattern of splicing (Figure 6-35). Most common, an exon is simply skipped (Figure 6-35B). In other cases, the mutation causes a cryptic splice junction to become the default choice (Figure 6-35C). Apparently, the splicing machinery has evolved to pick out the best possible pattern of splice junctions, and if the optimal one is damaged by mutation, it will seek out the next best pattern, and so on. This inherent plasticity in the process of RNA splicing suggests that changes in splicing patterns caused by random mutations have been important in the evolution of genes and organisms. It also means that mutations that affect splicing can be severely detrimental to the organism: in addition to the β -thalassemia example presented in Figure 6-35, aberrant splicing plays important roles in the development of cystic fibrosis, frontotemporal dementia, Parkinson's disease, retinitis pigmentosa, spinal muscular atrophy, myotonic dystrophy, premature aging, and cancer. It has been estimated that of the many point mutations that cause inherited human diseases, 10% produce aberrant splicing of the gene containing the mutation.

The plasticity of RNA splicing also means that the cell can easily regulate the pattern of RNA splicing. Earlier in this section we saw that alternative splicing can give rise to different proteins from the same gene and that this is a common strategy to enhance the coding potential of genomes. Some examples of alternative splicing are constitutive; that is, the alternatively spliced mRNAs are produced continually by cells of an organism. However, in many cases, the cell regulates the splicing patterns so that different forms of the protein are produced at different times and in different tissues (see Figure 6–27). In Chapter 7, we return to this issue to discuss some specific examples of regulated RNA splicing.

Spliceosome-catalyzed RNA Splicing Evolved from RNA Self-splicing Mechanisms

When the spliceosome was first discovered, it puzzled molecular biologists. Why do RNA molecules instead of proteins perform important roles in splice-site recognition and in the chemistry of splicing? Why is a lariat intermediate used rather than the apparently simpler alternative of bringing the 5' and 3' splice sites together in a single step, followed by their direct cleavage and rejoining? The answers to these questions reflect the way in which the spliceosome has evolved.

As discussed in the final section of this chapter, it is likely that early cells used RNA molecules rather than proteins as their major catalysts and that they stored their genetic information in RNA rather than in DNA sequences. RNA-catalyzed splicing reactions presumably had critical roles in these early cells. As evidence, some *self-splicing RNA* introns (that is, intron sequences in RNA whose splicing out can occur in the absence of proteins or any other RNA molecules) remain today, for example, in the nuclear rRNA genes of the ciliate *Tetrahymena*, in a few bacteriophage T4 genes, and in some mitochondrial and chloroplast genes. In these cases, the RNA molecule folds into a specific three-dimensional structure that brings the intron-exon junctions together and directly catalyzes the two transesterification reactions. A self-splicing intron sequence can be identified in a test tube by incubating a pure RNA molecule that contains the intron sequence and observing the splicing reaction. Because the basic chemistry as well as the structure of the active site of some self-splicing RNAs is so similar to those of the pre-mRNA spliceosome, the much more involved

Figure 6–35 Abnormal processing of the β -globin primary RNA transcript in humans with the disease β -thalassemia.

In the examples shown, the disease (a severe anemia due to aberrant hemoglobin synthesis) is caused by splice-site mutations found in the genomes of affected individuals. The dark blue boxes represent the three normal exon sequences; the red lines connect the 5' and 3' splice sites that are used. The light blue boxes depict new nucleotide sequences included in the final mRNA molecule as a result of the mutation denoted by the black arrowhead. Note that when a mutation leaves a normal splice site without a partner, an exon is skipped as in panel B or one or more abnormal cryptic splice sites nearby is used as the partner site as in panel C.

MBOC7_ptr_ch06_321-396.indd 347 02/12/21 2:17 PM

process of pre-mRNA splicing described earlier very likely evolved from a simpler, ancestral form of RNA self-splicing.

RNA-processing Enzymes Generate the 3' End of Eukaryotic mRNAs

We have seen that the 5' end of the pre-mRNA produced by RNA polymerase II is capped almost as soon as it emerges from the RNA polymerase. Then, as the polymerase continues its movement along a gene, spliceosomes assemble on the RNA and delineate the intron and exon boundaries. The long C-terminal tail of the RNA polymerase coordinates these processes by transferring capping and splicing components directly to the RNA as it emerges from the enzyme. In this section, we describe how a similar mechanism ensures that the 3' end of the pre-mRNA is properly processed as RNA polymerase II reaches the end of a gene.

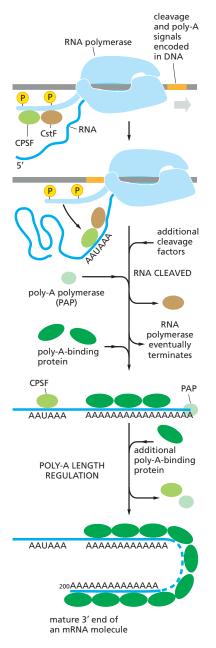

The position of the 3' end of each mRNA molecule is specified by signals encoded in the DNA nucleotide sequence (Figure 6–36). These signals are transcribed into RNA as the RNA polymerase II moves through them, and they are then recognized (as RNA) by a series of RNA-binding proteins and RNA-processing enzymes (Figure 6–37). Two multisubunit proteins (called CstF, cleavage stimulation factor; and CPSF, cleavage and polyadenylation specificity factor) are of special importance. Both of these proteins travel with the RNA polymerase tail and are transferred to the 3'-end processing sequence on an RNA molecule as it emerges from the RNA polymerase.

Once the two proteins bind to their recognition sequences on the emerging RNA molecule, additional proteins assemble with them to cleave the RNA (releasing it from the RNA polymerase) and complete the 3' end of the mRNA. Once the RNA is cleaved, an enzyme called *poly-A polymerase* (*PAP*) adds approximately 200 A nucleotides, one at a time, to the 3' end produced by the cleavage (see Figure 6–37). The precursor for these additions is ATP, and the same type of 5'-to-3' bonds are formed as in conventional RNA synthesis. But unlike other RNA polymerases, poly-A polymerase does not require a template; hence, the poly-A tail of eukaryotic mRNAs is not directly encoded in the genome. As the poly-A tail is synthesized, proteins called poly-A-binding proteins assemble onto it and, by a poorly understood mechanism, they help determine the final length of the tail.

The RNA polymerase II continues to transcribe after the 3' end of a eukaryotic pre-mRNA molecule has been cleaved, in some cases for hundreds of nucleotides. However, two factors increase the likelihood that an RNA polymerase will terminate transcription shortly after it has synthesized the RNA signal for 3'-end

Figure 6-37 Some of the major steps in generating the 3' end of a eukaryotic mRNA. This process is much more complicated than the analogous process in bacteria, where the RNA polymerase simply stops at a termination signal and releases both the 3' end of its transcript and the DNA template (see Figure 6-11).

Figure 6-36 The consensus nucleotide sequences in RNA that direct cleavage and polyadenylation to form the 3' end of a eukaryotic mRNA. These sequences are encoded in the genome, and specific proteins recognize them—as RNA after they are transcribed. As shown in Figure 6-37, the hexamer AAUAAA is bound by CPSF, and the GU-rich element beyond the cleavage site is bound by CstF: the CA sequence is bound by a third protein factor required for the cleavage step. Like other consensus nucleotide sequences discussed in this chapter (see Figure 6-12), the sequences shown in the figure represent optimal sequences: in reality, a variety of related cleavage and polyadenylation signals occur in nature.

MBOC7_ptr_ch06_321-396.indd 348 02/12/21 2:17 PM

cleavage and polyadenylation. First, the recruitment of the many proteins needed for 3'-end processing (which occurs while some of them are still bound to the RNA polymerase tail) causes a conformational change in the polymerase, slowing it down and decreasing its processivity. Second, once 3'-end cleavage has occurred, the newly synthesized RNA emerging from the polymerase lacks a 5' cap; this unprotected RNA is rapidly degraded by a $5' \rightarrow 3'$ exonuclease, and, when it catches up to the polymerase, it causes the RNA polymerase to release its grip on the template and terminate transcription.

In the simplest case, a gene carries a single site for 3' RNA cleavage and polyadenylation. However, many genes have several such sites and can therefore produce a variety of mRNAs that differ in their 3' ends. As will be discussed in the next chapter, cells can regulate 3'-end processing to produce different proteins from the same gene in a manner analogous to alternative splicing.

Mature Eukaryotic mRNAs Are Selectively Exported from the Nucleus

Eukaryotic pre-mRNA synthesis and processing take place in an orderly fashion within the cell nucleus. But of the pre-mRNA that is synthesized, only a small fraction—the mature mRNA—is of further use to the cell. Most of the rest—excised introns, broken RNAs, aberrantly processed pre-mRNAs, and accidently transcribed portions of the genome—is not only useless but potentially dangerous. How does the cell distinguish between the relatively rare mature mRNA molecules it wishes to keep and the overwhelming amount of useless debris?

The answer is that the RNAs are distinguished by the proteins bound to them. For example, we have seen that acquisition of cap-binding complexes, exon junction complexes, and poly-A-binding proteins marks the completion of capping, splicing, and poly-A addition, respectively. A properly completed mRNA molecule is also distinguished by the proteins it lacks. For example, the long-term presence of an snRNP protein would signify incomplete or aberrant splicing. Only when the proteins present on an mRNA molecule collectively signify that processing was successfully completed is the mRNA exported from the nucleus into the cytosol, where it can be translated into protein. Improperly processed mRNAs and other RNA debris are retained in the nucleus, where they are eventually degraded by the nuclear **RNA exosome**, a large protein complex whose interior is rich in 3'-to-5' RNA exonucleases (**Figure 6–38**). Indeed, the default fate of RNAs in the nucleus is degradation; only those bearing the proper constellation of proteins are spared.

Of all the proteins that assemble on pre-mRNA molecules as they emerge from transcribing RNA polymerases, the most abundant are the hnRNPs (heterogeneous nuclear ribonucleoproteins). Some of these proteins (there are approximately 30 different ones in humans) unwind the hairpin helices in the RNA so that splicing and other signals on the RNA can be read more easily. Others

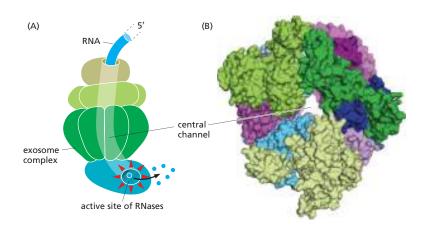

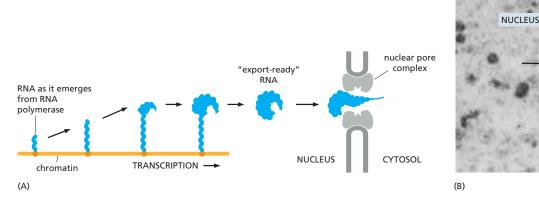

Figure 6-38 Structure of the nuclear RNA exosome. (A) RNA is fed into one end, passes through the central channel. and is degraded by RNases at the other end. (B) Structure of the central channel of the human RNA exosome viewed endon. Nine different protein subunits (each represented by a different color) make up this large ring structure. Eukarvotic cells have both a nuclear exosome and a cytoplasmic exosome; both forms include the central channel but differ in their additional subunits. The nuclear RNA exosome degrades aberrant RNAs (including excised intron sequences and incorrectly spliced RNAs) before they are exported to the cytosol. It also processes certain types of RNA (for example, the ribosomal RNAs) to produce their final form. The cytoplasmic form of the RNA exosome is responsible for degrading mRNAs in the cytosol and is thus crucial in determining the lifetime of each mRNA molecule. (A, adapted from C. Kilchert et al., Nat. Rev. Mol. Cell Biol. 17:227. 2016. With permission from Springer Nature; B, PDB code: 2NN6.)

Figure 6–39 Transport of a large mRNA molecule through the nuclear pore complex. (A) The maturation of an mRNA molecule as it is synthesized by RNA polymerase and packaged by a variety of nuclear proteins. This drawing of an unusually large and abundant insect RNA, called the Balbiani Ring mRNA, is based on electron microscope micrographs such as that shown in (B). (A, adapted from B. Daneholt, Cell 88:585–588, 1997; B, © 1966 B.J. Stevens and H. Swift. Originally published in J. Cell Biol. https://doi.org/10.1083/jcb.31.1.55. With permission from Rockefeller University Press.)

preferentially package the RNA contained in the very long intron sequences found in complex organisms (see Figure 6–31); these may also help to distinguish the debris left over from RNA processing from fully mature mRNAs.

Successfully processed mRNAs are guided through the **nuclear pore complexes** (NPCs)—aqueous channels in the nuclear membrane that directly connect the nucleoplasm and cytosol (Figure 6–39). Small molecules (less than 40,000 daltons or about 5 nm in diameter) can diffuse freely through these channels. However, most of the macromolecules in cells, including mRNAs complexed with proteins, are far too large to pass through the channels without a special process. The cell uses energy to actively transport such macromolecules in both directions through the nuclear pore complexes.

As explained in detail in Chapter 12, macromolecules are moved through nuclear pore complexes by *nuclear transport receptors*, which, depending on the identity of the macromolecule, escort it from the nucleus to the cytoplasm or vice versa. For mRNA export to occur, a specific nuclear transport receptor must be loaded onto the mRNA, a step that, in many organisms, takes place in concert with 3' cleavage and polyadenylation.

The export of mRNA-protein complexes from the nucleus can be readily observed with the electron microscope for the unusually abundant mRNA of the insect *Balbiani Ring genes*. As these genes are transcribed, the newly formed premRNA is seen to be packaged by proteins, including hnRNPs, SR proteins, and components of the spliceosome. This protein-pre-mRNA complex undergoes a series of structural transitions, probably reflecting RNA-processing events, culminating in a curved fiber. This curved fiber diffuses through the nucleoplasm, enters the nuclear pore complex (with its 5' cap proceeding first), and then undergoes additional structural transitions as it moves through the pore (see Figure 6-39). Such observations reveal that the pre-mRNA-protein and mRNA-protein complexes are dynamic structures that gain and lose specific proteins during RNA synthesis, processing, and export (Figure 6-40).

The journey of an individual mRNA molecule from the nucleus to the cytosol can also be tracked by fluorescently labeling it and observing it over time. A typical mRNA molecule that is released from its site of transcription spends several minutes randomly diffusing in the nucleus until it encounters a nuclear pore complex. During this time, RNA-processing events presumably continue, with the mRNA shedding previously bound proteins and acquiring new ones. Once it arrives at the entrance to the pore, the "export-ready" mRNA molecule hovers for several seconds, during which time the completion of RNA processing likely occurs, and it then is transported through the pore very rapidly. Some mRNA-protein complexes are

MBOC7_ptr_ch06_321-396.indd 350 02/12/21 2:17 PM

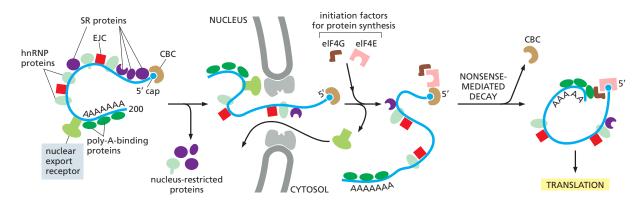

Figure 6-40 Schematic illustration of an export-ready mRNA molecule and its transport through the nuclear pore. As indicated, some proteins travel with the mRNA as it moves through the pore, whereas others remain in the nucleus. Some of the nuclear proteins that are lost are eventually replaced by cytosolic versions, such as those that bind the 5' cap. In some species (humans, for example), there are different poly-A-binding proteins in the nucleus and the cytosol; other species have only a single poly-A-binding protein. The nuclear export receptor for mRNAs is a complex of proteins that binds to an mRNA molecule once it has been correctly spliced and polyadenylated. After the mRNA has been exported to the cytosol, this export receptor dissociates from the mRNA and is re-imported into the nucleus, where it can be used again.

very large, and how they are moved through the nuclear pore complexes so rapidly (in about 10 milliseconds) remains a mystery.

Some of the proteins deposited on the mRNA while it is still in the nucleus can affect the fate of the mRNA after it is transported to the cytosol. Thus, the stability of an mRNA in the cytosol, the efficiency with which it is translated into protein, and its ultimate destination in the cell can all be determined by proteins acquired in the nucleus that remain bound to the mRNA in the cytosol.

Before discussing what next happens to the exported mRNAs, we briefly consider how the synthesis and processing of noncoding RNA molecules occur. There are many types of noncoding RNAs produced by cells (see Table 6–1, p. 327), but here we focus on the rRNAs, which are critically important for the translation of mRNAs into protein.

Noncoding RNAs Are Also Synthesized and Processed in the Nucleus

Of all the RNAs in a typical cell, only a few percent are mRNA. The bulk of RNA performs structural and catalytic functions (see Table 6–1). The most abundant RNAs in cells are the ribosomal RNAs (rRNAs), constituting approximately 80% of the RNA in rapidly dividing cells. As discussed later in this chapter, these RNAs form the core of the ribosome. Unlike bacteria—in which a single RNA polymerase synthesizes all RNAs in the cell—eukaryotes have a separate, specialized polymerase, RNA polymerase I, that is dedicated to producing rRNAs. RNA polymerase I is similar structurally to the RNA polymerase II discussed previously; however, the absence of a C-terminal tail in polymerase I helps to explain why its transcripts are neither capped nor polyadenylated.

Because multiple rounds of translation of each mRNA molecule can provide an enormous amplification in the production of protein molecules, many of the proteins that are very abundant in a cell can be synthesized from genes that are present in a single copy per haploid genome (see Figure 6–3). In contrast, the RNA components of the ribosome are final gene products, and a growing mammalian cell must synthesize approximately 10 million copies of each type of ribosomal RNA in each cell generation to construct its 10 million ribosomes. The cell can produce adequate quantities of ribosomal RNAs only because it contains multiple copies of the **rRNA genes** that code for **ribosomal RNAs (rRNAs)**. Even *E. coli* needs seven copies of its rRNA genes to meet the cell's need for ribosomes. Human cells contain about 200 rRNA gene copies per haploid genome, spread

MBOC7_ptr_ch06_321-396.indd 351 02/12/21 2:17 PM

Figure 6-41 Transcription from tandemly arranged rRNA genes, as seen in the electron microscope. The pattern of alternating transcribed gene and nontranscribed spacer is readily seen. A higher-magnification view of rRNA genes is shown in Figure 6-10. (From V.E. Foe, Cold Spring Harb. Symp. Quant. Biol. 42:723-740, 1978. With permission from Cold Spring Harbor Laboratory Press.)

out in small clusters on five different chromosomes (see Figure 4–12), while cells of the frog *Xenopus* contain about 600 rRNA gene copies per haploid genome in a single cluster on one chromosome (**Figure 6–41**).

There are four types of eukaryotic rRNAs, each present in one copy per ribosome. Three of the four rRNAs (18S, 5.8S, and 28S) are made by chemically modifying and cleaving a single large precursor rRNA (Figure 6-42); the fourth (5S RNA) is synthesized from a separate cluster of genes by a different polymerase, RNA polymerase III, and it does not require chemical modification.

Extensive chemical modifications occur in the 13,000-nucleotide-long precursor rRNA before the mature 18S, 5.8S, and 28S rRNAs are cleaved out of it. These include about 100 methylations of the 2'-OH positions on nucleotide sugars and 100 isomerizations of uridine nucleotides to pseudouridine (Figure 6-43A). The functions of these modifications are not understood in detail, but they probably aid in ribosome assembly, and they may also subtly affect the operation of completed ribosomes. Each modification is made at a specific position in the precursor rRNA, specified by "guide RNAs," which position themselves on the precursor rRNA through base-pairing and thereby bring an RNA-modifying enzyme to the appropriate position (Figure 6-43B). Other guide RNAs promote cleavage of the precursor rRNAs into the mature rRNAs, probably by causing conformational changes in the precursor rRNA that expose these sites to nucleases. All of these guide RNAs are members of a large class of RNAs called small nucleolar RNAs (snoRNAs), so named because these RNAs perform their functions in a subcompartment of the nucleus called the nucleolus. Many snoRNAs are encoded in the introns of other genes, especially those encoding ribosomal proteins. They are synthesized by RNA polymerase II and processed from excised intron sequences.

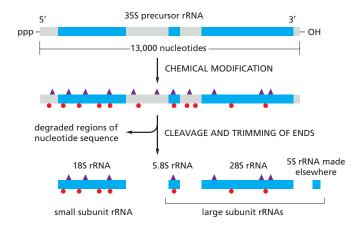

Figure 6-42 The chemical modification and nucleolytic processing of a eukaryotic precursor rRNA molecule into three separate ribosomal RNAs. Two types of chemical modifications (see Figure 6-43) are made to the precursor rRNA before it is cleaved. Nearly half of the nucleotide sequences in this precursor rRNA are discarded and degraded in the nucleus by the RNA exosome. The processing of the ribosomal RNAs begins while they are still being transcribed; the nascent transcripts also begin to be assembled with ribosomal proteins (see Figure 6-10). The rRNAs are named according to their "S" values, which refer to their rate of sedimentation in an ultracentrifuge. The larger the S value, the larger the rRNA.

MBOC7_ptr_ch06_321-396.indd 352 02/12/21 2:17 PM

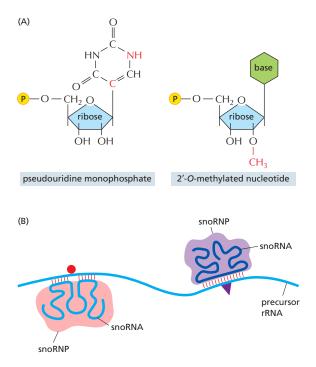

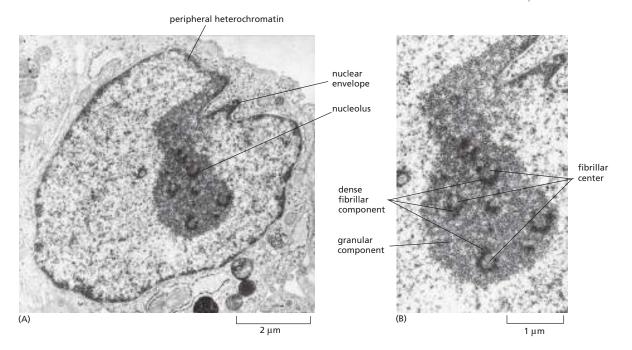

Figure 6-43 Modifications of the precursor rRNA by guide RNAs. (A) Two prominent covalent modifications made to rRNA; the differences from the initially incorporated nucleotide are indicated by red atoms. Pseudouridine is an isomer of uridine; the base has been "rotated" and is attached to the red C rather than to the red N of the sugar (compare to Figure 6-5B). (B) As indicated, snoRNAs determine the sites of modification by base-pairing to complementary sequences on the precursor rRNA. The snoRNAs are bound to proteins, and the complexes are called snoRNPs (small nucleolar ribonucleoproteins). The snoRNPs contain both the guide sequences and the enzymes that modify the rRNA.

The Nucleolus Is a Ribosome-producing Factory

The nucleolus is the most obvious structure seen in the nucleus of a eukaryotic cell when viewed in the light microscope. It was so closely scrutinized by early cytologists that an 1898 review could list some 700 references. We now know that the **nucleolus** is the site for the synthesis and processing of rRNAs and the assembly of ribosomes. Unlike many of the major organelles in the cell, the nucleolus is not bound by a membrane (**Figure 6-44**); instead, it is a huge *biomolecular condensate* of macromolecules, including the rRNA genes themselves, precursor

Figure 6–44 Electron micrograph of a thin section of a nucleolus in a human fibroblast, showing its three distinct zones. (A) View of entire nucleus. (B) Higher-power view of the nucleolus. It is believed that processing of the rRNAs and their assembly into the two subunits of the ribosome proceeds outward from the dense fibrillar component to the surrounding granular components (see Figure 6–46). Figure 6-45 Nucleoli exhibit fluidlike behavior when observed in vitro. A time course showing the fate of three nucleoli from frog oocytes that have begun to fuse with one another. The lower fusion joint eventually breaks while the other enlarges, completing the fusion event. This experiment was carried out in vitro under mineral oil, and the nucleoli were observed using differential-interference-contrast microscopy (see Chapter 9). (Courtesy of C.P. Brangwynne et al., Proc. Natl. Acad. Sci. USA 108:4334-4339, 2011).

rRNAs, mature rRNAs, rRNA-processing enzymes, snoRNPs, a large set of assembly factors (including ATPases, GTPases, protein kinases, and RNA helicases), ribosomal proteins, and partly assembled ribosomes. We discuss the formation of membraneless organelles in Chapter 12; here, we note that their assembly is likely driven by the type of phase transitions discussed in Chapter 3 (see Figure 3-77). The close, but loose, association of all these components, which allows the assembly of ribosomes to occur rapidly and smoothly, endows the nucleolus with liquid-like properties (Figure 6-45).

The rRNA genes themselves have an important role in forming the nucleolus (Figure 6-46). In a diploid human cell, the rRNA genes are distributed into 10 clusters, located near the tips of five different chromosome pairs (see Figure 4-12). During interphase, these 10 chromosomes contribute DNA loops (containing the rRNA genes) to the nucleolus; in M phase, when the chromosomes condense, the nucleolus fragments and then disappears. Then, in the telophase part of mitosis, as chromosomes return to their semi-dispersed state, the tips of the 10 chromosomes re-form small nucleoli, which progressively coalesce into a single nucleolus (Figure 6-47 and Figure 6-48). As might be expected, the size of the nucleolus reflects the number of ribosomes that the cell is producing. Its size therefore varies greatly in different cells and can change in a single cell, occupying nearly 25% of the total nuclear volume in cells that are making unusually large amounts of protein.

Ribosome assembly is a complex process, requiring, in addition to the proteins and RNA molecules that compose the finished ribosome, more than 200 proteins that aid the assembly of the finished ribosome. These include chaperones (discussed later in this chapter), ATP-dependent RNA helicases, nucleases, and a wide variety of RNA-binding proteins. In addition, assembly requires a number of small RNA molecules, such as the two snoRNAs of Figure 6-43. In many respects, building a ribosome resembles the process by which a spliceosome is formed, as we discussed earlier in the chapter. In particular, many ATP-driven RNA structural rearrangements occur as assembly proceeds. However, a key difference is that a new spliceosome must be constructed and disassembled for each splicing event,

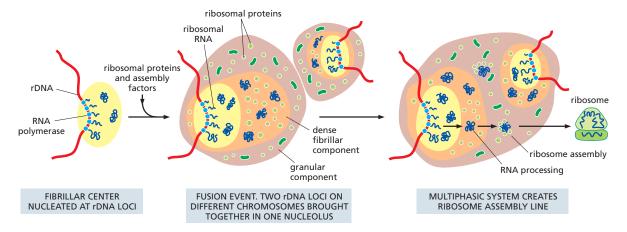

Figure 6-46 Schematic diagram of nucleolus formation after mitosis. According to this model, the nucleolus is formed from three distinct condensates, each with a different set of components. This arrangement is proposed to promote the orderly assembly of RNA-protein complexes, much like that observed on an assembly line. (Adapted from A.R. Strom and C.P. Brangwynne, J. Cell Sci. 132:ics235093, 2019.)

MBOC7_ptr_ch06_321-396.indd 354 02/12/21 2:17 PM

while a ribosome, once formed, is stable and is used repeatedly to translate many mRNAs into protein. In human cells, it is estimated that each ribosome makes, on average, 3000 individual proteins in its lifetime. Ribosome assembly is understood in great detail, and only a few of the key features are summarized in Figure 6-49.

In addition to its central role in ribosome biogenesis, the nucleolus is the site where other noncoding RNAs are produced and other RNA-protein complexes are assembled. For example, the U6 snRNP, a key component in pre-mRNA splicing (see Figure 6–29), is composed of one RNA molecule and seven proteins. The U6 snRNA is chemically modified by snoRNAs and assembled with its proteins in the nucleolus. Other important RNA-protein complexes, including telomerase (encountered in Chapter 5) and the signal-recognition particle (which we discuss in Chapter 12), are also assembled in the nucleolus. Finally, the tRNAs (transfer RNAs) that carry the amino acids for protein synthesis are processed there as well; like the rRNA genes, the genes encoding tRNAs are clustered in the nucleolus. Thus, the nucleolus can be thought of as a large factory at which different noncoding RNAs are transcribed, processed, and assembled with proteins to form a large variety of ribonucleoprotein complexes.

The Nucleus Contains a Variety of Subnuclear Biomolecular Condensates

Although the nucleolus is the most prominent structure in the nucleus, several other membraneless compartments have been observed and studied (Figure 6–50). These include Cajal bodies (named for the scientist who first described them in 1906) and interchromatin granule clusters (also called "speckles"). Like the nucleolus, these other compartments are highly dynamic depending on the needs of the cell, and their assembly is likely the result of the association of protein and RNA components involved in the synthesis, assembly, and storage of macromolecules involved in gene expression. Cajal bodies are sites where the snRNPs and snoRNPs undergo their final maturation steps, and where the snRNPs are recycled and their RNAs are "reset" after the rearrangements that occur during splicing (see pp. 344–345). In contrast, the interchromatin granule clusters are stockpiles of fully mature snRNPs and other RNA-processing components that are ready to be used in the production of mRNA.

Scientists have had difficulties in working out the exact function of these small compartments, in part because their appearances can change dramatically as cells traverse the cell cycle or respond to changes in their environment. Moreover, disrupting a particular type of nuclear body often has little effect on cell viability.

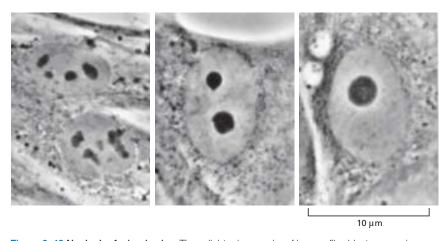

Figure 6-48 Nucleolar fusion in vivo. These light micrographs of human fibroblasts grown in culture show various stages of nucleolar fusion. After mitosis, each of the 10 human chromosomes that carry a cluster of rRNA genes begins to form a tiny nucleolus, but these rapidly coalesce as they grow to form the single large nucleolus typical of many interphase cells. (Courtesy of E.G. Jordan and J. McGovern.)

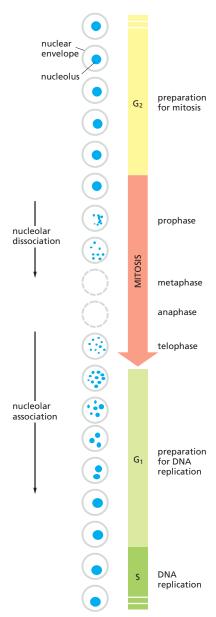

Figure 6–47 Changes in the appearance of the nucleolus in a human cell during the cell cycle. Only the cell nucleus is represented in this diagram. In most eukaryotic cells, the nuclear envelope breaks down during mitosis, as indicated by the dashed circles.

MBOC7_ptr_ch06_321-396.indd 355 02/12/21 2:17 PM

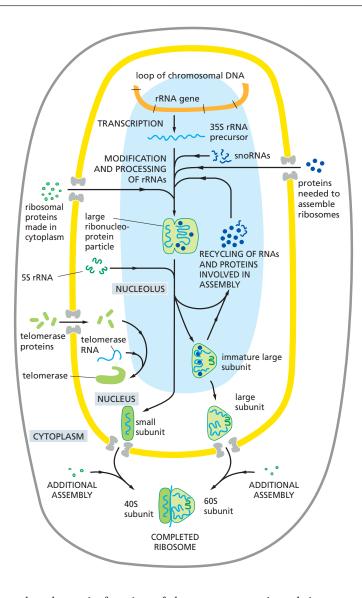

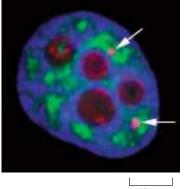

Figure 6-49 The function of the nucleolus in ribosome and other ribonucleoprotein synthesis. The 35S precursor rRNA is packaged in a large ribonucleoprotein particle containing many ribosomal proteins imported from the cytoplasm. While this particle remains at the nucleolus, selected components are added and others discarded as it is processed into immature large and small ribosomal subunits. The two ribosomal subunits attain their final functional form only after each is individually transported through the nuclear pores into the cytoplasm. Other ribonucleoprotein complexes, including telomerase shown here, are also assembled in the nucleolus. (Adapted from A.R. Strom and C.P. Brangwynne, J. Cell Sci. 132:jcs235093, 2019. With permission from the Company of Biologists.)

It seems that the main function of these aggregates is to bring components together at high concentration in order to speed up their assembly. For example, it is estimated that assembly of the U4/U6 snRNP (see Figure 6–29) occurs 10 times more rapidly in Cajal bodies than would be the case if the same number of components were dispersed throughout the nucleus. Consequently, Cajal bodies appear dispensable in many types of cells but are absolutely required in situations where cells must proliferate rapidly, such as in early vertebrate development. Here, protein synthesis (which depends on RNA splicing) must occur especially rapidly, and delays can be lethal.

Given the prominence of nuclear compartments in RNA processing, it might be expected that pre-mRNA splicing would occur in a particular location in the

Figure 6–50 Visualization of some prominent membraneless compartments in the nucleus. The protein fibrillarin (red), a component of several snoRNPs, is present in both nucleoli and Cajal bodies; the latter are indicated by the arrows. The Cajal bodies (but not the nucleoli) are also highlighted by staining one of their main components, the protein coilin; the superposition of the snoRNP and coilin stains appears pink. Interchromatin granule clusters (green) have been revealed by using antibodies against a protein involved in pre-mRNA splicing. DNA is stained blue by the dye DAPI. (From J.R. Swedlow and A.I. Lamond, Genome Biol. 2:1–7, 2001. Micrograph courtesy of Judith Sleeman.)

MBOC7_ptr_ch06_321-396.indd 356 02/12/21 2:17 PM

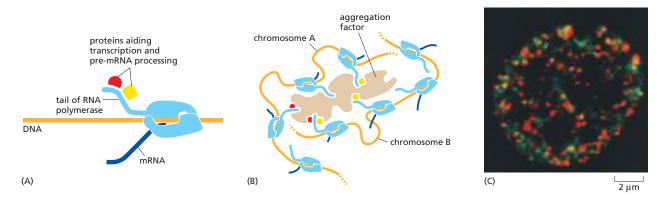

Figure 6–51 A model for an mRNA production factory. mRNA production is made more efficient in the nucleus by an aggregation of the many components needed for transcription and pre-mRNA processing, thereby producing a specialized biochemical factory. In (A), various components in the proximity of a transcribing RNA polymerase are carried on the tail (see Figure 6–23). In (B), a large number of RNA polymerase tails have been brought together to form a condensate that is highly enriched in the many components needed for the synthesis and processing of pre-mRNAs. Such a model can account for the several thousand sites of active RNA transcription and processing typically observed in the nucleus of a mammalian cell, each of which has a diameter of roughly 100 nm and is estimated to contain, on average, about 10 RNA polymerase II molecules in addition to many other proteins. (C) Here, mRNA production factories and DNA replication factories have been visualized in a mammalian cell by briefly incorporating differently modified nucleotides into each nucleic acid and detecting the RNA and DNA produced using antibodies, one (green) detecting the newly synthesized DNA and the other (red) detecting the newly synthesized RNA. (C, from D.G. Wansink et al., J. Cell Sci. 107:1449–1456, 1994. With permission from the Company of Biologists.)

nucleus, as it requires numerous RNA and protein components. However, as we have seen, the assembly of splicing components on pre-mRNA is co-transcriptional; thus, splicing must occur at many locations along chromosomes. Although a typical mammalian cell may be expressing on the order of 15,000 genes, transcription and RNA splicing takes place in only several thousand sites in the nucleus. These sites are highly dynamic and probably result from the association of transcription and splicing components to create small factories, the name given to specific condensates containing a high local concentration of selected components that create biochemical assembly lines (Figure 6-51). Indeed, it is thought that initial rounds of transcription and RNA processing are very slow and perhaps error-prone due to limiting concentrations of key components; only when a factory becomes fully assembled does mRNA production become rapid and accurate. Interchromatin granule clusters—which contain stockpiles of RNA-processing components—are often observed next to these sites of transcription, as though poised to replenish supplies. We can thus view the nucleus as organized into dynamic condensates of different sizes, with snRNPs, snoRNPs, and other nuclear components diffusing rapidly among them, so as to maintain high concentrations of the many components needed for each step of RNA production.

Summary

Before the synthesis of a particular protein can begin, the corresponding mRNA molecule must be produced by transcription. Bacteria contain a single type of RNA polymerase (the enzyme that carries out the transcription of DNA into RNA). An mRNA molecule is produced after this enzyme initiates transcription at a promoter, synthesizes the RNA by chain elongation, stops transcription at a terminator, and releases both the DNA template and the completed mRNA molecule. In eukaryotic cells, the process of transcription is much more complex, and there are three RNA polymerases—polymerase I, II, and III—that are related evolutionarily to one another and to the bacterial polymerase.

RNA polymerase II synthesizes eukaryotic mRNA. This enzyme requires a set of additional proteins, the general transcription factors, to initiate transcription on a DNA template. It requires still more proteins (including transcription activator

MBOC7_ptr_ch06_321-396.indd 357 02/12/21 2:17 PM

proteins, chromatin remodeling complexes, and histone-modifying enzymes) to initiate transcription on its chromatin templates inside the cell.

During the elongation phase of transcription, the nascent RNA undergoes three types of processing events: a special nucleotide is added to its 5' end (capping), intron sequences are removed from the middle of the RNA molecule (splicing), and the 3' end of the RNA is generated (cleavage and polyadenylation). Each of these processes is initiated by proteins that travel along with RNA polymerase II by binding to sites on its long, extended C-terminal tail. Splicing is unusual in that many assembly steps are required for each splicing event, and the catalytic site for the reaction is formed by RNA molecules rather than proteins. Only properly processed mRNAs are passed through nuclear pore complexes into the cytosol, where they are translated into protein.

For many genes, RNA, rather than protein, is the final product. In eukaryotes, the most abundant of these non-coding RNAs are transcribed by either RNA polymerase I or RNA polymerase III. RNA polymerase I makes the ribosomal RNAs, which are by far the most abundant RNAs in a cell. The rRNAs are chemically modified, cleaved, and assembled into the two ribosomal subunits in the nucleolus—a distinct membraneless organelle that also helps to process some smaller RNA-protein complexes in the cell. Additional biomolecular condensates in the nucleus (including Cajal bodies and interchromatin granule clusters) are sites where components involved in RNA processing are assembled, stored, and recycled. The high concentration of components in these and other biomolecular condensates ensures that the processes being catalyzed are rapid and efficient.

FROM RNA TO PROTEIN

In the preceding section, we saw that the final product of some genes is an RNA molecule itself, such as the RNAs present in the snRNPs and in ribosomes. However, most genes in a cell produce mRNA molecules that serve as intermediaries on the pathway to proteins. In this section, we examine how the cell converts the information carried in an mRNA molecule into a protein molecule. This feat of translation was a strong focus of attention for biologists in the late 1950s, when it was posed as the "coding problem": How is the information in a linear sequence of nucleotides in RNA translated into the linear sequence of a chemically quite different set of units—the amino acids in proteins? This fascinating question stimulated great excitement. Here was a cryptogram set up by nature that, after more than 3 billion years of evolution, could finally be solved by one of the products of evolution—human beings. And indeed, not only was the code cracked step by step, but in the year 2000 the structure of the elaborate machinery by which cells read this code—the ribosome—was finally revealed in atomic detail.

An mRNA Sequence Is Decoded in Sets of Three Nucleotides

Once an mRNA has been produced by transcription and processing, the information present in its nucleotide sequence is used to synthesize a protein. Transcription is simple to understand as a means of information transfer: because DNA and RNA are chemically and structurally similar, the DNA can act as a direct template for the synthesis of RNA by complementary base-pairing. As the term "transcription" signifies, it is as if a message written out by hand is being converted, say, into a typewritten text. The language itself and the form of the message do not change, and the symbols used are closely related.

In contrast, the conversion of the information in RNA into protein represents a **translation** of the information into another language that uses quite different symbols. Moreover, because there are only 4 different nucleotides in mRNA and 20 different types of amino acids in a protein, this translation cannot be accounted for by a direct one-to-one correspondence between a nucleotide in RNA and an amino acid in protein. The nucleotide sequence of a gene, through the intermediary of mRNA, is instead translated into the amino acid sequence of a protein by rules that are known as the **genetic code**. This code was deciphered in the early 1960s.

Figure 6–52 The genetic code. The standard one-letter abbreviation for each amino acid is presented below its three-letter abbreviation (see Panel 3–1, pp. 118–119, for the full name of each amino acid and its structure). By convention, codons are always written with the 5′-terminal nucleotide to the left. Note that most amino acids are represented by more than one codon, and that there are some regularities in the set of codons that specifies each amino acid: codons for the same amino acid tend to contain the same nucleotides at the first and second positions, and vary at the third position. Three codons do not specify any amino acid but act as termination sites (stop codons), signaling the end of the protein-coding sequence. One codon—AUG—acts both as an initiation codon, signaling the start of a protein-coding message, and also as the codon that specifies methionine.

The sequence of nucleotides in the mRNA molecule is read in consecutive groups of three. RNA is a linear polymer of four different nucleotides, so there are $4\times4\times4=64$ possible combinations of three nucleotides: the triplets AAA, AUA, AUG, and so on. However, only 20 different amino acids are commonly found in proteins. Either some nucleotide triplets are never used or the code is redundant and some amino acids are specified by more than one triplet. The second possibility is, in fact, the correct one, as shown by the completely deciphered genetic code in **Figure 6–52**. Each group of three consecutive nucleotides in mRNA is called a **codon**, and each codon specifies either one amino acid or a stop to the translation process.

In principle, an RNA sequence can be translated in any one of three different reading frames, depending on where the decoding process begins (Figure 6–53). However, only one of the three possible reading frames in an mRNA encodes the required protein. We see later how a special punctuation signal at the beginning of each RNA message sets the correct reading frame at the start of protein synthesis.

tRNA Molecules Match Amino Acids to Codons in mRNA

The codons in an mRNA molecule do not directly recognize the amino acids they specify: the group of three nucleotides does not, for example, bind directly to the amino acid. Rather, the translation of mRNA into protein depends on *adaptor* molecules that can recognize and bind both to the codon and, at another site on their surface, to the amino acid. These adaptors consist of a set of small RNA molecules known as **transfer RNAs (tRNAs)**, each about 80 nucleotides in length.

We saw earlier in this chapter that RNA molecules can fold into precise three-dimensional structures, and the tRNA molecules provide striking examples. Four short segments of each folded tRNA are double-helical, producing a molecule that looks like a cloverleaf when drawn schematically (Figure 6–54). For example, a 5'-GCUC-3' sequence in one part of a polynucleotide chain can form a relatively strong base-pairing association with a 5'-GAGC-3' sequence in another region of the same molecule. The cloverleaf undergoes further folding to form a compact L-shaped structure that is held together by additional hydrogen bonds between different regions of the molecule (see Figure 6–54B and C).

Two regions of unpaired nucleotides situated at either end of the L-shaped molecule are crucial to the function of tRNA in protein synthesis. One of these regions forms the **anticodon**, a set of three consecutive nucleotides that pairs with the complementary codon in an mRNA molecule. The other is a short single-strand region at the 3' end of the molecule; this is the site where the amino acid that matches the codon is attached to the tRNA.

We saw above that the genetic code is redundant; that is, several different codons can specify a single amino acid. This redundancy implies either that there is more than one tRNA for many of the amino acids or that some tRNA molecules can base-pair with more than one codon. In fact, both situations occur. Some

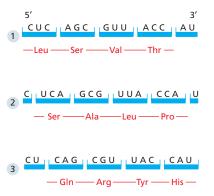

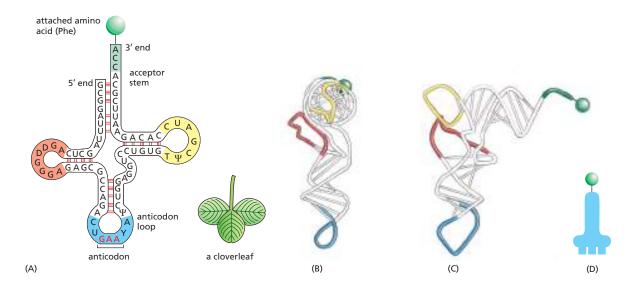

Figure 6–53 The three possible reading frames in protein synthesis.

In the process of translating a nucleotide sequence (blue) into an amino acid sequence (red), the sequence of nucleotides in an mRNA molecule is read from the 5' end to the 3' end in consecutive sets of three nucleotides. In principle, therefore, the same RNA sequence can specify three completely different amino acid sequences, depending on the reading frame. In reality, however, only one of these reading frames contains the actual message.

Figure 6–54 A tRNA molecule. A tRNA specific for the amino acid phenylalanine (Phe) is depicted in various ways. (A) The cloverleaf structure showing the complementary base-pairing (red lines) that creates the double-helical regions of the molecule. The anticodon is the sequence of three nucleotides that base-pairs with a codon in mRNA. The amino acid matching the codon–anticodon pair is attached at the 3' end of the tRNA. tRNAs contain some unusual bases, which are produced by chemical modification after the tRNA has been synthesized. For example, the bases denoted Ψ (pseudouridine—see Figure 6–43) and D (dihydrouridine—see Figure 6–57) are derived from uracil. (B and C) Views of the L-shaped molecule that are based on x-ray diffraction analysis. Although this diagram shows the tRNA for the amino acid phenylalanine, all other tRNAs have similar structures. (D) The tRNA icon we use in this book. (E) The linear nucleotide sequence of the molecule, color-coded to match the illustrations in A, B, and C.

amino acids have more than one tRNA, and some tRNAs are constructed so that they require accurate base-pairing only at the first two positions of the codon and can tolerate a mismatch (or *wobble*) at the third position (Figure 6–55). This wobble base-pairing explains why so many of the alternative codons for an amino acid differ only in their third nucleotide (see Figure 6–52). In bacteria, wobble base-pairings make it possible to fit the 20 amino acids to their 61 codons with as

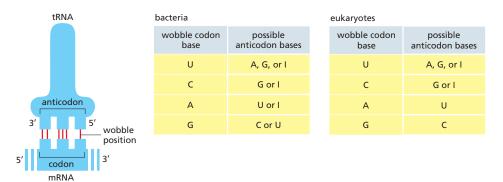

Figure 6-55 Wobble base-pairing between codons and anticodons. If the nucleotide listed in the first column is present at the third, or wobble, position of the codon, it can base-pair with any of the nucleotides listed in the second column. Thus, for example, when inosine (I) is present in the wobble position of the tRNA anticodon, the tRNA can recognize any one of three different codons in bacteria and either of two codons in eukaryotes. The inosine in tRNAs is formed from the deamination of adenosine (see Figure 6-57), a chemical modification that takes place after the tRNA has been synthesized. The nonstandard base pairs, including those made with inosine, are generally weaker than conventional base pairs. Codon–anticodon base-pairing is more stringent at positions 1 and 2 of the codon, where only conventional base pairs are permitted. The differences in wobble base-pairing interactions between bacteria and eukaryotes presumably result from subtle structural differences between bacterial and eukaryotic ribosomes, the molecular machines that perform protein synthesis. Figure 6–56 Structure of a tRNA-splicing endonuclease docked to a precursor tRNA. The endonuclease (a four-subunit enzyme) removes the tRNA intron (dark blue, bottom). A second enzyme, a multifunctional tRNA ligase (not shown), then joins the two tRNA halves together. (Courtesy of H. Li, C. Trotta, and J. Abelson. PDB code: 2A9L.)

few as 31 kinds of tRNA molecules. The exact number of different kinds of tRNAs, however, differs from one species to the next. For example, humans have nearly 500 tRNA genes that encode tRNAs with 48 different anticodons.

tRNAs Are Covalently Modified Before They Exit from the Nucleus

Like most other eukaryotic RNAs, tRNAs are covalently modified before they are allowed to exit from the nucleus. Eukaryotic tRNAs are synthesized by RNA polymerase III. Both bacterial and eukaryotic tRNAs are typically synthesized as larger precursor tRNAs, which are then trimmed to produce the mature tRNA. In addition, some tRNA precursors (from both bacteria and eukaryotes) contain introns that must be spliced out. This splicing reaction differs chemically from that of premRNA splicing discussed earlier in the chapter; rather than generating a lariat intermediate, tRNA splicing uses a cut-and-paste mechanism that is catalyzed by proteins (Figure 6–56). Trimming and splicing both require the precursor tRNA to be correctly folded in its cloverleaf configuration. Because misfolded tRNA precursors will not be processed properly, the trimming and splicing reactions serve as quality-control steps in the generation of tRNAs. Those that do not pass the tests are degraded by the nuclear exosome (see Figure 6–38).

All tRNAs are modified chemically—nearly 1 in 10 nucleotides in each mature tRNA molecule is an altered version of a standard G, U, C, or A ribonucleotide. More than 50 different types of tRNA modifications are known; a few are shown in Figure 6–57. Some of the modified nucleotides lie within the anticodon—most notably inosine, produced by the deamination of adenosine—and affect the base-pairing of the anticodon, thereby facilitating the recognition of the appropriate mRNA codon by the tRNA molecule (see Figure 6–55). Other modifications affect the accuracy with which the tRNA is attached to the correct amino acid.

Specific Enzymes Couple Each Amino Acid to Its Appropriate tRNA Molecule

We have seen that, to read the genetic code in DNA, cells make a series of different tRNAs. We now consider how each tRNA molecule becomes linked to the one amino acid in 20 that is its appropriate partner. Recognition and attachment of

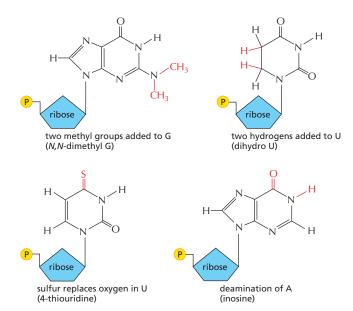

Figure 6–57 A few of the unusual nucleotides found in tRNA molecules.

These nucleotides are produced by covalent modification of a normal nucleotide after it has been incorporated into an RNA chain. Two other types of modified nucleotides are shown in Figure 6–43. In most tRNA molecules, about 10% of the nucleotides are modified (see Figure 6–54). As shown in Figure 6–55, inosine is sometimes present at the wobble position in the tRNA anticodon.

MBOC7_ptr_ch06_321-396.indd 361 02/12/21 2:17 PM

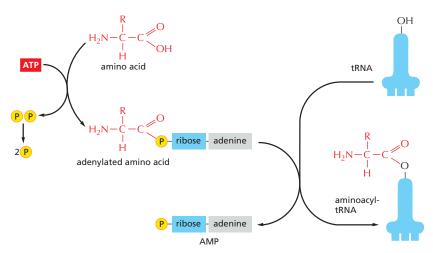

Figure 6–58 Amino acid activation by synthetase enzymes. An amino acid is attached to its corresponding tRNA in two steps by an aminoacyl-tRNA synthetase enzyme. As indicated, the energy of ATP hydrolysis is used in the reaction to produce a high-energy linkage. The amino acid is first activated through attachment of its carboxyl group directly to AMP, forming an adenylated amino acid; the linkage of the AMP, normally an unfavorable reaction, is driven by the hydrolysis of the ATP molecule that donates the AMP. Without leaving the synthetase enzyme, the AMP-linked carboxyl group on the amino acid is then transferred to a hydroxyl group on the sugar at the 3' end of the tRNA molecule. This transfer joins the amino acid by an activated ester linkage to the tRNA and forms the final aminoacyl-tRNA molecule. The synthetase enzyme is not shown in this diagram.

the correct amino acid depends on enzymes called aminoacyl-tRNA synthetases, which covalently couple each amino acid to its appropriate set of tRNA molecules (Figure 6–58 and Figure 6–59). Most cells have a different synthetase enzyme for each amino acid (that is, 20 synthetases in all); one attaches glycine to all tRNAs that recognize codons for glycine, another attaches alanine to all tRNAs that recognize codons for alanine, and so on. Many bacteria, however, have fewer than 20 synthetases, and the same synthetase enzyme is responsible for coupling more

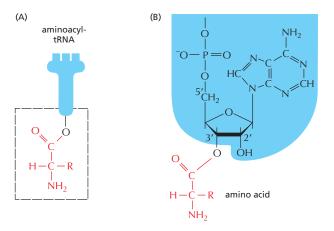

Figure 6–59 The structure of the aminoacyl-tRNA linkage. The carboxyl end of the amino acid forms an ester bond to ribose. Because the hydrolysis of this ester bond is associated with a large favorable change in free energy, an amino acid held in this way is said to be activated. (A) Schematic drawing of the structure. The amino acid is linked to the nucleotide at the 3' end of the tRNA (see Figure 6–54). (B) Actual structure corresponding to the boxed region in A. There are two major classes of synthetase enzymes: one links the amino acid directly to the 3'-OH group of the ribose, and the other links it initially to the 2'-OH group. In the latter case, a subsequent transesterification reaction shifts the amino acid to the 3' position. The "R" is a standard symbol used to represent the side chain of an amino acid.

MBOC7_ptr_ch06_321-396.indd 362 02/12/21 2:17 PM

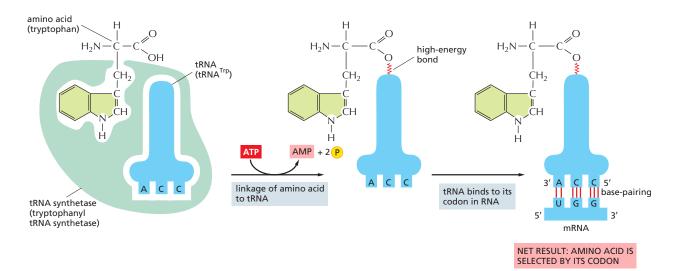

Figure 6-60 The genetic code is translated by means of two adaptors that act one after another. The first adaptor is the aminoacyl-tRNA synthetase, which couples a particular amino acid to its corresponding tRNA; the second adaptor is the tRNA molecule itself, whose anticodon forms base pairs with the appropriate codon on the mRNA. An error in either step would cause the wrong amino acid to be incorporated into a protein chain (Movie 6.6). In the sequence of events shown, the amino acid tryptophan (Trp) is selected by the codon UGG on the mRNA.

than one amino acid to the appropriate tRNAs. In these cases, a single synthetase places the identical amino acid on two different types of tRNAs, only one of which has an anticodon that matches the amino acid. A second enzyme then chemically modifies each "incorrectly" attached amino acid so that it now corresponds to the anticodon displayed by its covalently linked tRNA.

The synthetase-catalyzed reaction that attaches the amino acid to the 3' end of the tRNA is one of many reactions coupled to the energy-releasing hydrolysis of ATP (see pp. 70–72), and it produces a high-energy bond between the tRNA and the amino acid. The energy of this bond is used at a later stage in protein synthesis to link the amino acid covalently to the growing polypeptide chain.

The aminoacyl-tRNA synthetase enzymes and the tRNAs are equally important in the decoding process (Figure 6-60). This was established by an experiment in which one amino acid (cysteine) was chemically converted into a different amino acid (alanine) after it already had been attached to its specific tRNA. When such "hybrid" aminoacyl-tRNA molecules were used for protein synthesis in a cell-free system, the wrong amino acid was inserted at every point in the protein chain where that tRNA was used. Although, as we shall see, cells have several quality-control mechanisms to avoid this type of mishap, the experiment did establish that the genetic code is translated by two sets of adaptors that act sequentially. Each matches one molecular surface to another with great specificity, and it is their combined action that associates each sequence of three nucleotides in the mRNA molecule—that is, each codon—with its particular amino acid.

Editing by tRNA Synthetases Ensures Accuracy

Several mechanisms working together ensure that an aminoacyl-tRNA synthetase links the correct amino acid to each tRNA. Most synthetase enzymes select the correct amino acid by a two-step mechanism. The correct amino acid has the highest affinity for the active-site pocket of its synthetase and is therefore favored over the other 19; in particular, amino acids larger than the correct one are excluded from the active site. However, accurate discrimination between two similar amino acids, such as isoleucine and valine (which differ by only a methyl group), is very difficult to achieve in a single step. A second

MBOC7_ptr_ch06_321-396.indd 363 02/12/21 2:17 PM

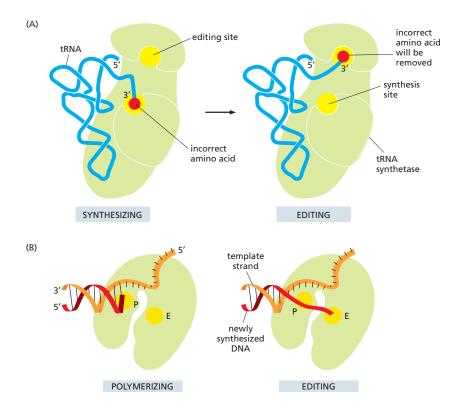

Figure 6-61 Hydrolytic editing in biology. (A) Aminoacyl-tRNA synthetases correct their own coupling errors through the hydrolytic editing of incorrectly attached amino acids. As described in the text, errors are selectively removed because the correct amino acid is rejected by the editing site on the synthetase. (B) The error-correction process performed by DNA polymerase, as described in the previous chapter. Here error removal depends on the wrong nucleotide mispairing with the DNA template (see Figure 5–9). (P, polymerization site; E, editing site.)

discrimination step occurs after the amino acid has been covalently linked to AMP (see Figure 6–58): when tRNA binds, the synthetase tries to force the adenylated amino acid into a second editing pocket in the enzyme. The precise dimensions of this pocket exclude the correct amino acid, while allowing access by closely related amino acids. In the editing pocket, an amino acid is removed from the AMP (or from the tRNA itself if the aminoacyl-tRNA bond has already formed) by hydrolysis. This hydrolytic editing, which is analogous to the exonucleolytic proofreading by DNA polymerases, increases the overall accuracy of tRNA charging so that only about one mistake is made in 40,000 couplings (Figure 6–61).

The tRNA synthetase must also recognize the correct set of tRNAs, and extensive structural and chemical complementarity between the synthetase and the tRNA allows the synthetase to probe various features of the tRNA (Figure 6–62). Most tRNA synthetases directly recognize the matching tRNA anticodon; these synthetases contain three adjacent nucleotide-binding pockets, each of which is complementary in shape and charge to a nucleotide in the anticodon. For other synthetases, the nucleotide sequence of the amino acid-accepting arm (acceptor stem) is the key recognition determinant. In most cases, however, the synthetase "reads" the nucleotides at several different positions on the tRNA, thereby increasing the accurate linking of amino acids to their appropriate tRNAs.

Amino Acids Are Added to the C-terminal End of a Growing Polypeptide Chain

Having seen that amino acids are first coupled to specific tRNA molecules that serve as adaptors, we now turn to the mechanism that joins these amino acids together to form proteins. The fundamental reaction of protein synthesis is the formation of a peptide bond between the carboxyl group at the end of a growing polypeptide chain and a free amino group on an incoming amino acid.

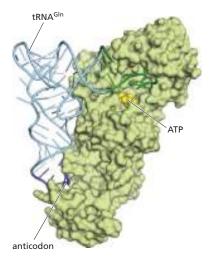

Figure 6–62 The recognition of a tRNA molecule by its aminoacyl-tRNA synthetase. For this tRNA (tRNAGIN), specific nucleotides in both the anticodon (dark blue) and the amino acid–accepting arm (green) allow the correct tRNA to be recognized by the synthetase enzyme (yellow-green). The ATP molecule used in the coupling reaction is yellow. (Courtesy of Tom Steitz. PDB code: 1QRS.)

MBOC7_ptr_ch06_321-396.indd 364 02/12/21 2:17 PM

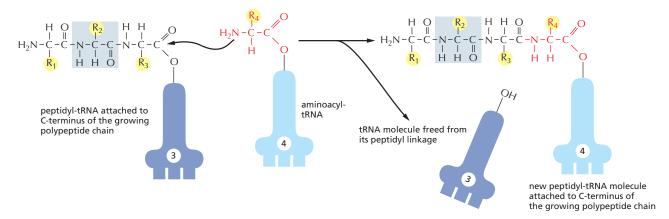

Figure 6–63 The incorporation of an amino acid into a protein. A polypeptide chain grows by the stepwise addition of amino acids to its C-terminal end. The formation of each peptide bond is energetically favorable because the growing C-terminus has been activated by the covalent attachment of a tRNA molecule. Note that the peptidyl-tRNA linkage that activates the growing end is regenerated during each addition. The amino acid side chains have been abbreviated as R₁, R₂, R₃, and R₄; as a reference point, all of the atoms in the second amino acid in the polypeptide chain are shaded *gray*. The figure shows the addition of the fourth amino acid (*red*) to the growing chain.

Consequently, a protein is synthesized from its N-terminal end to its C-terminal end, one amino acid at a time. Throughout the entire process, the growing carboxyl end of the polypeptide chain remains activated by its covalent attachment to a tRNA molecule (forming a *peptidyl-tRNA*). Each addition disrupts this high-energy covalent linkage but immediately replaces it with an identical linkage on the most recently added amino acid (**Figure 6–63**). In this way, each amino acid added carries with it the activation energy for the addition of the next amino acid rather than the energy for its own addition—an example of the *polymer-end activation* mechanism for polymer synthesis described in Figure 2–44.

The RNA Message Is Decoded in Ribosomes

The synthesis of proteins is guided by information carried by mRNA molecules. To maintain the correct reading frame and to ensure accuracy (about 1 mistake every 10,000 amino acids), protein synthesis is performed by the **ribosome**, a complex catalytic machine made from more than 50 different proteins (the *ribosomal proteins*) and several RNA molecules, the ribosomal RNAs (rRNAs). A typical eukaryotic cell contains millions of ribosomes in its cytoplasm (**Figure 6–64**), and it takes approximately 1 minute to synthesize an average-sized

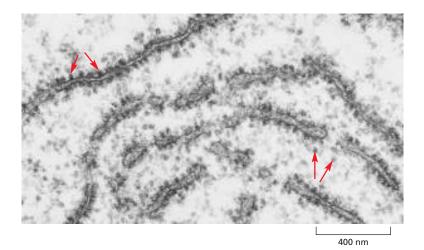

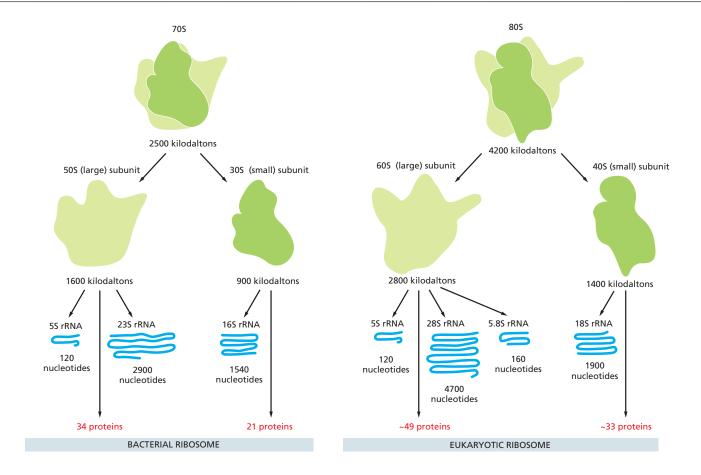

Figure 6-64 Ribosomes in the cytoplasm of a eukaryotic cell. This electron micrograph shows a thin section of a small region of cytoplasm. The ribosomes appear as black dots (red arrows). Some are free in the cytosol; others are attached to membranes of the endoplasmic reticulum. (Courtesy of Daniel S. Friend, by permission of E.L. Bearer.)

MBOC7_ptr_ch06_321-396.indd 365 02/12/21 2:17 PM

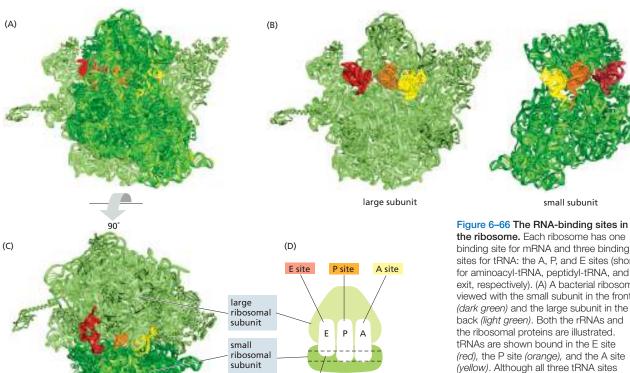

protein. As we saw earlier in the chapter, the large and small ribosome subunits of eukaryotes are assembled in the nucleolus, where newly transcribed and modified rRNAs are brought into association with the ribosomal proteins that have been transported into the nucleus after their synthesis in the cytoplasm. These two ribosomal subunits are then exported to the cytoplasm, where they each undergo further assembly and join together as fully mature ribosomes to synthesize proteins (see Figure 6-49).

Eukaryotic and bacterial ribosomes have similar structures and functions, being composed of one large and one small subunit that fit together to form a complete ribosome with a mass of several million daltons (Figure 6–65). The small subunit provides the framework on which the tRNAs are accurately matched to the codons of the mRNA, while the large subunit catalyzes the formation of the peptide bonds that link the amino acids together into a polypeptide chain.

When not actively synthesizing proteins, the two subunits of the ribosome are separate. They join together on an mRNA molecule, usually near its 5' end, to initiate the synthesis of a protein. The mRNA is then pulled through the ribosome, three nucleotides at a time. As its codons enter the core of the ribosome, the mRNA nucleotide sequence is translated into an amino acid sequence using the tRNAs as adaptors to add each amino acid in the correct sequence to the growing end of the polypeptide chain. When a stop codon is encountered, the ribosome releases the finished protein, and its two subunits separate again. These subunits can then be used to start the synthesis of another protein on the same or another mRNA molecule. On average, a eukaryotic ribosome adds about four amino acids to a polypeptide chain every second; the ribosomes of bacterial cells operate even faster, at a rate of about 20 amino acids per second.

Figure 6–65 A comparison of bacterial and eukaryotic ribosomes. Despite differences in the number and size of their rRNA and protein components, both bacterial and eukaryotic ribosomes have nearly the same structure and they function similarly. Although the 18S and 28S rRNAs of the eukaryotic ribosome contain many nucleotides not present in their bacterial counterparts, these extra nucleotides are present as multiple insertions that form extra domains and leave the basic structure of the rRNA largely unchanged.

MBOC7_ptr_ch06_321-396.indd 366 02/12/21 2:17 PM

mRNA-

binding site

To choreograph the many coordinated movements required for efficient translation, a ribosome contains four binding sites for RNA molecules: one is for the mRNA and three (called the A site, the P site, and the E site) are for tRNAs (Figure 6–66). A tRNA molecule is held tightly at the A and P sites only if its anticodon forms base pairs with a complementary codon (allowing for wobble) on the mRNA molecule that is threaded through the ribosome (Figure 6–67). The A

the ribosome. Each ribosome has one binding site for mRNA and three binding sites for tRNA: the A, P, and E sites (short for aminoacyl-tRNA, peptidyl-tRNA, and exit, respectively). (A) A bacterial ribosome viewed with the small subunit in the front (dark green) and the large subunit in the back (light green). Both the rRNAs and the ribosomal proteins are illustrated. tRNAs are shown bound in the E site (red), the P site (orange), and the A site (yellow). Although all three tRNA sites are shown occupied here, during the process of protein synthesis not more than two of these sites are thought to contain tRNA molecules at any one time (see Figure 6-68). (B) Large and small ribosomal subunits shown separately, and arranged as though the ribosome in panel A were opened like a book. (C) The entire ribosome in panel A rotated through 90° and viewed with the large subunit on top and small subunit on the bottom. (D) Schematic representation of the ribosome in the same orientation as that in panel C, which is how the ribosome will be depicted in subsequent figures. (A. B. and C. adapted from M.M. Yusupov et al., Science 292:883-896, 2001. With permission from AAAS.)

Figure 6–67 The path of mRNA (blue) through the small ribosomal subunit. The orientation is the same as that for the small subunit in the right-hand panel of Figure 6–66B, allowing the position of the three tRNA-binding sites to be compared to that of the mRNA shown here. MBOC7_ptr_ch06_321-396.indd 367 02/12/21 2:17 PM

Figure 6–68 Translating an mRNA molecule. Each amino acid added to the growing end of a polypeptide chain is selected by complementary base-pairing between the anticodon on its attached tRNA molecule and the next codon on the mRNA chain. Because only one of the many types of tRNA molecules in a cell can base-pair with each codon, the codon determines the specific amino acid to be added to the growing polypeptide chain. The four-step cycle shown is repeated over and over during the synthesis of a protein. In step 1, an aminoacyl-tRNA molecule binds to a vacant A site on the ribosome. In step 2, a new peptide bond is formed. In step 3, the large subunit translocates relative to the small subunit, leaving the two tRNAs in hybrid sites: P on the large subunit and A on the small, for one tRNA; E on the large subunit and P on the small, for the other tRNA. In step 4, the small subunit translocates carrying its mRNA a distance of three nucleotides through the ribosome. This "resets" the ribosome with a fully empty A site, ready for the next aminoacyl-tRNA molecule to bind. As indicated, the mRNA is translated in the 5'-to-3' direction, and the N-terminal end of a protein is made first, with each cycle adding one amino acid to the C-terminus of the polypeptide chain (Movie 6.7 and Movie 6.8).

and P sites are close enough together for their two tRNA molecules to be forced to form base pairs with adjacent codons on the mRNA molecule. This feature of the ribosome maintains the correct reading frame on the mRNA.

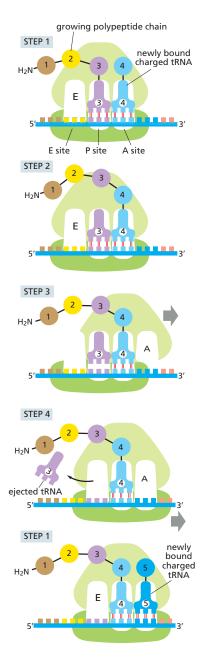

Once protein synthesis has been initiated, each new amino acid is added to the elongating chain in a cycle of reactions containing four major steps: tRNA binding (step 1), peptide bond formation (step 2), large subunit translocation (step 3), and small subunit translocation (step 4). As a result of the two translocation steps, the entire ribosome moves three nucleotides along the mRNA and is positioned to start the next cycle. Figure 6-68 illustrates this four-step process, beginning at a point at which three amino acids have already been linked together, and there is a tRNA molecule in the P site on the ribosome, covalently joined to the C-terminal end of the short polypeptide. In step 1, a tRNA carrying the next amino acid in the chain binds to the ribosomal A site by forming base pairs with the mRNA codon positioned there, so that the P site and the A site contain adjacent bound tRNAs. In step 2, the carboxyl end of the polypeptide chain is released from the tRNA at the P site (by breakage of the high-energy bond between the tRNA and its amino acid) and joined to the free amino group of the amino acid linked to the tRNA at the A site, forming a new peptide bond. This central reaction of protein synthesis is catalyzed by a peptidyl transferase contained in the large ribosomal subunit. In step 3, the large subunit moves relative to the mRNA held by the small subunit, thereby shifting the acceptor stems of the two tRNAs to the E and P sites of the large subunit. In step 4, another series of conformational changes moves the small subunit and its bound mRNA exactly three nucleotides, ejecting the spent tRNA from the E site and resetting the ribosome so it is ready to receive the next aminoacyl-tRNA. Step 1 is then repeated with a new incoming aminoacyl-tRNA, and so on.

This four-step cycle is repeated each time an amino acid is added to the polypeptide chain, as the chain grows from its amino to its carboxyl end.

Elongation Factors Drive Translation Forward and Improve Its Accuracy

The basic cycle of polypeptide elongation shown in outline in Figure 6–68 has an additional feature that makes translation especially efficient and accurate. Two *elongation factors* enter and leave the ribosome during each cycle, each hydrolyzing GTP to GDP and undergoing conformational changes in the process. These factors are called EF-Tu and EF-G in bacteria, and EF1 and EF2 in eukaryotes. **Figure 6–69** illustrates how their cycles of ribosome association, GTP hydrolysis, and ribosome dissociation contribute to the process of protein synthesis that was just outlined in Figure 6–68.

Under some conditions *in vitro*, ribosomes can be forced to synthesize proteins without the aid of these elongation factors and their GTP hydrolysis; but this synthesis is very slow, inefficient, and inaccurate. The coupling of GTP hydrolysis–driven changes in these elongation factors to transitions between

MBOC7_ptr_ch06_321-396.indd 368 02/12/21 2:17 PM

Figure 6–69 Detailed view of the translation cycle. The outline of translation presented in Figure 6–68 has been expanded to show the roles of the two elongation factors EF-Tu and EF-G, which drive translation in the forward direction. As explained in the text, EF-Tu provides two opportunities for proofreading of the codon–anticodon match. In this way, incorrectly paired tRNAs are preferentially rejected, and the accuracy of translation is improved. The binding of a molecule of EF-G to the ribosome and that elongation factor's subsequent hydrolysis of GTP lead to a rearrangement of the ribosome structure, moving the mRNA being decoded exactly three nucleotides through it (Movie 6.9).

different states of the ribosome speeds up protein synthesis enormously, ensuring that the many changes required occur only in the "forward" direction.

In addition to driving translation forward, EF-Tu increases its accuracy. As we discussed in Chapter 3, EF-Tu can simultaneously bind GTP and aminoacyl-tRNAs (see Figures 3–68 and 3–69), and it is in this form that the initial codon–anticodon interaction occurs in the A site of the ribosome. Because of the free-energy change associated with base-pair formation, a correct codon–anticodon match will bind more tightly than an incorrect interaction. However, this difference in affinity is relatively modest, and it cannot by itself account for the high accuracy of translation.

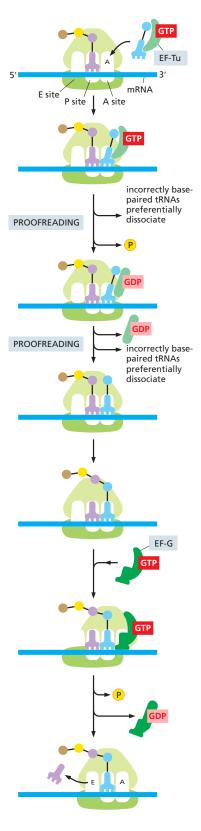

To increase the accuracy of aminoacyl-tRNA binding in the first step of protein synthesis, the ribosome and EF-Tu work together in the following ways. First, the 16S rRNA in the small subunit of the ribosome assesses the "correctness" of the codon–anticodon match by folding around it and probing its molecular details (Figure 6–70). When a correct match is found, the rRNA closes tightly around the codon–anticodon pair, causing a conformational change in the ribosome that triggers GTP hydrolysis by EF-Tu. Only when GTP is hydrolyzed does EF-Tu release its grip on the aminoacyl-tRNA and allow it to be used in protein synthesis. Because incorrect codon–anticodon matches do not readily trigger this conformational change, most of these errant tRNAs fall off the ribosome before they can be used in protein synthesis (see the first proofreading step in Figure 6–69).

After GTP is hydrolyzed and EF-Tu dissociates from the ribosome, there is a second opportunity for the ribosome to prevent an incorrect amino acid from being added to the growing chain. This arises due to a time delay before the amino acid carried by the tRNA moves into its correct position on the ribosome. Not only is this time delay shorter for correct than incorrect codon-anticodon pairs, but incorrectly matched tRNAs dissociate more rapidly than those that are correctly bound. Thus, most of the incorrectly bound tRNA molecules that remain (as well as a significant number of correctly bound molecules) will leave the ribosome without being used for protein synthesis (see the second proof-reading step in Figure 6–69). The two proofreading steps, acting in series, are largely responsible for the 99.99% accuracy of the ribosome in translating RNA into protein.

Induced Fit and Kinetic Proofreading Help Biological Processes Overcome the Inherent Limitations of Complementary Base-Pairing

We have seen in this and the previous chapter that DNA replication, repair, transcription, RNA splicing, and translation all rely on complementary base-pairing—G with C, and A with T (or U). However, if only the difference in hydrogen bonding is considered, a correct versus incorrect match should differ in affinity only by a factor of 10- to 100-fold. These processes have an accuracy much higher than can be accounted for by this difference. Although the mechanisms used to "squeeze out" additional specificity from complementary base-pairing differ from one process to the next, two principles exemplified by the ribosome appear to be general.

The first is **induced fit**. We have seen that, before an amino acid is added to a growing polypeptide chain, the ribosome folds around the codon-anticodon

MBOC7_ptr_ch06_321-396.indd 369 02/12/21 2:17 PM

Figure 6–70 Recognition of correct codon–anticodon matches by the small-subunit rRNA of the ribosome. Shown here is the interaction between a nucleotide of the small-subunit rRNA and the first nucleotide pair of a correctly paired codon–anticodon. Similar interactions form between other nucleotides of the rRNA and the second and third positions of the codon–anticodon pair. The small-subunit rRNA can form this network of hydrogen bonds only when an anticodon is correctly matched to a codon. As explained in the text, this codon–anticodon monitoring by the small-subunit rRNA increases the accuracy of protein synthesis. (From J.M. Ogle et al., *Science* 292:897–902, 2001. With permission from AAAS.)

interaction, and only when the match is correct is this folding completed and the reaction allowed to proceed. Thus, the codon-anticodon interaction is thereby checked twice—once by the initial complementary base-pairing and a second time by the folding of the ribosome, which depends on the correctness of the match. This same principle of induced fit is seen in transcription by RNA polymerase; here, an incoming nucleoside triphosphate initially forms a base pair with the template; at this point the enzyme folds around the base pair (thereby assessing its correctness) and, in doing so, creates the active site of the enzyme. The enzyme then covalently adds the nucleotide to the growing chain. Because their geometry is "wrong," incorrect base pairs impair this induced fit, and they are therefore likely to dissociate before being incorporated into the growing chain.

A second principle used to increase the specificity of complementary base-pairing is called **kinetic proofreading**. We have seen that after the initial codon-anticodon pairing and conformational change of the ribosome, GTP is hydrolyzed. This creates an irreversible step and starts the clock on a time delay during which the aminoacyl-tRNA moves into the proper position for catalysis. During this delay, those incorrect codon-anticodon pairs that have somehow slipped through the induced-fit scrutiny have a higher likelihood of dissociating than correct pairs. There are two reasons for this: (1) the interaction of the wrong tRNA with the codon is weaker, and (2) the delay is longer for incorrect matches than for correct matches.

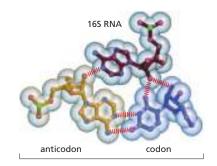

In its most general form, kinetic proofreading refers to a time delay that begins with an irreversible step such as ATP or GTP hydrolysis, during which an incorrect substrate is more likely to dissociate than a correct one. In this case, kinetic proofreading thus increases the specificity of complementary base-pairing far above what is possible from simple thermodynamic associations alone. In fact, kinetic proofreading can increase the fidelity of a reaction from one error in 10^{2x} , assuming that dissociation rate differences underlie the specificity of the molecular interactions involved.

The increase in specificity produced by kinetic proofreading comes at an energetic cost in the form of ATP or GTP hydrolysis. Kinetic proofreading operates in biological processes that range from DNA replication and DNA repair to RNA splicing and protein translation, helping to make life possible by greatly increasing the specificity of biochemical reactions.

Accuracy in Translation Requires a Large Expenditure of Free Energy

Translation by the ribosome is a compromise between the opposing constraints of accuracy and speed. We have seen, for example, that the accuracy of translation (one mistake per 10^4 amino acids joined) requires time delays each time a new amino acid is added to a growing polypeptide chain, producing an overall speed of translation of 20 amino acids incorporated per second in bacteria. Mutant bacteria with a specific alteration in the small ribosomal subunit have longer delays and translate mRNA into protein with an accuracy considerably higher than this; however, protein synthesis is so slow in these mutants that the bacteria are barely able to survive.

We have also seen that attaining the observed accuracy of protein synthesis requires the expenditure of a great deal of free energy; this is expected, because,

MBOC7_ptr_ch06_321-396.indd 370 02/12/21 2:17 PM

as discussed in Chapter 2, there is a price to be paid for any increase in order in the cell. In most cells, protein synthesis consumes more energy than any other biosynthetic process. At least four high-energy phosphate bonds are split to make each new peptide bond: two are consumed in charging a tRNA molecule with an amino acid (see Figure 6–58), and two more drive steps in the cycle of reactions occurring on the ribosome during protein synthesis itself (see Figure 6–69). In addition, extra energy is consumed each time that an incorrect amino acid linkage is hydrolyzed by a tRNA synthetase (see Figure 6–61) and whenever an incorrect tRNA enters the ribosome, triggers GTP hydrolysis, and is rejected (see Figure 6–69). To be effective, any proofreading mechanism must also allow an appreciable fraction of correct interactions to be removed, and this adds an even greater energy cost to proofreading.

The Ribosome Is a Ribozyme

The ribosome is a large complex composed, by mass, of two-thirds RNA and one-third protein. The determination, in 2000, of the entire three-dimensional conformation of its large and small subunits was a major triumph of modern structural biology. The ribosomal RNAs are folded into highly compact, precise three-dimensional structures that form the compact core of the ribosome and determine its overall shape (Figure 6–71). These observations confirmed earlier evidence that rRNAs—and not proteins—are responsible for the ribosome's overall structure, its ability to position tRNAs on the mRNA, and its catalytic activity in forming covalent peptide bonds.

In marked contrast to the central positions of the rRNAs, the ribosomal proteins are generally located on the surface and fill in the gaps and crevices of the

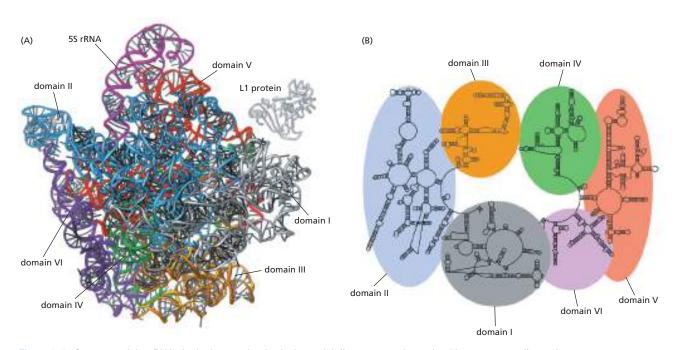

Figure 6–71 Structure of the rRNAs in the large subunit of a bacterial ribosome, as determined by x-ray crystallography. (A) Three-dimensional conformations of the large-subunit rRNAs (5S and 23S) as they appear in the ribosome. One of the protein subunits of the ribosome (L1) is also shown as a reference point, because it forms a characteristic protrusion on the ribosome. (B) Schematic diagram of the secondary structure of the 23S rRNA, showing the extensive network of base-pairing. The structure has been divided into six "domains" whose colors correspond to those in A. The secondary-structure diagram is highly schematized to represent as much of the structure as possible in two dimensions. To do this, several discontinuities in the RNA chain have been introduced, although in reality the 23S rRNA is a single RNA molecule. For example, the base of domain III is continuous with the base of domain IV even though a gap appears in the diagram. (Adapted from N. Ban et al., Science 289:905–920, 2000. With permission from AAAS.)

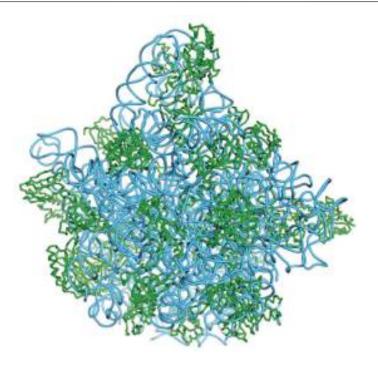

Figure 6–72 Location of the protein components of the bacterial large ribosomal subunit. The rRNAs (5S and 23S) are shown in *blue* and the proteins of the large subunit in *green*. This view is toward the backside of the ribosome relative to Figure 6–66A; the interface with the small subunit is facing into the page. (PDB code: 1FFK.)

folded RNA (**Figure 6–72**). Some of these proteins send out extended regions of polypeptide chain that penetrate short distances into holes in the RNA core (**Figure 6–73**). The main role of the ribosomal proteins seems to be to stabilize the RNA core, while permitting the changes in rRNA conformation that are necessary for this RNA to catalyze efficient protein synthesis. As discussed earlier, eukaryotic ribosome assembly takes place primarily in the nucleolus; ribosomal proteins are synthesized in the cytoplasm and brought to the nucleolus largely in unfolded form, escorted by specific *chaperones*. Only as ribosomes are assembled do their proteins assume their final, folded state, which is highly dependent on the rRNA structural framework.

Not only are the A, P, and E binding sites for tRNAs formed primarily by ribosomal RNAs, but the catalytic site for peptide bond formation is also formed by RNA, as the nearest amino acid is located more than 1.8 nm away. This discovery came as a surprise to biologists because, unlike proteins, RNA does not contain easily ionizable functional groups that can be used to catalyze sophisticated reactions such as peptide bond formation. Moreover, metal ions, which are often used by RNA molecules to catalyze chemical reactions (as is the case for RNA splicing, discussed earlier), were not observed at the active site of the ribosome. Instead, it is believed that the 23S rRNA forms a highly structured pocket that, through a network of hydrogen bonds, precisely orients the two reactants (the growing peptide chain and an aminoacyl-tRNA) and thereby greatly accelerates their covalent joining. An additional surprise came from the discovery that the tRNA in the P site contributes an important -OH group to the active site and participates directly in the catalysis. This mechanism may ensure that catalysis occurs only when the P-site tRNA is properly positioned in the ribosome.

RNA molecules that possess catalytic activity are known as **ribozymes**. We saw earlier in this chapter that the spliceosome is also a ribozyme, although its catalytic site is formed from several different RNA molecules rather than a single RNA, as is the case in the ribosome. In the final section of this chapter, we consider what the ability of RNA molecules to function as catalysts might mean for the early evolution of living cells. For now, we merely note that there is good reason to suspect that RNA rather than protein molecules served as the first catalysts for living cells. Thus the ribosome, with its RNA core, is suspected to be a relic of an earlier time in life's history—when protein synthesis evolved in cells that were run almost entirely by ribozymes.

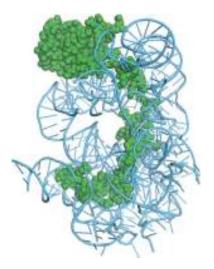

Figure 6–73 How proteins help shape ribosomal RNA. Shown here is the L15 protein in the large subunit of the bacterial ribosome. The globular domain of the protein lies on the surface of the ribosome, and an extended region penetrates deeply into the RNA core of the ribosome. The protein is shown in *green* and a portion of the ribosomal RNA core is shown in *blue*. (From D. Klein et al., *J. Mol. Biol.* 340:141–177, 2004. PDB code: 1S72.)

MBOC7_ptr_ch06_321-396.indd 372 02/12/21 2:17 PM

Nucleotide Sequences in mRNA Signal Where to Start Protein Synthesis

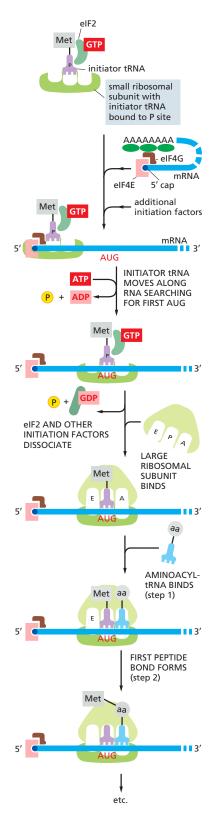

The initiation and termination of translation share properties of the translation elongation cycle described earlier but have additional features. The site at which protein synthesis begins on the mRNA is especially crucial, because it sets the reading frame for the whole length of the message. An error of one nucleotide either way at this stage would cause every subsequent codon in the message to be misread, resulting in a nonfunctional protein with a garbled sequence of amino acids. The initiation step is also important because, for most genes, it is the last point at which the cell can decide whether the mRNA is to be translated to produce a protein. The efficiency of this step is thus one determinant of the rate at which any particular protein will be synthesized. We shall see in Chapter 7 how regulation of this step occurs.

The translation of an mRNA usually begins with the codon AUG, and a special tRNA is required to start translation. This **initiator tRNA** always carries the amino acid methionine (in bacteria, a modified form of methionine—formylmethionine—is used), with the result that all newly made proteins have methionine as the first amino acid at their N-terminus, the end of a protein that is synthesized first. (This methionine is usually removed later by a specific protease.) The initiator tRNA is specially recognized by initiation factors because it has a nucleotide sequence distinct from that of the tRNA that normally carries methionine.

In eukaryotes, the initiator tRNA-methionine complex (Met-tRNAi) is first loaded into the small ribosomal subunit along with additional proteins called **eukaryotic initiation factors**, or **eIFs**. Of all the aminoacyl-tRNAs in the cell, only the methionine-charged initiator tRNA is capable of tightly binding the small ribosomal subunit without the complete ribosome being present, and unlike other tRNAs, it binds directly to the P site (**Figure 6–74**). Next, the small ribosomal subunit binds to the 5' end of an mRNA molecule, which is recognized by virtue of its 5' cap that has previously bound two initiation factors, eIF4E and eIF4G (see Figure 6–40). The small ribosomal subunit then moves forward (5' to 3') along the mRNA, searching for the first AUG; additional initiation factors that act as ATP-powered helicases facilitate this movement. In about 90% of mRNAs, translation begins at the first AUG encountered by the small subunit. At this point, the initiation factors dissociate, allowing the large ribosomal subunit to assemble with the complex and complete the ribosome. The initiator tRNA remains at the P site, leaving the A site vacant. Protein synthesis is therefore ready to begin (see Figure 6–69).

The nucleotides immediately surrounding the start site in eukaryotic mRNAs influence the efficiency of AUG recognition during the above scanning process. If this recognition site differs substantially from the consensus recognition sequence (5'-ACCAUGG-3', known as the Kozak sequence after its discoverer), scanning ribosomal subunits will sometimes ignore the first AUG codon in the mRNA and move to the second or third AUG codon instead. Cells frequently use this phenomenon, known as "leaky scanning," to produce two or more proteins, differing in their N-termini, from the same mRNA molecule. This mechanism allows some genes to produce the same protein with and without a signal sequence attached at its N-terminus, for example, so that the protein is directed to two different compartments in the cell.

Figure 6–74 The initiation of protein synthesis in eukaryotes. Only three of the many translation initiation factors required for this process are shown. In addition to an initiating AUG codon, efficient translation initiation requires the poly-A tail of the mRNA bound by poly-A-binding proteins. In this way, the translation apparatus ascertains that both ends of the mRNA are intact before initiating protein synthesis. The communication between the 5' and 3' ends of the mRNA is mediated, at least in part, by interactions between the poly-A-binding proteins and eIF4G, as shown. This interaction appears to be transient; once translation begins, the 5' and 3' ends of the mRNA dissociate. Although only one GTP-hydrolysis event is shown in the figure, a second is known to occur just before the large and small ribosomal subunits join. In the last two steps shown in the figure, the ribosome has begun the standard elongation cycle, depicted in Figure 6–68.

MBOC7_ptr_ch06_321-396.indd 373 02/12/21 2:17 PM

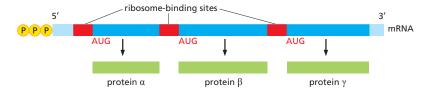

Figure 6–75 Structure of a typical bacterial mRNA molecule. Unlike eukaryotic ribosomes, which typically require a capped 5' end on the mRNA, prokaryotic ribosomes initiate translation at ribosome-binding sites (Shine–Dalgarno sequences), which can be located anywhere along an mRNA molecule. This property of their ribosomes permits bacteria to synthesize more than one type of protein from a single mRNA molecule.

Although protein synthesis in eukaryotes usually begins at an AUG codon, there are exceptions. For some proteins, translation begins at a codon that differs from AUG by a single base, particularly in the third position. In these cases, the normal initiator tRNA (carrying methionine) is used, but because the codon-anticodon match is not perfect, translation of these proteins is typically less efficient than translation of those that begin with an AUG. This deviation from the norm allows the cell to make very low amounts of some proteins compared with others. In a few rare cases, however, translation can begin with an entirely different tRNA. For example, a few proteins begin with a CUG codon, and a leucine tRNA (the perfect codon-anticodon match) begins translation with leucine as the first amino acid. In the next chapter, we will discuss how these and other deviations from the standard translation initiation process can be used to regulate protein synthesis in response to signals from the environment.

The mechanism for selecting a start codon in bacteria is fundamentally different from that in eukaryotes. Bacterial mRNAs have no 5' caps to signal the ribosome where to begin searching for the start of translation. Instead, each bacterial mRNA contains a specific ribosome-binding site (called the Shine-Dalgarno sequence, named after its discoverers) that is located a few nucleotides upstream of the AUG at which translation is to begin. This nucleotide sequence, with the consensus 5'-AGGAGGU-3', forms base pairs with the 16S rRNA of the small ribosomal subunit to position the initiating AUG codon in the ribosome. A set of translation initiation factors orchestrates this interaction, as well as the subsequent assembly of the large ribosomal subunit to complete the ribosome.

A bacterial ribosome can readily assemble directly on a start codon that lies in the interior of an mRNA molecule, so long as a ribosome-binding site precedes it by several nucleotides. As a result, bacterial mRNAs are often *polycistronic*; that is, they encode several entirely different proteins, each of which is translated from the same mRNA molecule (Figure 6–75). In contrast, a eukaryotic mRNA generally encodes only a single protein, or more accurately, a single set of closely related proteins. We will see in the next chapter that there are some exceptions to this generalization, where a eukaryotic mRNA can carry information for two or more distinct proteins.

Stop Codons Mark the End of Translation

The end of the protein-coding message is signaled by the presence of one of three *stop codons* (UAA, UAG, or UGA) (see Figure 6–52). These are not recognized by a tRNA and do not specify an amino acid, but instead signal to the ribosome to stop translation. Proteins known as *release factors* bind to any ribosome with a stop codon positioned in the A site, forcing the peptidyl transferase in the ribosome to catalyze the addition of a water molecule instead of an amino acid to the peptidyl-tRNA (Figure 6–76). This reaction frees the carboxyl end of the growing polypeptide chain from its attachment to a tRNA molecule, and as only this attachment normally holds the growing polypeptide to the ribosome, the completed protein chain is released into the cytoplasm. The ribosome then releases its bound mRNA molecule and separates into the large

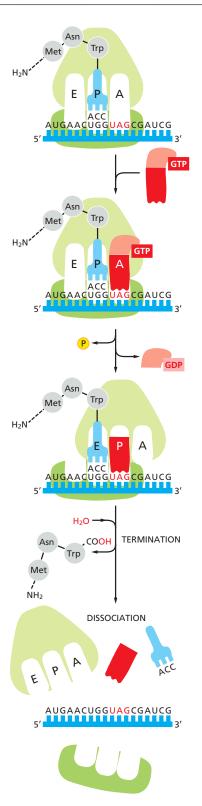

Figure 6–76 The final phase of eukaryotic protein synthesis. The binding of a two-subunit release factor to an A site bearing a stop codon terminates translation. Release factors are proteins that resemble tRNAs in their overall shape and charge distribution.

MBOC7_ptr_ch06_321-396.indd 374 02/12/21 2:17 PM

and small subunits. These subunits can then assemble on this or another mRNA molecule to begin a new round of protein synthesis.

During translation, the nascent polypeptide moves through a large, waterfilled exit tunnel (approximately $10~\rm nm \times 1.5~\rm nm$) in the large subunit of the ribosome. The walls of this tunnel, made primarily of 23S rRNA, are a patchwork of tiny hydrophobic surfaces embedded in a more extensive hydrophilic surface. This structure is not complementary to any peptide and thus provides a "Teflon" coating through which a polypeptide chain can easily slide. We will see later in the chapter that, although some protein folding can occur in the exit tunnel, most of it takes place as the newly synthesized protein emerges from the ribosome.

Proteins Are Made on Polyribosomes

The synthesis of most protein molecules takes between 20 seconds and several minutes. During this short period, multiple initiations generally take place on each mRNA molecule being translated. As soon as the preceding ribosome has translated enough of the nucleotide sequence to move out of the way, the 5' end of the mRNA is threaded into a new ribosome. For this reason, most mRNA molecules, and particularly those being translated at high rates, are found in the form of *polyribosomes* (or *polysomes*): large cytoplasmic assemblies made up of several ribosomes spaced as close as 80 nucleotides apart along a single mRNA molecule (Figure 6–77). The multiple initiations allow the cell to make many more protein molecules in a given time than would be possible if each protein had to be completed before the next could start. It is estimated that, in a typical human cell, about one-third of the mRNAs lack ribosomes altogether, and the remainder have 10–20 ribosomes per mRNA.

There Are Minor Variations in the Standard Genetic Code

As discussed in Chapter 1, the genetic code (shown in Figure 6-52) applies to all three major branches of life, providing important evidence for the common ancestry of all life on Earth. Although rare, there are exceptions to this code. For example, *Candida albicans*, the most prevalent fungal pathogen of humans, translates the codon CUG as serine, whereas nearly all other organisms translate it as leucine. And in some ciliates (unicellular eukaryotes that propel themselves using cilia), the three conventional stop codons specify particular amino

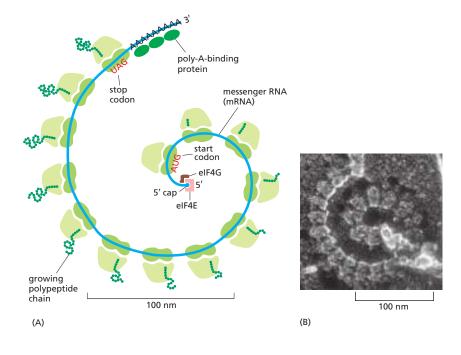

Figure 6-77 A polyribosome.

MBOC7_ptr_ch06_321-396.indd 375 02/12/21 2:17 PM

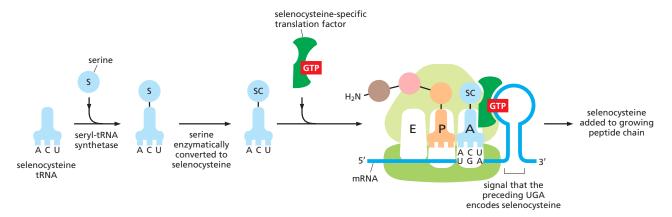

Figure 6–78 Incorporation of selenocysteine into a growing polypeptide chain. A specialized tRNA is charged with serine by the normal seryl-tRNA synthetase, and the serine is subsequently converted enzymatically to selenocysteine. A specific RNA structure in the mRNA (a stem-and-loop structure with a particular nucleotide sequence) signals that selenocysteine is to be inserted at the neighboring UGA codon. As indicated, this event requires the participation of a selenocysteine-specific translation factor. After the addition of selenocysteine, translation continues until a conventional stop codon is encountered.

acids, and the end of translation is instead signaled by the 3' end of the mRNA. Mitochondria of many species (which have their own genomes and encode much of their translational apparatus) routinely deviate from the standard code. For example, in mammalian mitochondria AUA is translated as methionine, whereas in the cytosol of the cell it is translated as isoleucine (see Table 14–4, p. 864).

A common type of variation, sometimes called *translation recoding*, is used to incorporate selenocysteine into proteins. In this case, neighboring nucleotide sequence information present in an mRNA changes the meaning of the genetic code at a particular site in the mRNA molecule. The standard code allows cells to manufacture proteins using only 20 amino acids. However, bacteria, archaea, and eukaryotes have selenocysteine available as a twenty-first amino acid that can be incorporated directly into a growing polypeptide chain. Selenocysteine, which contains a selenium atom in place of the sulfur atom of cysteine, is essential for the efficient function of a variety of enzymes. It is enzymatically produced from a serine attached to a special tRNA molecule that base-pairs with the UGA codon, a codon normally used to signal a translation stop. The mRNAs for those proteins in which selenocysteine is to be inserted at a UGA codon carry an additional nearby nucleotide sequence in the mRNA that triggers this recoding event (Figure 6-78).

Inhibitors of Prokaryotic Protein Synthesis Are Useful as Antibiotics

Many of the most effective antibiotics used in modern medicine are compounds that inhibit bacterial protein synthesis. Although chemists have improved these compounds, most were originally isolated from bacteria and fungi, where they are thought to have arisen over evolutionary time because of the warfare between competing microbes. Because many of these drugs are selective for bacterial ribosomes, humans can take high dosages without undue toxicity. Many of these antibiotics lodge in pockets in the ribosomal RNAs and simply "gum up" the smooth operation of the ribosome; others block specific parts of the ribosome such as the exit tunnel (Figure 6–79). Table 6–4 lists some common antibiotics of this kind, along with several other inhibitors of protein synthesis, some of which act on eukaryotic cells and therefore cannot be used as antibiotics.

Because they block specific steps in the processes that lead from DNA to protein, many of the compounds listed in Table 6–4 are useful for cell biological studies. Among the most commonly used drugs in such investigations are *chloramphenicol*, *cycloheximide*, and *puromycin*, all of which specifically inhibit

MBOC7_ptr_ch06_321-396.indd 376 02/12/21 2:17 PM

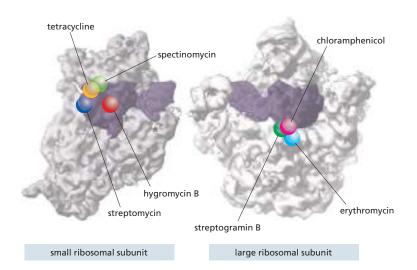

Figure 6-79 Binding sites for antibiotics on the bacterial ribosome. The small (left) and large (right) subunits of the ribosome are arranged as though the ribosome has been opened like a book. Antibiotic-binding sites are marked with colored spheres. and the bound tRNA molecules are shown in purple (see Figure 6-66). Most of the antibiotics shown bind directly to pockets formed by the ribosomal RNA molecules. Hygromycin B induces errors in translation, spectinomycin blocks the translocation of the peptidyl-tRNA from the A site to the P site, and streptogramin B prevents elongation of nascent peptides. Table 6-4 lists the inhibitory mechanisms of additional commonly used antibiotics. (Adapted from J. Poehlsgaard and S. Douthwaite, Nat. Rev. Microbiol. 3:870-881, 2005.)

02/12/21 2:17 PM

protein synthesis. In a eukaryotic cell, for example, chloramphenicol inhibits protein synthesis on ribosomes only in mitochondria (and in chloroplasts in plants), presumably reflecting the bacterial origins of these organelles (discussed in Chapter 14). Cycloheximide, in contrast, affects only ribosomes in the cytoplasm. Puromycin is especially interesting because it is a structural analog of a tRNA molecule linked to an amino acid and is therefore a fascinating example of molecular mimicry. The ribosome mistakes it for an authentic charged tRNA and covalently incorporates it at the C-terminus of the growing peptide chain, causing premature termination and release of the polypeptide. As might be expected, puromycin inhibits protein synthesis in both bacteria and eukaryotes.

these antibiotics can have a deleterious effect on human mitochondria.

MBOC7_ptr_ch06_321-396.indd 377

TABLE 6-4 Inhibitors of Protein or RNA Synthesis								
Inhibitor	Specific effect							
Acting only on bacteria								
Tetracycline	Blocks binding of aminoacyl-tRNA to the A site of the ribosome							
Streptomycin	Prevents the transition from translation initiation to chain elongation and also causes miscoding							
Chloramphenicol	Blocks the peptidyl transferase reaction on ribosomes (step 2 in Figure 6-68)							
Erythromycin	Binds in the exit tunnel of the ribosome and thereby inhibits elongation of the peptide chain							
Rifamycin	Blocks initiation of RNA chains by binding to RNA polymerase (prevents RNA synthesis)							
Acting on bacteria and eukaryotes								
Puromycin	Causes the premature release of nascent polypeptide chains by its addition to the growing chain end							
Actinomycin D	Binds to DNA and blocks the movement of RNA polymerase (prevents RNA synthesis)							
Acting on eukaryotes but not bacteria								
Harringtonine	Blocks the A site of the 60S ribosome subunit after translation initiation, but before elongation (see Figure 6–74)							
Anisomycin	Blocks the peptidyl transferase reaction on ribosomes (step 2 in Figure 6-68)							
α-Amanitin	Blocks mRNA synthesis by binding preferentially to RNA polymerase II							
The ribosomes of eukaryotic mitochondria (and chloroplasts) often resemble those of bacteria in their sensitivity to inhibitors. Therefore, some of								

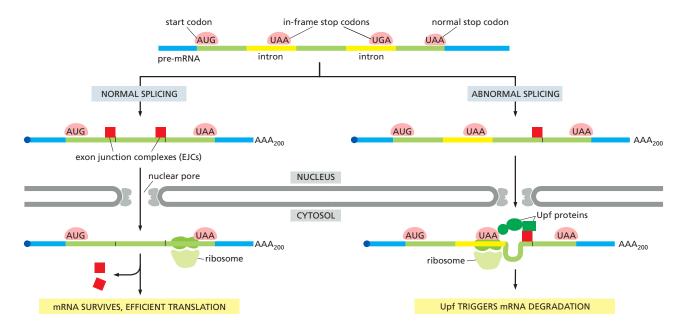

Quality-Control Mechanisms Act to Prevent Translation of Damaged mRNAs

In eukaryotes, mRNA production involves both transcription and a series of elaborate RNA-processing steps; as we have seen, these take place in the nucleus, segregated from ribosomes, and only when the processing is complete and the mRNAs deemed "export-ready" are they transported to the cytosol to be translated (see Figure 6–40). However, this scheme is not foolproof, and some incorrectly processed mRNAs are inadvertently sent to the cytosol. In addition, mRNAs that were flawless when they left the nucleus can become broken or otherwise damaged in the cytosol. The danger of translating damaged or incompletely processed mRNAs (which would produce truncated or otherwise aberrant proteins) is apparently so great that the cell has several backup measures to prevent this from happening. To avoid translating broken mRNAs, for example, the 5' cap and the poly-A tail are both recognized by the translation initiation machinery before translation begins (see Figure 6–74).

One of the most powerful mRNA surveillance systems, called **nonsense-mediated mRNA decay**, prevents defective mRNAs from escaping from the nuclear envelope. This mechanism is brought into play when the cell determines that an mRNA molecule has a nonsense (stop) codon (UAA, UAG, or UGA) in the "wrong" place. This situation is likely to arise in an mRNA molecule that has been improperly spliced, because aberrant splicing will usually result in the random introduction of a nonsense codon into the reading frame of the mRNA—especially in organisms, such as humans, that have large introns.

The nonsense-mediated mRNA decay mechanism begins as an mRNA molecule is being transported from the nucleus to the cytosol. As soon as its 5' end emerges from a nuclear pore, the mRNA is met by a ribosome, which begins to translate it. As translation proceeds, the exon junction complexes (EJCs) that are bound to the mRNA at each completed splice site (see Figure 6–29) are displaced by the moving ribosome. The normal stop codon should lie within the last exon, so by the time the ribosome reaches it, the mRNA should be free of EJCs. In this case, the mRNA "passes inspection" and is released to the cytosol where it can be translated in earnest (Figure 6–80). However, if the ribosome reaches a stop codon earlier, when EJCs remain bound, the mRNA molecule is rapidly degraded. In this way, the first round of translation allows the cell to test the fitness of each mRNA molecule as it exits the nucleus.

Figure 6-80 Nonsense-mediated mRNA decay. As shown on the right, the failure to correctly splice a pre-mRNA often introduces a premature stop codon into the reading frame for the protein. These abnormal mRNAs are destroyed by the nonsense-mediated decay mechanism. To activate this mechanism, an mRNA molecule, bearing the exon junction complexes (EJCs) that mark successfully completed splices, is quickly met by a ribosome that performs a "test" round of translation. As the mRNA passes through the ribosome, the EJCs are stripped off, and successful mRNAs are released to undergo multiple rounds of translation (left side). However, if an in-frame stop codon is encountered before the final EJC is reached (right side), the mRNA undergoes nonsense-mediated decay. which is triggered by the Upf proteins (green that bind to each EJC. This mechanism ensures that nonsensemediated decay is triggered only when the premature stop codon is in the same reading frame as that of the normal protein. (Adapted from J. Lykke-Andersen et al., Cell 103:1121-1131, 2000.)

MBOC7_ptr_ch06_321-396.indd 378 02/12/21 2:17 PM

Nonsense-mediated decay may have been especially important in evolution, allowing eukaryotic cells to more easily explore new genes formed by DNA rearrangements, mutations, or alternative patterns of splicing—by selecting only those mRNAs for translation that can produce a full-length protein. Nonsense-mediated decay is also important in cells of the developing immune system, where the extensive DNA rearrangements that occur (see Figure 24–28) often generate premature termination codons. The surveillance system degrades the mRNAs produced from these faulty rearranged genes, thereby avoiding the potential toxic effects of truncated proteins.

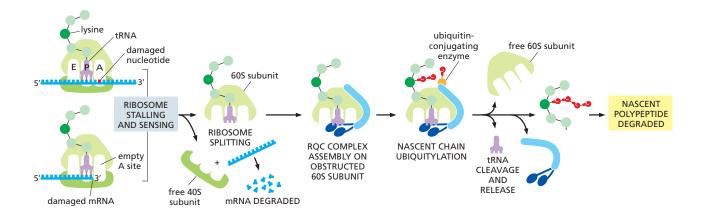

The nonsense-mediated surveillance pathway also plays an important role in mitigating the symptoms of many inherited human diseases. As we have seen, inherited diseases are usually caused by mutations that spoil the function of a key protein, such as hemoglobin or one of the blood-clotting factors. Approximately one-third of all genetic disorders in humans result from mutations that change a normal codon into a stop (nonsense) codon or mutations (such as frameshift mutations or splice-site mutations) that place nonsense mutations into the gene's reading frame. In individuals that carry one mutant and one functional gene, nonsense-mediated decay eliminates the aberrant mRNA, and thereby prevents a potentially toxic protein from being made. Without this safeguard, individuals with one functional and one mutant "disease gene" would likely suffer much more severe symptoms.

Stalled Ribosomes Can Be Rescued

Even when an mRNA molecule passes all the initial inspections, additional problems can arise as it is being translated in the cytosol, and the cell has several ways to deal with them. In a sense, translating ribosomes constantly act as sensors for mRNA "health," and when one stalls, those upstream of it collide with it (and each other), generating a string of nonfunctioning ribosomes. For example, if an mRNA becomes broken and thereby lacks an in-frame stop codon, the ribosome will translate to the 3' end of the RNA but will not be released. Damaged RNA bases (which cannot form stable codon-anticodon interactions), stable mRNA secondary structures, and stretches of rare codons (that is, codons that have very low concentrations of their matching tRNAs) can also stall ribosomes. Although some of these problems can be overcome simply by allowing the ribosome sufficient time, many are dealt with more aggressively by a set of mechanisms known collectively as ribosome-associated quality control (Figure 6-81). Although the detailed pathways differ for the different types of barriers that stall ribosomes, three steps are common: the mRNA is degraded, the nascent protein is degraded, and the stalled ribosome is disengaged so it can be used again.

All of these steps make conceptual sense: the first removes a damaged mRNA so it will cause no further problems, the second prevents an aberrant protein from

Figure 6-81 Eukaryotic ribosomeassociated quality control. A ribosome can stall at damaged bases, rare codons, or other barriers (top left); here, the signal to correct the problem is generated by a collision between the stalled ribosome and the one immediately upstream of it. Ribosomes also stall at the ends of broken mRNAs (bottom left); in this case the empty A site is the cue for rescue. Although the mechanisms differ somewhat depending on the nature of the stall, in general a stalled ribosome is split (immediately releasing the 40S subunit for reuse), the mRNA is degraded, and the 60S subunit, which contains a tRNA lodged in its P site attached to a partially synthesized protein, is rescued by the ribosome quality control (RQC) complex (indicated in blue). The nascent protein is ubiquitylated and the tRNA cleaved from it, freeing the protein from the ribosome. As will be described shortly, this ubiquitylation serves as a signal for the protein to be destroyed. (Adapted from C.A.P. Joazeiro, Nat. Rev. Mol. Cell Biol. 20:368-383, 2019. With permission from Springer Nature.)

MBOC7_ptr_ch06_321-396.indd 379 02/12/21 2:17 PM

being released into the cell, and the third rescues a valuable RNA-protein machine complex that requires many resources to assemble. It is estimated that each ribosome in a human cell synthesizes approximately 3000 protein molecules, and the ability to rescue stalled ribosomes (as opposed to degrading them) makes a major contribution to their longevity.

The Ribosome Coordinates the Folding, Enzymatic Modification, and Assembly of Newly Synthesized Proteins

The process of gene expression is not over when the genetic code has been used to create the sequence of amino acids that constitutes a protein. To be useful to the cell, this new polypeptide chain must fold up into its unique three-dimensional conformation, bind any small-molecule cofactors required for its activity, be appropriately modified by protein kinases and other protein-modifying enzymes, and assemble correctly with the other protein subunits with which it functions (Figure 6-82).

The information needed for all of the steps listed above is ultimately contained in the sequence of amino acids that the ribosome produces when it translates an mRNA molecule into a polypeptide chain. As discussed in Chapter 3, when a protein folds into a compact structure, it buries most of its hydrophobic residues in an interior core. In addition, large numbers of noncovalent interactions form between various parts of the molecule. It is the sum of all of these energetically favorable arrangements that determines the final folding pattern of the polypeptide chain—as the conformation of lowest free energy (see p. 121).

For some proteins, folding begins in the exit tunnel of the ribosome. Although too narrow to accommodate the folding of complete proteins, the exit tunnel widens toward its end, and simple structures such as short α helices can form as the growing peptide is pushed through by the translation process. But the major portion of protein folding begins as the protein emerges from the ribosome exit tunnel, where the new protein is also met by enzymes that modify its N-terminus. We saw earlier in the chapter that translation of a typical mRNA always begins with a methionine (see Figure 6–74); however, in most eukaryotic proteins (70% of cytosolic proteins), this amino acid is cleaved off and the resulting N-terminus modified by acetylation. The enzymes that carry out these and other modifications have a weak affinity for the ribosome and "hover" (that is, rapidly associate and dissociate with the ribosome) near the exit tunnel—in position to act on the growing protein as it first emerges.

Molecular Chaperones Help Guide the Folding of Most Proteins

Most proteins on their own do not fold correctly during their synthesis; instead, they require a special class of proteins called **molecular chaperones** to do so. Molecular chaperones are useful for cells because there are many different folding paths available to an unfolded or partially folded protein. Without these chaperones, some of these pathways would not lead to the correctly folded (and most stable) form; instead, the protein would become "kinetically trapped" in structures that are off-pathway. Some of these off-pathway conformations would aggregate and be left as irreversible dead ends, producing nonfunctional (and potentially dangerous) structures. As we will see shortly, chaperones help solve this problem by repeatedly binding and releasing a protein's partially folded regions, giving them many chances to fold correctly.

Many molecular chaperones are called *heat-shock proteins* (designated *hsp*), because they are synthesized in dramatically increased amounts after a brief exposure of cells to an elevated temperature (for example, 42°C for cells that normally live at 37°C). This increase reflects the operation of a feedback system that responds to an increase in misfolded proteins (such as those produced by elevated temperatures) by boosting the synthesis of the chaperones that help these proteins refold. However, even under normal conditions, the heat-shock proteins

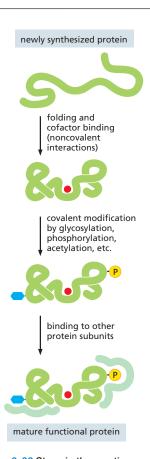

Figure 6-82 Steps in the creation of a functional protein. As indicated, translation of an mRNA sequence into an amino acid sequence on the ribosome is not the end of the process of forming a protein. To function, the completed polypeptide chain must fold correctly into its three-dimensional conformation, bind any cofactors required, and assemble with its partner protein chains, if any. Noncovalent bond formation drives these changes. As indicated, many proteins also require covalent modifications of selected amino acids. Although the most frequent modifications are protein alvcosylation and protein phosphorylation, more than 200 different types of covalent modifications are known (see pp. 175-176). As described in the text, many of these steps begin while the protein is still being synthesized.

MBOC7_ptr_ch06_321-396.indd 380 02/12/21 2:17 PM

are so abundant that all proteins should be considered to be embedded in a rich soup of these molecules.

There are several major families of molecular chaperones, including the hsp60 and hsp70 proteins, with different family members functioning in different organelles. Thus, as discussed in Chapter 12, mitochondria contain their own hsp60 and hsp70 molecules that are distinct from those that function in the cytosol, and a special hsp70 (called *BiP*) helps to fold proteins in the endoplasmic reticulum

In all, humans have thirteen hsp70 proteins, including a group that associates with the ribosome and helps nearly all emerging proteins fold correctly. They do this by rapidly binding and releasing short sequences (approximately five amino acids each) as a new protein is pushed through the ribosome exit tunnel. When one of these chaperones encounters a sequence rich in hydrophobic amino acids, which typically form the core of folded proteins, it clamps down on it, thereby delaying the folding of the emerging protein until enough of it has been made to begin to fold correctly. Hydrophobic stretches that emerge early from the ribosome are thereby prevented from aggregating with other hydrophobic surfaces until they can be properly folded into the core of the nascent protein. The hsp70 clamping and release reactions required are regulated by ATP hydrolysis catalyzed by the nucleotide-binding domain of hsp70 (Figure 6-83).

Most proteins are at least partially folded when they are released from the ribosome, but the final folding for many occurs as additional hsp70 molecules associate with them away from the ribosome. By undergoing multiple cycles of ATP hydrolysis, these hsp70 molecules allow proteins to complete their folding.

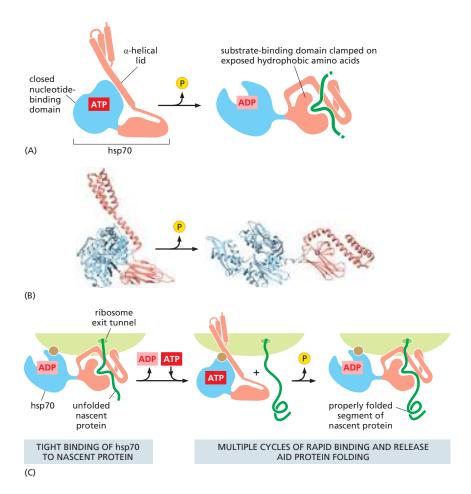

Figure 6-83 The hsp70 family of molecular chaperones. These are among the most abundant of all proteins. constituting several percent of total cell protein, and they thus play prominent roles inside the cell. (A) Short stretches of hydrophobic amino acids that are abnormally exposed in misfolded proteins (green) trigger the hydrolysis of ATP to ADP, causing hsp70 to close down on its substrate, trapping it in an extended conformation. The rebinding of another molecule of ATP will open the hsp70 "clamp." releasing the substrate in its extended form. Repeated cycles of hsp70 clamping and release, often involving multiple hsp70 molecules on the same target, help fold the target protein by keeping its hydrophobic regions from aggregating. This can continue until these regions are assimilated into the core of the properly folded protein. (B) The threedimensional structures of hsp70 that produce the mechanism schematically illustrated in A. (C) Some hsp70 family members bind to the ribosome and act early in the life of a newly synthesized protein. Aided by other proteins (not shown), ATP-bound hsp70 molecules rapidly bind and release the nascent protein as it emerges from the ribosome. (B, PDB codes: 2KHO and 4JNE.)

MBOC7_ptr_ch06_321-396.indd 381 02/12/21 2:17 PM

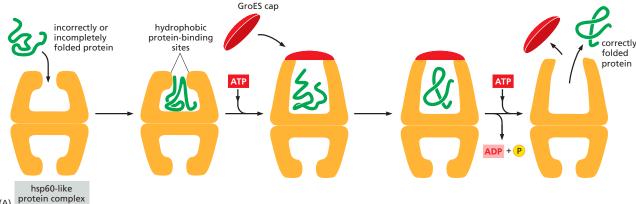

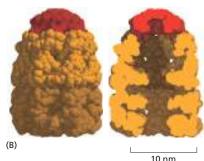

Figure 6–84 The structure and function of the hsp60 family of molecular chaperones. (A) A misfolded protein is initially captured by hydrophobic interactions with the exposed surface of the opening. This initial binding often helps to unfold a misfolded protein. The subsequent binding of ATP and a cap releases the substrate protein into an enclosed space, where it has a new opportunity to fold. After about 10 seconds, ATP hydrolysis occurs, weakening the binding of the cap. Subsequent binding of additional ATP molecules ejects the cap, and the protein is released. As indicated, only half of the symmetric barrel operates on a client protein at any one time. This hsp type of chaperone, known also as a *chaperonin*, is designated as hsp60 in mitochondria, TRiC in the cytosol of vertebrate cells, and GroEL in bacteria. (B) The structure of GroEL bound to its GroES cap, as determined by x-ray crystallography. On the left is shown the outside of the barrel-like structure, and on the right is a cross section through its center. (B, adapted from B. Bukau and A.L. Horwich, *Cell* 92:351–366, 1998. With permission from Elsevier.)

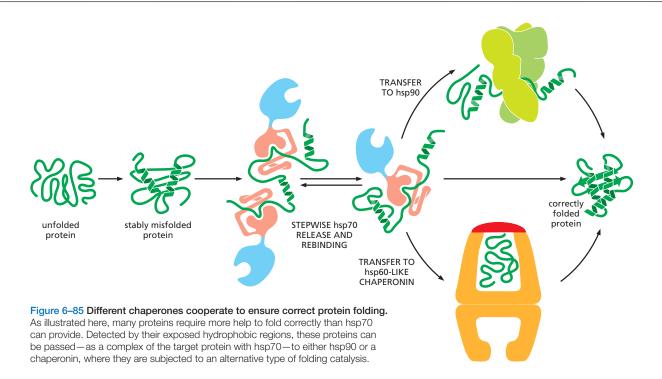

Some proteins produced by the cell cannot properly fold with help from the hsp70 proteins alone, and other types of chaperones are brought into play. An important class is exemplified by the hsp60 proteins. These form a large barrelshaped structure that acts after a protein has been fully synthesized but before it has folded correctly. This type of chaperone, sometimes called a *chaperonin*, forms an "isolation chamber" for the folding process (Figure 6-84). As we have seen, incorrectly folded proteins are often characterized by exposed hydrophobic patches. The entrance to the hsp chamber is itself hydrophobic and attracts these patches. In conjunction with ATP binding, the lid to the chamber closes, forcing the incorrectly folded protein into the chamber interior and causing a twisting of the chamber subunits whereby some of the hydrophobic surfaces of the inner chamber are moved out of the way and replaced with hydrophilic surfaces. The substrate protein is thereby given a chance to fold into its final configuration (which generally favors hydrophilic amino acids on its outside) in the absence of any other proteins with which to aggregate. When ATP is hydrolyzed, the lid pops off, and the substrate protein, whether correctly folded or not, is released from the chamber.

Folding and maintaining the enormous diversity of proteins in cells require a wide range of chaperones with versatile surveillance and correction capabilities. Although our discussion has focused on only two types of chaperones, the cell has a variety of others. These include an hsp90 chaperone that can harness mechanical forces to help proteins fold as part of a collaborative chaperone network (Figure 6–85).

The hsp70, hsp60, and hsp90 chaperones often need many cycles of ATP binding and hydrolysis to fold a single polypeptide chain correctly. This energy is used to create movements in each of these chaperone "machines," converting them back and forth between binding and releasing conformations. Thus, just as we saw for transcription, splicing, and translation, a great deal of free energy is used by cells to improve the accuracy of a biological process—in this case the correct folding of proteins (Movie 6.11).

MBOC7_ptr_ch06_321-396.indd 382 02/12/21 2:17 PM

Proper Folding of Newly Synthesized Proteins Is Also Aided by Translation Speed and Subunit Assembly

In addition to the highly abundant chaperones, two additional mechanisms help to correctly fold newly synthesized proteins. First, translation is not a smooth process; the ribosome moves in fits and starts, translating some RNA sequences rapidly and pausing at others. The pauses are typically caused by a series of rare codons (which require extra time for the corresponding low-abundance charged tRNAs to enter the ribosome by diffusion) or by mRNA secondary structures that form ahead of the ribosome, slowing down or temporarily blocking its smooth passage. It is thought that many of these pauses are not accidental; rather, they are spaced to allow extra time for "problem" portions of newly synthesized proteins to fold as they exit the ribosome. If true, it means that an mRNA molecule, in addition to coding for a protein, specifies changes in the speed of translation matched to its protein's folding characteristics.

A second mechanism reflects the fact that a protein molecule does not typically work on its own; instead, it usually assembles with other subunits to form multisubunit structures. As a protein emerges from the ribosome, it often begins assembling with one or more of its fully folded partner subunits, which, by acting as complementary surfaces, help the newly synthesized protein adopt its correct three-dimensional structure. We have seen in both bacteria and eukaryotes that a given mRNA molecule can be simultaneously translated by many ribosomes. For protein complexes made up of identical subunits, fully synthesized protein molecules will therefore always be in proximity to aid in the folding of those being synthesized. In bacteria, different proteins can be translated from the same mRNA, providing an opportunity for different subunits of a protein complex to efficiently help each other fold. In eukaryotes, where only a single protein is typically produced from each mRNA, it has been proposed that mRNAs that code for different subunits of a protein complex are held in proximity, perhaps by information in the untranslated portion of the message, providing a high local concentration of mature subunits to aid in the assembly and folding of newly synthesized subunits.

MBOC7_ptr_ch06_321-396.indd 383 02/12/21 2:17 PM

Proteins That Ultimately Fail to Fold Correctly Are Marked for Destruction by Polyubiquitin

We have seen that the cell relies on many resources to ensure that a newly synthesized protein is folded properly. Yet occasionally, normal proteins simply fail to fold properly despite numerous attempts. In addition, errors in transcription, RNA splicing, and translation can produce aberrant proteins that will never fold properly. Finally, proteins that were once correctly folded can become damaged by chemical reactions (such as oxidation), which can cause their misfolding. In all these cases, the cell destroys the aberrant protein. Although the cell uses many cues to ascertain whether a given protein is misfolded, the most important is an exposed hydrophobic patch, the same signal that is recognized by chaperones. The continued presence of a chaperone is thus an indication that the protein has failed to fold. In this case, a series of specialized enzymes recognizes the hydrophobic patch (possibly with the aid of chaperones) and attaches the small protein ubiquitin to a nearby lysine (see Figure 3-65A). Additional ubiquitin molecules are subsequently added to build a polyubiquitin chain. As we saw in Chapter 3, ubiquitin modification of proteins is used for many purposes in the cell. The particular type of ubiquitin linkage that concerns us here is a chain of ubiquitin molecules linked together at lysine 48 (see Figure 3-65B), which is the distinguishing feature of the ubiquitin tag that marks a protein for destruction. This polyubiquitin chain delivers the protein to a protein-destruction machine, a complex protease known as the proteasome.

The Proteasome Is a Compartmentalized Protease with Sequestered Active Sites

Proteasomes are very abundant, constituting approximately 1% of the total proteins in cells. They are dispersed throughout the cytosol and the nucleus, but the proteasome also destroys aberrant proteins that have entered the endoplasmic reticulum (ER). In this case, an ER-based surveillance system detects proteins that have failed either to fold or to be assembled properly after they enter the ER and *retrotranslocates* them back to the cytosol for degradation by the proteasome (discussed in Chapter 12).

Each proteasome consists of a central hollow cylinder (the 20S core proteasome) formed from multiple protein subunits that assemble as a stack of four heptameric rings. Some of the subunits are proteases whose active sites face the cylinder's inner chamber, thus preventing them from running rampant through the cell. Each end of the cylinder is normally associated with a large protein complex (the 19S cap) that contains a six-subunit protein ring through which target proteins are threaded into the proteasome core, where they are degraded (Figure 6–86). The threading reaction, driven by ATP hydrolysis, unfolds the target

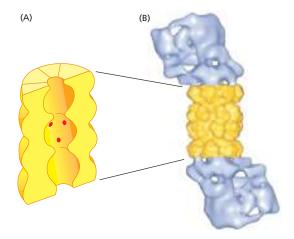

Figure 6-86 The proteasome. (A) A cutaway view of the structure of the central 20S cylinder, as determined by x-ray crystallography, with the active sites of the proteases indicated by red dots. (B) The entire proteasome, in which the central cylinder (yellow) is supplemented by a 19S cap (blue) at each end. The complex cap selectively binds proteins that are marked by ubiquitin for destruction: if the protein also contains a loosely structured region, the cap uses ATP hydrolysis to further unfold its polypeptide chain and feed it through the narrow channel (see Figure 6-87) into the inner chamber of the 20S cylinder for digestion to short peptides. (B, from W. Baumeister et al., Cell 92:367-380, 1998. With permission from Elsevier.)

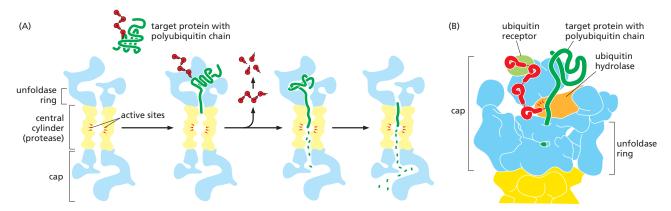

Figure 6–87 Processive protein digestion by the proteasome. (A) The proteasome cap recognizes proteins marked by a polyubiquitin chain (see Figure 3–65B). Most of these proteins also contain an unfolded region, and the cap translocates these proteins into the proteasome core, where they are digested. Before moving through the proteasome cap, the ubiquitin is cleaved from the substrate protein and is recycled. Translocation into the core of the proteasome is mediated by a ring of ATPases that unfold the substrate protein as it is threaded through the ring and into the proteasome core. (B) Detailed structure of the proteasome cap. The cap includes a ubiquitin receptor, which holds a ubiquitylated protein in place while attempts are made to pull it into the proteasome core, and a ubiquitin hydrolase, which cleaves ubiquitin from the protein. (A, from S. Prakash and A. Matouschek, Trends Biochem. Sci. 29:593–600, 2004. With permission from Elsevier; B, adapted from G.C. Lander et al., Nature 482:186–191, 2012.)

proteins as they move through the cap, exposing them to the proteases lining the proteasome core (**Figure 6-87**). The proteins that make up the ring structure in the proteasome cap belong to a large class of protein "unfoldases" known as *AAA proteins*. Many of them function as hexamers, and they share mechanistic features with the ATP-dependent DNA helicases that unwind DNA (**Figure 6-88**; see also Figure 5-14).

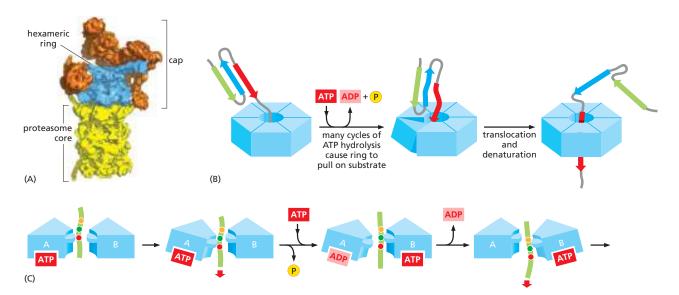

Figure 6-88 A hexameric protein unfoldase. (A) The proteasome cap includes a hexameric ring (blue) through which proteins to be destroyed are threaded. The hexameric ring (also called the unfoldase ring) is formed from six subunits, each belonging to the AAA family of proteins. (B) Model for the ATP-dependent unfoldase activity of AAA proteins. The ATP-bound form of a hexameric ring of AAA proteins grasps a substrate protein, and a conformational change, driven by ATP hydrolysis, further pulls the substrate and strains the ring structure. At this point, the substrate protein, which is being tugged upon, can partially unfold and enter further into the pore or it can maintain its structure and partially withdraw. Some protein substrates may require hundreds of cycles of ATP hydrolysis and dissociation before they are successfully pulled through the AAA protein ring; some proteins continue to resist these efforts and are ultimately de-ubiquitylated and released. (C) How the successive tilting of adjacent subunits (only two of which are shown), driven by ATP hydrolysis, is thought to pull the unfolded polypeptide chain through the hexameric ring into the proteasome. The motions of the ring subunits resemble a hand-over-hand pulling motion on the substrate protein, with the hands often slipping until the substrate is unfolded. Once unfolding occurs, the substrate protein moves relatively quickly through the ring by successive rounds of ATP hydrolysis. (A, adapted from G.C. Lander et al., Nature 482:186–191, published 2012 by Macmillan Publishers Ltd. Reproduced with permission of SNCSC; B, adapted from R.T. Sauer et al., Cell 119:9–18, 2004.)

MBOC7_ptr_ch06_321-396.indd 385 02/12/21 2:17 PM

A crucial property of the proteasome, and one reason for its complexity, is the processivity of its mechanism: in contrast to a "simple" protease that cleaves a substrate's polypeptide chain just once before dissociating, the proteasome keeps the entire substrate bound until all of it is converted into short peptides. One would expect that a machine as efficient as the proteasome would be tightly regulated; in particular, it must be able to distinguish abnormal proteins from those that are properly folded. The 19S cap of the proteasome acts as a gate at the entrance to the inner proteolytic core, and only those proteins to be destroyed are threaded through the cap. We saw above that proteins marked for destruction are distinguished by carrying a particular type of polyubiquitin chain. This chain binds specifically to a receptor in the 19S cap of the proteasome, and here a second "check" is made by the cell to determine whether or not the protein will be destroyed. If the protein has, in addition to the ubiquitin mark, an unfolded region (which can span the mark), it is grasped tightly by the 19S cap, de-ubiquitylated, and pulled through the cap into the proteasome core. Ubiquitylated proteins that lack such a region are typically de-ubiquitylated and released back into solution.

As might be expected, there is competition for misfolded proteins between chaperones and the protein degradation machinery. Proteins that are folded quickly escape destruction (at least early in their life before they accumulate damage), whereas those that undergo many rounds of chaperone-assisted folding are more likely to be degraded. Some chaperones can directly hand off those proteins that remain improperly folded, after many attempts, to the protein destruction machinery. It is estimated that between 1 and 5% of all newly synthesized proteins fail to fold properly and are degraded by the proteasome.

Many Proteins Are Controlled by Regulated Destruction

One function of intracellular proteolytic mechanisms is to recognize and eliminate misfolded or otherwise abnormal proteins, as just described. Indeed, every protein in the cell eventually accumulates damage and is probably degraded by the proteasome. Yet another function of these proteolytic pathways is to confer short lifetimes on specific normal proteins whose concentrations must change promptly with alterations in the state of a cell. Some of these short-lived proteins are degraded rapidly at all times, while many others are *conditionally* short-lived; that is, they are metabolically stable under some conditions but become unstable upon a change in the cell's state. For example, mitotic cyclins are long-lived throughout the cell cycle until their sudden degradation at the end of mitosis, as explained in Chapter 17.

How is such a regulated destruction of a protein controlled? Many such proteins contain short, unfolded regions, and a key step in regulating their destruction is the addition of ubiquitin. Several general mechanisms for controlling this step are illustrated in Figure 6-89. Specific examples of each mechanism are discussed in later chapters. In one general class of mechanism (Figure 6-89A), the activity of a ubiquitin ligase is turned on either by E3 phosphorylation or by an allosteric transition in an E3 protein caused by its binding to a specific small or large molecule. For example, the anaphase-promoting complex/cyclosome (APC/C) is a multisubunit ubiquitin ligase that is activated by a cell-cycle-timed subunit addition at mitosis. The activated APC then recognizes specific amino acid sequences in mitotic cyclins and several other regulators of the metaphase-anaphase transition and ubiquitylates them, thereby sending them to the proteasome (see Figure 17-18). We saw another example of regulated destruction earlier in this chapter, where a nascent polypeptide extending from a stalled ribosome is ubiquitylated, targeting it for destruction. Here, the signal for bringing the ubiquitin ligase into proximity to its target is a "gummed up" large ribosome subunit (see Figure 6-81).

Alternatively, in response either to intracellular signals or to signals from the environment, a ubiquitylation site can be created in a protein (Figure 6–89B). One common way to create such a signal is by phosphorylation of a specific amino

MBOC7_ptr_ch06_321-396.indd 386 02/12/21 2:17 PM

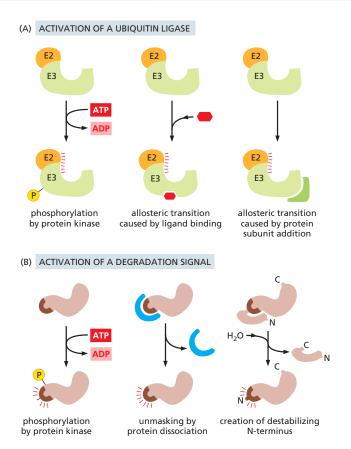

Figure 6–89 Two general ways of inducing the destruction of a specific protein. (A) Activation of a specific E3 molecule creates a new ubiquitin ligase. Eukaryotic cells have many different E3 molecules, each activated by a different signal. (B) Creation of an exposed destruction signal in the protein to be degraded. This signal binds a ubiquitin ligase, causing the addition of a polyubiquitin chain to a nearby lysine on the target protein. All six pathways shown are known to be used by cells to induce the movement of selected proteins into the proteasome for destruction.

acid sequence, which completes a ubiquitin ligase recognition site on the protein. Another is preexisting degradation signals that are unmasked by the regulated dissociation of a protein subunit. Finally, powerful degradation signals can be created by cleaving a single peptide bond, provided that this cleavage creates a new N-terminus that is recognized by a specific E3 protein as a "destabilizing" N-terminal residue. This E3 protein recognizes only certain amino acids at the N-terminus of a protein; thus, not all protein-cleavage events will lead to degradation of the C-terminal fragment produced.

In humans, nearly 70% of cytosolic proteins are acetylated on their N-terminal residue, and we now know that this modification is recognized by a specific E3 enzyme, which directs the ubiquitylation of the protein and sends it to the proteasome for degradation. Thus, the majority of human proteins carry their own signals for destruction. It has been proposed that when a protein is properly folded (and, before that, when it is in contact with a chaperone), this acetylated N-terminus is buried and therefore inaccessible to the E3. According to this idea, as a protein ages and becomes damaged (or if it fails to fold correctly from the start), this destruction signal becomes exposed, and the protein is destroyed.

There Are Many Steps from DNA to Protein

We have seen in this chapter that many different types of chemical reactions are required to produce a properly folded protein from the information contained in a gene (Figure 6–90). The final level of a useful protein in a cell therefore depends on the efficiency with which each of the many steps is performed. We also now know that the cell devotes enormous resources to selectively degrading proteins, particularly those that fail to fold properly or accumulate damage as they age. It is

MBOC7_ptr_ch06_321-396.indd 387 02/12/21 2:17 PM

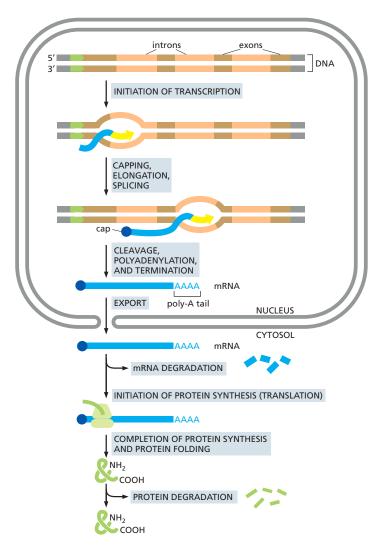

Figure 6–90 The production of a protein by a eukaryotic cell: a summary. The final level of each protein in a eukaryotic cell depends on the efficiency of each step depicted.

the balance between the rates of synthesis and degradation that determines the final amount of every protein in the cell.

In the following chapter, we shall see that cells have the ability to change the levels of their proteins according to their needs. In principle, any or all of the steps in Figure 6–90 could be regulated for each individual protein. As we shall see, there are examples of regulation at each step from gene to protein.

Summary

The translation of the nucleotide sequence of an mRNA molecule into protein takes place in the cytosol on a large ribonucleoprotein assembly called a ribosome. Each amino acid used for protein synthesis is first attached to a tRNA molecule that recognizes, by complementary base-pair interactions, a particular set of three nucleotides (codons) in the mRNA. As an mRNA is threaded through a ribosome, its sequence of nucleotides is then read from one end to the other in sets of three according to the genetic code.

To initiate translation, a small ribosomal subunit binds to the mRNA molecule at a start codon (AUG) that is recognized by a unique initiator tRNA molecule.

MBOC7_ptr_ch06_321-396.indd 388 02/12/21 2:17 PM

A large ribosomal subunit then binds to complete the ribosome and begin protein synthesis. During this phase, aminoacyl-tRNAs—each bearing a specific amino acid—bind sequentially to the appropriate codons in mRNA through complementary base-pairing between tRNA anticodons and mRNA codons. Each amino acid is added to the C-terminal end of the growing polypeptide in four sequential steps: aminoacyl-tRNA binding, followed by peptide bond formation, followed by two ribosome translocation steps. Elongation factors use GTP hydrolysis both to drive these reactions forward and to improve the accuracy of amino acid selection. The mRNA molecule progresses codon by codon through the ribosome in the 5'-to-3' direction until it reaches one of three stop codons. A release factor then binds to the ribosome, terminating translation and releasing the completed polypeptide.

Eukaryotic and bacterial ribosomes are closely related, despite differences in the number and size of their rRNA and protein components. The rRNA has the dominant role in translation, determining the overall structure of the ribosome, forming the binding sites for the tRNAs, matching the tRNAs to codons in the mRNA, and creating the active site of the peptidyl transferase enzyme that links amino acids together during translation.

Several distinct types of molecular chaperones, including hsp60 and hsp70, illustrate how the energy of ATP hydrolysis is used to help newly synthesized proteins assume their correct three-dimensional conformations. This protein-folding process competes with a control mechanism that destroys proteins that are abnormally folded by recognizing exposed hydrophobic patches and other unstructured regions. In this case, ubiquitin is covalently added to a misfolded protein by a ubiquitin ligase, and the resulting polyubiquitin chain is recognized by the cap on a proteasome that unfolds the protein as it is threaded into the interior of the proteasome for proteolytic degradation. A closely related proteolytic mechanism, based on special degradation signals recognized by ubiquitin ligases, is used to determine the lifetimes of many normally folded proteins, as well as to remove selected proteins from the cell in response to specific signals.

THE RNA WORLD AND THE ORIGINS OF LIFE

We have seen that the expression of hereditary information requires extraordinarily complex machinery and proceeds from DNA to protein through an RNA intermediate. This machinery presents a central paradox: if nucleic acids are required to synthesize proteins and proteins are required, in turn, to synthesize nucleic acids, how did such a system of interdependent components ever arise? A widely held view is that an RNA world existed on Earth before modern cells arose (Figure 6–91). According to this hypothesis, RNA not only stored genetic information but also directly catalyzed the chemical reactions in primitive cells—thus serving as enzymes ("ribozymes"). Only later in evolutionary time did DNA take over as the genetic material and proteins become the major catalysts and structural components of cells. But the transition out of the RNA world was never complete; as we have seen in this chapter, RNA still catalyzes several fundamental reactions in modern-day cells, which can be viewed as molecular holdovers from an earlier world.

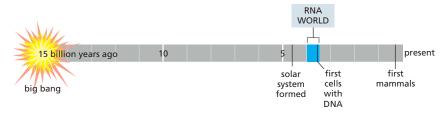

Figure 6–91 Timeline for the universe, highlighting the possible early existence of an "RNA world" in the evolution of Earth's living systems.

MBOC7_ptr_ch06_321-396.indd 389 02/12/21 2:17 PM

The RNA world hypothesis relies on the fact that, among present-day biological molecules, RNA is unique in being able to act as both a carrier of genetic information and as a catalyst for chemical reactions. In this section, we discuss these properties of RNA and how they may have been especially important in early cells.

Single-Strand RNA Molecules Can Fold into Highly Elaborate Structures

We have seen in this chapter that RNA can carry genetic information in mRNAs, and we saw in Chapter 5 that the genomes of some viruses are composed solely of RNA. We have also seen that complementary base-pairing and other types of hydrogen bonds can occur between nucleotides in the same chain of RNA, causing an RNA molecule to fold up in a unique way that is determined by its nucleotide sequence (see, for example, Figures 6–54 and 6–71). Comparisons of many RNA structures have revealed conserved structural motifs, short elements that often appear as parts of larger structures (Figure 6–92).

Protein catalysts require a surface with unique contours and chemical properties on which a given set of substrates can react (discussed in Chapter 3). In exactly the same way, an RNA molecule with an appropriately folded shape can serve as a catalyst (Figure 6–93). Like some proteins, many of these ribozymes work by positioning metal ions at their active sites. This feature gives them a wider range of catalytic activities than can be provided by the limited chemical groups of a polynucleotide chain.

Ribozymes Can Be Produced in the Laboratory

Much of our inference about the RNA world has come from experiments in which large pools of RNA molecules of random nucleotide sequences are generated in the laboratory. Those rare RNA molecules with a property specified by the experimenter are then selected out and studied (Figure 6–94). Experiments of this type have created RNAs that can catalyze a wide variety of biochemical reactions (Table 6–5), with reaction rate enhancements only a few orders of magnitude lower than those of the "fastest" protein enzymes. Given these findings, it is not clear why protein catalysts greatly outnumber ribozymes in modern cells. Experiments have shown, however, that RNA molecules may have more difficulty than proteins in binding to flexible, hydrophobic substrates and in forming pockets specific for different small molecules. The availability of 20 types of amino acids

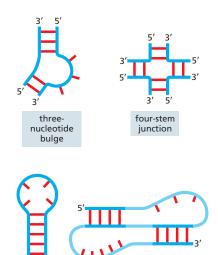

Figure 6–92 Some common elements of RNA structure. Conventional, complementary base-pairing interactions are indicated by *red* "rungs" in doublehelical portions of the RNA.

pseudoknot

hairpin

loop

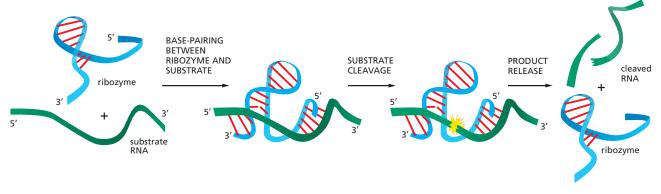

Figure 6–93 The activity of a well-studied ribozyme. This simple RNA molecule catalyzes the cleavage of a second RNA at a specific site. This ribozyme is found embedded in larger RNA genomes called viroids, which infect plants. The cleavage, which occurs in nature at a distant location on the same RNA molecule that contains the ribozyme, is a step in the replication of the viroid genome. Although not shown in the figure, the reaction requires a magnesium ion positioned at the active site. (Adapted from T.R. Cech and O.C. Uhlenbeck, *Nature* 372:39–40, 1994.)

MBOC7_ptr_ch06_321-396.indd 390 02/12/21 2:17 PM

Figure 6–94 *In vitro* selection of a synthetic ribozyme. Beginning with a large pool of different nucleic acid molecules synthesized in the laboratory, those rare RNA molecules that possess a specified catalytic activity can be isolated and studied. Although only one specific example (that of an autophosphorylating ribozyme) is shown, variations of this procedure have been used to generate many of the ribozymes listed in Table 6–5. For the strategy shown here, the RNA molecules are kept sufficiently dilute during the phosphorylation step to prevent the "cross-phosphorylation" of other RNA molecules. In reality, several repetitions of this procedure are necessary to select the very rare RNA molecules with this catalytic activity. Thus, the material initially eluted from the column is converted back into DNA, amplified many-fold (using reverse transcriptase and PCR, as explained in Chapter 8), transcribed back into RNA, and subjected to repeated rounds of selection. (Adapted from J.R. Lorsch and J.W. Szostak, *Nature* 371:31–36, 1994.)

presumably provides proteins with a much greater number of binding and catalytic strategies.

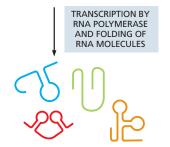

RNA Can Both Store Information and Catalyze Chemical Reactions

RNA molecules have one property that contrasts with those of proteins: they can directly guide the formation of copies of their own sequence. This capacity depends on complementary base-pairing of their nucleotide subunits, which enables one RNA to act as a template for the formation of another. As we have seen in this and the preceding chapter, these complementary templating mechanisms lie at the heart of DNA replication and transcription in modern-day cells. But the efficient synthesis of RNA by such complementary templating mechanisms requires catalysts to promote the polymerization reaction: without catalysts, polymer formation would be slow, error-prone, and inefficient.

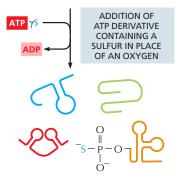

TABLE 6–5 Some Biochemical Reactions That Can Be Catalyzed by Ribozymes							
Activity	Ribozymes						
Peptide bond formation in protein synthesis	Ribosomal RNA						
RNA cleavage, RNA ligation	Self-splicing RNAs; RNase P; also in vitro selected RNA						
DNA cleavage	Self-splicing RNAs						
RNA splicing	Self-splicing RNAs; RNAs of the spliceosome						
RNA polymerization	In vitro selected RNA						
RNA and DNA phosphorylation	In vitro selected RNA						
RNA aminoacylation	In vitro selected RNA						
RNA alkylation	In vitro selected RNA						
Amide bond formation	In vitro selected RNA						
Glycosidic bond formation	In vitro selected RNA						
Oxidation-reduction reactions	In vitro selected RNA						
Carbon-carbon bond formation	In vitro selected RNA						
Phosphoamide bond formation	In vitro selected RNA						
Disulfide exchange	In vitro selected RNA						

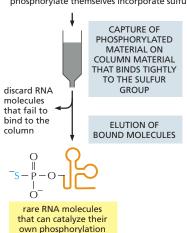

large pool of double-strand DNA molecules, each with a different, randomly generated nucleotide sequence

large pool of single-strand RNA molecules, each with a different, randomly generated nucleotide sequence

only the rare RNA molecules able to phosphorylate themselves incorporate sulfur

using ATP as a substrate

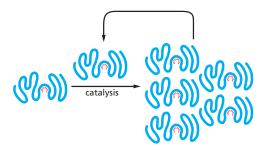

Figure 6–95 An RNA molecule that can catalyze its own synthesis. This hypothetical process would require synthesis of a second RNA strand complementary to the original strand (not shown) and the use of this second RNA molecule as a template to synthesize many molecules of RNA possessing the original sequence. The *red* rays represent the active site of this hypothetical RNA enzyme (ribozyme).

Because RNA has all the properties required of a molecule that could catalyze a variety of chemical reactions, including those that lead to its own synthesis (Figure 6–95), it has been proposed that RNAs served long ago as the catalysts for their own template-dependent RNA synthesis. Although self-replicating systems of RNA molecules have not been found in nature, scientists have made progress toward constructing such systems in the laboratory. Experiments of this type cannot prove that self-replicating RNA molecules were central to the origin of life on Earth, but they can help establish whether such a scenario is plausible.

Today, there is a widespread interest in investigating the exciting possibility that a primitive form of life once existed, or may even still exist, in some water-containing regions below the surface of Mars. Vehicles are being sent to promising sites on that planet to collect subterranean samples for eventual return to Earth, with the hope that their analysis will allow scientists to refine scenarios like that just described.

How Did Protein Synthesis Evolve?

The molecular processes underlying protein synthesis in present-day cells seem inextricably complex. Although we understand most of them, they do not make conceptual sense in the way that DNA transcription, DNA repair, and DNA replication do. It is especially difficult to imagine how protein synthesis evolved because it is now performed by a complex interlocking system of protein and RNA molecules; obviously, the proteins could not have existed until an early version of the translation apparatus was already in place. As attractive as the RNA world idea is for envisioning early life, it does not explain how the modern-day system of protein synthesis arose.

In modern cells, some short peptides (such as antibiotics) are synthesized without the ribosome; peptide synthetase enzymes assemble these peptides, with their proper sequence of amino acids, without mRNAs to guide their synthesis. It is plausible that this noncoded, primitive version of protein synthesis first developed in the RNA world, where it would have been catalyzed by RNA molecules. This idea presents no conceptual difficulties because, as we have seen, rRNA catalyzes peptide bond formation in present-day cells. Moreover, short simple peptides (for example, polylysine) have been shown to enhance the function of ribozymes created in the laboratory, raising the possibility that the first peptides were "selected" for their ability to help RNA molecules fold, assemble with each other, and catalyze reactions. These ideas, however, leave unexplained how the genetic code—which lies at the core of protein synthesis in today's cells—might have arisen. We know that ribozymes created in the laboratory can perform specific aminoacylation reactions; that is, they can match specific amino acids to specific tRNAs. It is therefore possible that tRNA-like adaptors, each matched to a specific amino acid, could have arisen in the RNA world, marking the beginnings

MBOC7_ptr_ch06_321-396.indd 392 02/12/21 2:17 PM

Figure 6–96 The hypothesis that RNA preceded DNA and proteins in evolution. In the earliest cells, RNA molecules (or their close analogs) would have had combined genetic, structural, and catalytic functions. In present-day cells, DNA is the repository of genetic information, and proteins perform the vast majority of catalytic functions in cells. RNA primarily functions today as a go-between in protein synthesis, although it remains a catalyst for a small number of crucial reactions.

of a genetic code. And, although we can only speculate on the code's evolution, scientists have provided plausible scenarios, in which the first codons specified only 10 or so of today's 20 amino acids.

Once coded protein synthesis evolved, the transition to a protein-dominated world could proceed, with proteins eventually taking over the majority of catalytic and structural tasks because of their greater versatility, with 20 rather than 4 different subunits. Although these ideas are highly speculative, they are consistent with the known properties of RNA and protein molecules.

All Present-Day Cells Use DNA as Their Hereditary Material

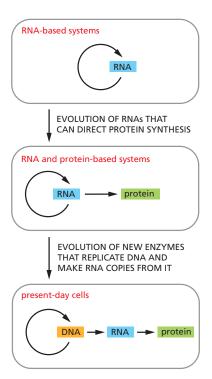

If the evolutionary speculations embodied in the RNA world hypothesis are correct, early cells would have differed fundamentally from the cells we know today in having their hereditary information stored in RNA rather than in DNA (Figure 6–96).

Evidence that RNA arose before DNA in evolution can be found in the chemical differences between them. Ribose, like glucose and other simple carbohydrates, can be formed from formaldehyde (HCHO), a simple chemical that is readily produced in laboratory experiments that attempt to simulate conditions on the primitive Earth. The sugar deoxyribose is harder to make, and in present-day cells it is produced from ribose in a reaction catalyzed by a protein enzyme, suggesting that ribose predates deoxyribose in cells. Presumably, DNA appeared on the scene later, but then proved more suitable than RNA as a permanent repository of genetic information. In particular, the deoxyribose in its sugar-phosphate backbone makes chains of DNA chemically more stable than chains of RNA, so that much greater lengths of DNA can be maintained without breakage. Because DNA and RNA use similar base-pairing rules for their template-dependent synthesis, the transition between the two is not difficult to envision. Consistent with this idea, a ribozyme has been created in the laboratory that can synthesize both RNA using a DNA template and DNA using an RNA template.

The other differences between RNA and DNA—the double-helical structure of DNA and the use of thymine rather than uracil—further enhance DNA stability by making the many unavoidable accidents that occur to the molecule much easier to repair, as discussed in detail in Chapter 5 (p. 288).

Summary

From our knowledge of present-day organisms and the molecules they contain, it seems likely that the development of the distinctive autocatalytic mechanisms fundamental to living systems began with the evolution of families of RNA molecules that could catalyze their own replication. DNA is thought to have been a later addition: as the accumulation of protein catalysts allowed more efficient and complex cells to evolve, the DNA double helix replaced RNA as a much more stable molecule for storing the increased amounts of genetic information required by such cells.

MBOC7_ptr_ch06_321-396.indd 393 02/12/21 2:17 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **6–1** Errors in transcription are less dangerous to an organism than errors in DNA replication.
- **6–2** Because introns are largely genetic "junk," they do not have to be removed precisely during RNA splicing.
- **6–3** Wobble pairing occurs between the first position in the codon and the third position in the anticodon.
- **6–4** During protein synthesis, the thermodynamics of base-pairing between tRNAs and mRNAs sets the upper limit for the accuracy with which protein molecules are made.
- **6–5** Protein enzymes are thought to greatly outnumber ribozymes in modern cells because they can catalyze a much greater variety of reactions, and all of them have faster rates than any ribozyme.

Discuss the following problems.

6–6 You have attached an RNA polymerase molecule to a glass slide and have allowed it to initiate transcription on a template DNA that has both strands tethered to a magnetic bead as shown in Figure Q6–1. If the DNA with its attached magnetic bead moves relative to the RNA polymerase as indicated by the arrows in the figure, in which direction will the bead rotate?

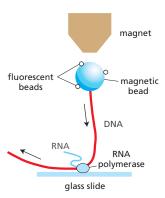

Figure Q6–1 System for measuring the rotation of DNA caused by RNA polymerase (Problem 6–6). The magnet holds the bead upright (but doesn't interfere with its rotation), and the attached tiny fluorescent beads allow the direction of motion to be visualized under the microscope. RNA polymerase is held in place by attachment to the glass slide. (Adapted from Y. Harada et al., *Nature* 409: 113–115, 2001. With permission from Springer Nature.)

6–7 In which direction along the template must the RNA polymerase in **Figure Q6–2** be moving to have generated the supercoiled structures that are shown? Would you expect supercoils to be generated if the RNA polymerase were free to rotate about the axis of the DNA as it progressed along the template?

Figure Q6–2 Supercoils produced by a moving RNA polymerase (Problem 6–7).

- **6–8** The human α -tropomyosin gene is alternatively spliced to produce different forms of α -tropomyosin mRNA in different cell types (**Figure Q6–3**). All forms of the mRNA contain the protein sequences encoded by exon 1 and exon 10. Exons 2, 3, 7, and 8 are alternative exons used in different mRNAs. Which one of the following statements about exons 2 and 3 is the most accurate? Is that statement also the most accurate one for exons 7 and 8? Explain your answers.
- **A.** Exons 2 and 3 must have the same number of nucleotides.
- B. Exons 2 and 3 must each contain an integral number of codons (that is, the number of nucleotides divided by 3 must be an integer).
- C. Exons 2 and 3 must each contain a number of nucleotides that when divided by 3 leaves the same remainder (that is, 0, 1, or 2).

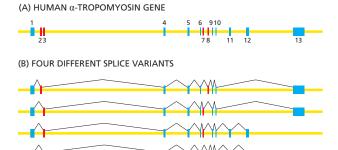

Figure Q6–3 Alternatively spliced mRNAs from the human α -tropomyosin gene (Problem 6–8). (A) Exons in the human α -tropomyosin gene. The locations and relative sizes of exons are shown by the *blue* and *red rectangles*, with alternative exons in *red.* (B) Splicing patterns for four α -tropomyosin mRNAs. Splicing is indicated by *lines* connecting the exons present in each mRNA.

6–9 After treating cells with a chemical mutagen, you isolate two mutants. One carries alanine and the other carries methionine at a site in a protein that normally contains valine (**Figure Q6–4**). After treating these two mutants again with the mutagen, you isolate mutants from each that now carry threonine at the site of the original valine (Figure Q6–4). Assuming that all mutations involve single-nucleotide changes, which codons are used for valine, methionine, threonine, and alanine at this site in the protein? Would you expect to be able to isolate valine-to-threonine mutants in one step?

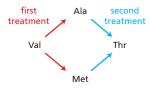

Figure Q6–4 Two rounds of mutagenesis and the altered amino acids at a single position in a protein (Problem 6–9).

MBOC7_ptr_ch06_321-396.indd 394

REFERENCES 395

- **6–10** Which one of the following mutational changes would you predict to be the most deleterious to gene function? Explain your answers.
- 1. Insertion of a single nucleotide near the end of the coding sequence.
- 2. Removal of a single nucleotide near the beginning of the coding sequence.
- **3.** Deletion of three consecutive nucleotides in the middle of the coding sequence.
- **4.** Substitution of one nucleotide for another in the middle of the coding sequence.
- **6–11** Prokaryotes and eukaryotes both protect against the dangers of translating broken mRNAs. What dangers do partial mRNAs pose for the cell?
- **6–12** Both hsp60-like and hsp70 molecular chaperones share an affinity for exposed hydrophobic patches on proteins, using them as indicators of incomplete folding. Why do you suppose hydrophobic patches serve as critical signals for the folding status of a protein?
- **6–13** Most proteins require molecular chaperones to assist in their correct folding. How do you suppose the chaperones themselves manage to fold correctly?

6–14 If an RNA molecule could form a hairpin with a symmetric internal loop, as shown in **Figure Q6–5**, could the complement of this RNA form a similar structure? If so, would there be any regions of the two structures that are identical? Which ones?

Figure Q6–5 An RNA hairpin with a symmetric internal loop (Problem 6–14).

- **6–15** What is so special about RNA that it is hypothesized to be an evolutionary precursor to DNA and protein? What is it about DNA that makes it a better material than RNA for storage of genetic information?
- 6–16 Imagine a warm pond on primordial Earth. Chance processes have just assembled a single copy of an RNA molecule with a catalytic site that can carry out RNA replication. This RNA molecule folds into a structure that is capable of linking nucleotides according to instructions in an RNA template. Given an adequate supply of nucleotides, will this single RNA molecule be able to use itself as a template to catalyze its own replication? Why or why not?

Control of Gene Expression

CHAPTER

7

An organism's DNA encodes all of the RNA and protein molecules required to construct its cells. Yet a complete description of the DNA sequence of an organism—be it the few million nucleotides of a bacterium or the few billion nucleotides of a human—no more enables us to reconstruct the organism than a list of English words enables us to reconstruct a play by Shakespeare. In both cases, the problem is to know how the elements in the DNA sequence or the words on the list are used. Under what conditions is each gene product made, and, once made, what does it do?

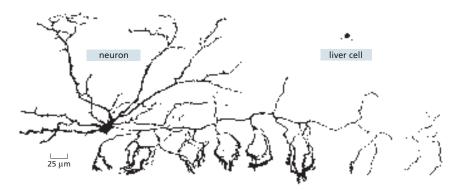

In this chapter, we focus on the first half of this problem—the rules and mechanisms that enable a subset of genes to be selectively expressed in each cell and also determine the amount of each gene product. These mechanisms operate at many levels, and we shall discuss each level in turn. But first we present some of the basic principles involved.

AN OVERVIEW OF GENE CONTROL

The different cell types in a multicellular organism differ dramatically in both structure and function. If we compare a mammalian neuron with a liver cell, for example, the differences are so extreme that it is difficult to imagine that the two cells contain the same genome (Figure 7–1). For this reason, and because cell differentiation often seemed irreversible, biologists originally suspected that genes might be selectively lost when a cell differentiates. We now know, however, that cell differentiation generally occurs without changes in the nucleotide sequence of a cell's genome.

The Different Cell Types of a Multicellular Organism Contain the Same DNA

The cell types in a multicellular organism become different from one another because they synthesize and accumulate different sets of RNA and protein molecules. The initial evidence that they do this without altering the sequence of their DNA came from a classic set of experiments in frogs. When the nucleus of a fully differentiated frog cell is injected into a frog egg whose nucleus has been

Post-transcriptional Controls

Regulation of Gene Expression by Noncoding RNAs

Figure 7-1 A neuron and a liver cell share the same genome. The long branches of this neuron from the retina enable it to receive electrical signals from many other neurons and convey them to neighboring neurons. The liver cell, which is drawn to the same scale, is involved in many metabolic processes, including digestion and the detoxification of alcohol and other drugs. Both of these mammalian cells contain the same genome, but they express different sets of RNAs and proteins. (Neuron adapted from S. Ramón y Cajal, Histologie du Système Nerveux de l'Homme et de Vertébrés, 1909-1911. Paris: A. Maloine Éditeur; reprinted, Madrid: C.S.I.C., 1972.)

MBOC7_ptr_ch07_397-474.indd 397 02/12/21 12:44 PM

removed, the injected donor nucleus is capable of directing the recipient egg to produce a normal tadpole (Figure 7-2A). Because this tadpole contains a full range of differentiated cells, each of which derived their DNA sequences from the nucleus of the original donor skin cell, that differentiated cell cannot have lost any important DNA sequences. Experiments performed with plants produced a similar conclusion. When differentiated pieces of plant tissue are placed in culture and then dissociated into single cells, often one of these individual cells can regenerate an entire adult plant (Figure 7-2B). More recently, the same principle has been demonstrated for mammals that include sheep, mice, pigs, goats, dogs, and cattle (Figure 7-2C).

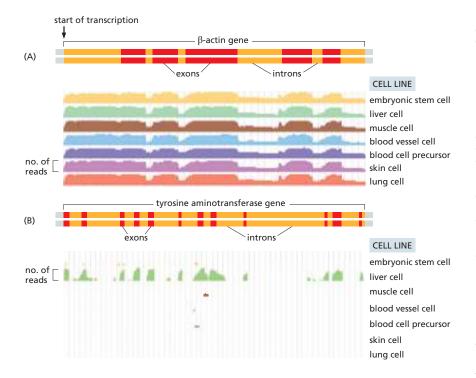

CHROMOSOMES

Detailed DNA sequencing of genomes present in different tissues also shows that the changes in gene expression that underlie the normal development of multicellular organisms do not generally involve changes in the DNA sequence of the genome.

Different Cell Types Synthesize Different Sets of RNAs and Proteins

As a first step in understanding cell differentiation, we would like to know how many differences there are between any one cell type and another. to direct the formation of a complete organism. (A) The nucleus of a skin cell from an adult frog transplanted into an enucleated egg can give rise to an entire tadpole. The broken arrow indicates that. to give the transplanted genome time to adjust to an embryonic environment, a further transfer step is required in which one of the nuclei is taken from an early embryo that begins to develop and is put back into a second enucleated egg. (B) In many types of plants, differentiated cells retain the ability to "de-differentiate," so that a single cell can form a clone of progeny cells that later give rise to an entire plant. (C) A nucleus removed from a differentiated cell from an adult cow and introduced into an enucleated egg from a different cow can give rise to a calf. Different calves produced from the same differentiated cell donor are all clones of the donor and are therefore genetically identical. (A, modified from J.B. Gurdon, Sci. Am. 219:24-35, 1968.)

MBOC7_ptr_ch07_397-474.indd 398 02/12/21 12:44 PM

Although we still do not have an exact answer for each cell type, we can make several general statements.

- 1. Many processes are common to all cells, and any two cells in a single organism therefore have many gene products in common. These include the structural proteins of chromosomes, RNA and DNA polymerases, DNA repair enzymes, ribosomal proteins and RNAs, the enzymes that catalyze the central reactions of metabolism, and many of the proteins that form the cytoskeleton such as actin (Figure 7–3A).
- 2. Some RNAs and proteins are abundant in the specialized cells in which they function and cannot be detected elsewhere, even by sensitive tests. Hemoglobin, for example, is expressed specifically in red blood cells, where it carries oxygen, whereas the enzyme tyrosine aminotransferase (which breaks down tyrosine in food) is expressed in liver but not in most other tissues (Figure 7–3B).
- 3. Analyses of RNAs reveal that, at any one time, a typical human cell expresses 30–60% of its approximately 25,000 genes at some meaningful level. There are about 20,000 protein-coding genes and an estimated 5000 noncoding RNA genes in humans. When the patterns of RNA expression in different human cell lines are compared, the level of expression of almost every gene is found to vary from one cell type to another. A few of these differences are striking, like those of hemoglobin and tyrosine aminotransferase noted above, but most are much more subtle. But even those genes that are expressed in all cell types usually vary in their *level* of expression from one cell type to the next.
- 4. Although there are striking differences in the protein-coding RNAs (mRNAs) in specialized cell types, they underestimate the full range of differences in the final pattern of protein production. As we shall discuss later in this chapter, there are many steps after RNA production at which gene expression can be regulated. And, as we saw in Chapter 3, proteins are often covalently modified after they are synthesized. The differences in gene expression between cell types are therefore most fully revealed through methods that directly display the levels of proteins, along with their post-translational modifications (Figure 7-4).

Figure 7-3 Differences in RNA levels for two human genes in seven different tissues. To obtain RNA data by the technique known as RNA-seq (see pp. 514-516), RNA was collected from seven different human cell lines grown in culture, each derived from a different tissue. Millions of "sequence reads" were obtained for each RNA sample and mapped by matching RNA sequences to the DNA sequence of the human genome. At each position along the genome, the height of the colored trace is proportional to the number of sequence reads that match the genome sequence at that point. As seen in the figure, the exon sequences in transcribed genes are present at high levels, reflecting their presence in mature mRNAs. Intron sequences are present at much lower levels and reflect pre-mRNA molecules that have not vet been spliced, plus intron sequences that have been spliced out but not yet degraded. (A) The data for one of the genes coding for actin, a major component of the cytoskeleton in all cells. Note that the left-hand end of the mature B-actin mRNA is not translated into protein. As explained later in this chapter, many mRNAs have 5' untranslated regions that regulate their translation into protein. (B) The same type of data displayed for the enzyme tyrosine aminotransferase, which is highly expressed in liver cells but not in the other cell types tested. [Information for both panels from the University of California, Santa Cruz, Genome Browser (https:// genome.ucsc.edu), which provides this type of information for every human gene. See also S. Djebali et al., Nature 489:101-108, 2012.]

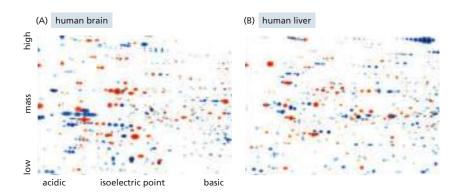

Figure 7–4 Differences in the proteins expressed by two human tissues, (A) brain and (B) liver. The proteins have been separated by size (top to bottom) and isoelectric point, the pH at which the protein has no net charge (right to left). The protein spots artificially colored red are common to both samples; those in blue are specific to that tissue. The differences between the two tissue samples vastly outweigh their similarities: even for proteins that are shared between the two tissues, their relative abundances are usually different. Note that this technique separates proteins by both size and charge; therefore, a protein that has several different phosphorylation states will appear as a series of horizontal spots (see upper right-hand portion of right panel). Only a small portion of the complete protein spectrum is shown for each sample.

The method used to display proteins in these panels is known as *two-dimensional gel electrophoresis* (see Figure 8–16). Although it is useful for easily visualizing the extent of protein differences between the two cell types, newer methods based on mass spectrometry (see pp. 491–492) provide much more detailed information, including the identity of each protein, the position of each modification, and the nature of the modification. (Courtesy of Tim Myers and Leigh Anderson, Large Scale Biology Corporation.)

The Spectrum of mRNAs Present in a Cell Can Be Used to Accurately Identify the Cell Type

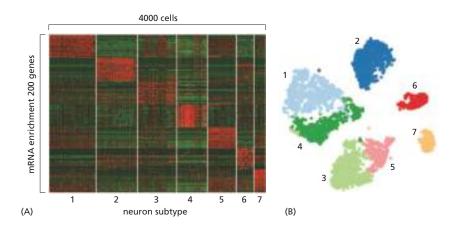

We have seen that each cell type produces a characteristic set of mRNAs. Therefore, if all the mRNAs present in a cell are known, the cell type can be unambiguously identified, using prior knowledge from cell lines or analyses of tissues. This approach is made possible by the ability to determine the nucleotide sequence of all the mRNAs produced by a single cell (see pp. 537–538). Thus, for example, because human cells have approximately 20,000 mRNA-producing genes, this strategy provides very fine resolution of the differences among our different individual cells.

In general, the mRNA approach agrees well with the traditional categorization of cell types that is based on staining and microscopy, but the mRNA strategy has also revealed that many cells that "look" the same can differ significantly in their mRNA content and therefore in their function. This strategy has thereby identified many new cell types, most of which are subdivisions of cell types that had been classically defined (Figure 7–5). The ability to determine the mRNA content of individual cells also provides a new appreciation for how cells present in a tissue (liver, for example) differ according to their positions in the tissue.

External Signals Can Cause a Cell to Change the Expression of Its Genes

Although the specialized cells in a multicellular organism have characteristic patterns of gene expression, each cell is capable of altering its pattern of gene expression in response to extracellular cues. If a liver cell is exposed to a glucocorticoid hormone, for example, the production of a set of proteins is dramatically increased, and once the hormone is no longer present, the production of these proteins drops back to its normal, unstimulated level. Glucocorticoids are released in the body during periods of starvation or intense exercise, and they signal the liver to increase the production of energy from amino acids and other

MBOC7_ptr_ch07_397-474.indd 400 02/12/21 12:44 PM

small molecules. The set of induced proteins includes the enzyme tyrosine aminotransferase, mentioned earlier.

Other cell types respond to glucocorticoids differently. Fat cells, for example, reduce the production of tyrosine aminotransferase, while some other cell types do not respond to glucocorticoids at all. These examples illustrate a general feature of cell specialization: different cell types can respond very differently to the same extracellular signal. Other features of the gene expression pattern do not change and give each cell type its permanently distinctive character.

Gene Expression Can Be Regulated at Many of the Steps in the Pathway from DNA to RNA to Protein

We have seen that differences among the various cell types of an organism depend on the particular genes that the cells express. But at what level does this control of gene expression occur? As we saw in the previous chapter, there are many steps in the pathway leading from DNA to protein, and all of them can in principle be regulated. Thus, as illustrated in Figure 7-6, a cell can control the proteins it makes by (1) controlling when and how often a given gene is transcribed (transcriptional control), (2) controlling the splicing and processing of RNA transcripts (RNA-processing control), (3) selecting which completed mRNAs are exported from the nucleus to the cytosol and determining where in the cytosol they are localized (RNA transport and localization control), (4) selecting which mRNAs in the cytoplasm are translated by ribosomes (translational control), (5) selectively destabilizing certain mRNA molecules in the cytoplasm (mRNA degradation control), (6) selectively degrading specific protein molecules (protein degradation control), and (7) activating, inactivating, or localizing specific protein molecules (protein activity control).

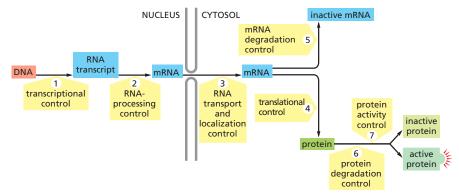

Figure 7-5 Classification of a group of neurons in the mouse brain into seven different subtypes by single-cell mRNA sequencing. For this experiment, approximately 4000 individual neurons (which were activated in response to a particular stimulus) were dissected from the brain and separated from each other. The mRNAs produced by each cell were isolated and their sequences determined by the methods described in Chapter 8. On the basis of the spectrum of the mRNAs produced by each cell, the 4000 different cells could be grouped into seven distinctive subtypes. Within each subtype, the mRNAs were similar from cell to cell, but between subtypes they differed significantly. (A) Here, the level of the mRNAs detected for approximately 200 different genes is plotted for each cell as a tiny rectangle, whose color intensity is proportional to the amount of that mRNA in that cell, with red indicating increased expression and green decreased expression, relative to all the samples. These data are plotted for each of the 4000 cells along the X axis. The cells have been arranged so that similar cells are located next to each other. In this way it is possible, using mRNA sequence data alone, to recognize seven distinctive types of neurons, as indicated. To highlight similarities, the data for the 25 mRNAs specifically enriched in each of the seven subtypes is indicated by red blocks. (B) By analyzing the mRNA data using a mathematical method known as unsupervised clustering (see Figure 8-66). the seven different subtypes can readily be distinguished on a two-dimensional "cluster diagram," with each dot representing a single cell. In addition, information regarding the extent of differences among the subgroups can also be ascertained. For example, subtypes 1 and 4 are more closely related to each other in the mRNAs they make than are subtypes 1 and 7. This type of analysis helps us to understand how the brain processes sensory information and indicates that, even though neurons may look the same under the microscope, they can differ significantly in gene expression patterns and therefore in their functions. (A and B, from M.B. Chen et al., Nature 587:437-442, 2020. doi 10.1038/s41586-020-2905-5. With permission from Springer Nature.)

Figure 7–6 Seven steps at which eukaryotic gene expression can be controlled. Controls that operate at steps 1 through 5 are discussed in this chapter. Step 7, the regulation of protein activity, occurs largely through covalent post-translational modifications including phosphorylation, acetylation, and ubiquitylation (see Table 3–4, p. 175). Steps 6 and 7 were introduced in Chapters 3 and 6 and will be subsequently discussed in other chapters throughout the book.

MBOC7_ptr_ch07_397-474.indd 401 02/12/21 12:44 PM

For many genes, transcriptional controls are paramount. This makes sense because, of all the possible control points illustrated in Figure 7–6, only transcriptional control ensures that the cell will not synthesize superfluous intermediates. In the following sections, we discuss the DNA and protein components that regulate the initiation of gene transcription, before moving on to discuss other types of controls.

Summary

The genome of a cell contains in its entire DNA sequence the information to make many thousands of different protein and RNA molecules. But a cell typically expresses only a fraction of its genes, and the different types of cells in multicellular organisms arise because different sets of genes are expressed. All cells can change the pattern of genes they express in response to changes in their environment, such as signals from other cells. The regulation of gene expression is thus crucial for life. Although all of the many steps involved in expressing a gene can in principle be regulated, for most genes it is the initiation of RNA transcription that provides the most important point of control.

CONTROL OF TRANSCRIPTION BY SEQUENCE-SPECIFIC DNA-BINDING PROTEINS

How does a cell determine which of its thousands of genes to transcribe? Perhaps the most important concept, one that applies to all species on Earth, is based on a group of proteins known as **transcription regulators**. These proteins recognize specific sequences of DNA (typically 5–12 nucleotide pairs in length) that are often called *cis-regulatory sequences*, because they must be on the same chromosome (that is, *in cis*) to the genes they control. Transcription regulators bind to these sequences, which are dispersed throughout genomes, and this binding puts into motion a series of reactions that ultimately specify which genes are to be transcribed and at what rate. Approximately 10% of the protein-coding genes of most organisms are devoted to transcription regulators, making them one of the largest classes of proteins in the cell. A given transcription regulator typically recognizes a specific *cis-*regulatory sequence that is different from those recognized by the other transcription regulators in the cell.

The transcription of each gene is, in turn, controlled by its unique collection of *cis*-regulatory DNA sequences, which thus constitute a crucial part of the information coded in genomes. These sequences typically lie near the gene, often in the intergenic region directly upstream from the transcription start point of the gene. Although a few genes are controlled by a single *cis*-regulatory sequence that is recognized by a single transcription regulator, the majority have complex arrangements of *cis*-regulatory sequences, each of which is recognized by a different transcription regulator. It is therefore the positions, identity, and arrangement of *cis*-regulatory sequences that ultimately determine the time and place that each gene is transcribed. We begin our discussion by describing how transcription regulators "read" the information present in *cis*-regulatory sequences; later in the chapter, we shall discuss how they carry out their functions.

The Sequence of Nucleotides in the DNA Double Helix Can Be Read by Proteins

As discussed in Chapter 4, the DNA in a chromosome consists of a very long double helix that has both a major and a minor groove (Figure 7-7). Transcription regulators must recognize short, specific *cis*-regulatory sequences within this structure. When first discovered in the 1960s, it was thought that these proteins might require direct access to the interior of the double helix to distinguish between one DNA sequence and another, analogous to complementary basepairing. It is now clear, however, that the outside of the double helix is studded with DNA sequence information that transcription regulators can recognize directly: the outside edges of each base pair display distinctive patterns of hydrogen-bond

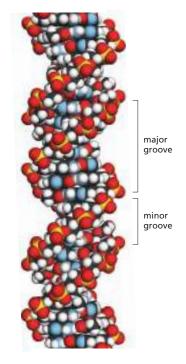

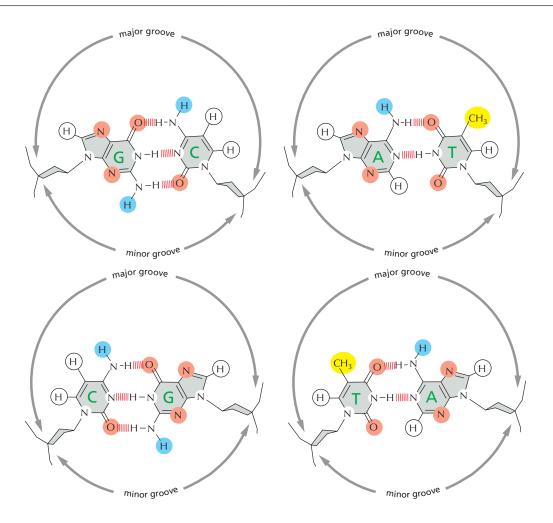

Figure 7–7 Double-helical structure of DNA. A space-filling model of DNA showing the major and minor grooves on the outside of the double helix (see Movie 4.1). The atoms are colored conventionally as follows: carbon, black; nitrogen, blue; hydrogen, white; oxygen, red; phosphorus, yellow.

MBOC7_ptr_ch07_397-474.indd 402 02/12/21 12:44 PM

donors, hydrogen-bond acceptors, and hydrophobic patches in both the major and minor grooves, allowing each base to be distinguished from the other three (Figure 7-8). Because the major groove is wider and displays more molecular features than does the minor groove, nearly all transcription regulators make the majority of their contacts with the major groove—as we shall see.

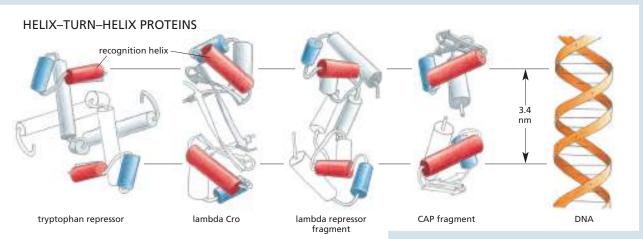

Transcription Regulators Contain Structural Motifs That Can Read DNA Sequences

Molecular recognition in biology generally relies on an exact fit between the surfaces of two molecules, and the study of transcription regulators provides some of the clearest examples of this principle. Thus, a transcription regulator recognizes its specific *cis*-regulatory sequence because the surface of the protein is complementary to surface features of the double helix that displays that sequence. Each transcription regulator makes a series of contacts with the DNA, involving hydrogen bonds, ionic bonds, and hydrophobic interactions. Although each individual contact is weak, the 20 or so contacts that are typically formed at the protein–DNA interface add together to ensure that the interaction is both highly specific and very strong (Figure 7–9). In fact, DNA–protein interactions include some of the tightest and most specific molecular interactions known in biology.

Although each example of protein–DNA recognition is unique in detail, x-ray crystallographic and nuclear magnetic resonance (NMR) spectroscopic studies of hundreds of transcription regulators reveal that many contain one or another of a small set of DNA-binding structural motifs (Panel 7–1). These motifs generally

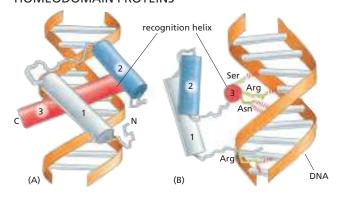

Figure 7-8 How the different base pairs in DNA can be recognized from their edges without the need to open the double helix. The four possible configurations of base pairs are shown, with potential hydrogen-bond donors indicated in blue, potential hydrogen-bond acceptors in red. and hydrogen bonds of the base pairs themselves as a series of short, parallel red lines. Methyl groups, which form hydrophobic protuberances, are shown in yellow, and hydrogen atoms that are attached to carbons, and are therefore unavailable for hydrogen-bonding, are white. From the major groove, each of the four base-pair configurations projects a unique pattern of features. (From C. Branden and J. Tooze, Introduction to Protein Structure. 2nd ed. New York: Garland Publishing, 1999. With permission from Taylor & Francis.)

MBOC7_ptr_ch07_397-474.indd 403 02/12/21 12:44 PM

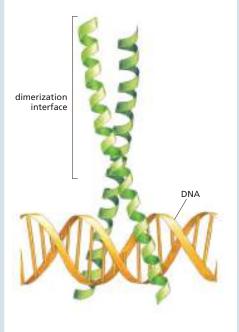

Originally identified in bacterial transcription regulators, this motif has since been found in many hundreds of DNA-binding proteins from eukaryotes, bacteria, and archaea. It is constructed from two α helices (blue and red) connected by a short extended chain of amino acids, which constitutes the "turn." The two helices are held at a fixed angle, primarily through interactions between the two helices. The more C-terminal helix (in red) is called the recognition helix because it fits into the major groove of DNA; its amino acid side chains, which differ from protein to protein, play an important part in recognizing the specific DNA sequence to which the protein binds. All of the proteins shown here bind DNA as dimers in which the two copies of the recognition helix (in red) are separated by exactly one turn of the DNA helix (3.4 nm); thus both recognition helices of the dimer can fit into the major groove of DNA.

HOMEODOMAIN PROTEINS

Not long after the first transcription regulators were discovered in bacteria, genetic analyses of the fruit fly *Drosophila* led to the characterization of an important class of genes, the *homeotic selector genes*, that play a critical part in orchestrating fly development (discussed in Chapter 21). It was later shown that these genes coded for transcription regulators that bound DNA through a structural motif named the homeodomain. Two different views of the same structure are shown. (A) The homeodomain is folded into three α helices, which are packed tightly together by hydrophobic interactions. The part containing helices 2 and 3 closely resembles the bacterial helix–turn–helix motif. (B) The recognition helix (helix 3, *red*) forms important contacts with the major groove of DNA. The asparagine (Asn) of helix 3, for example, contacts an adenine, as shown in Figure 7–9. A flexible arm attached to helix 1 forms contacts with nucleotide pairs in the minor groove (Movie 7.1).

LEUCINE ZIPPER PROTEINS

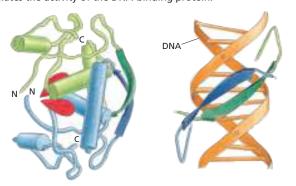

The leucine zipper motif is named because of the way the two α helices, one from each monomer, are joined together to form a short coiled-coil. These proteins bind DNA as dimers where the two long α helices are held together by interactions between hydrophobic amino acid side chains (often on leucines) that extend from one side of each helix. Just beyond the dimerization interface, the two $\boldsymbol{\alpha}$ helices separate from each other to form a Y-shaped structure, which allows their side chains to contact the major groove of DNA. The dimer thus grips the double helix like a clothespin on a clothesline (Movie 7.2).

MBOC7_ptr_ch07_397-474.indd 404 02/12/21 12:44 PM

β-SHEET DNA RECOGNITION PROTEINS

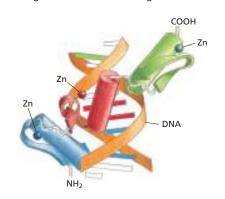

In the other DNA-binding motifs displayed in this panel, α helices are the primary mechanism used to recognize specific DNA sequences. In one group of transcription regulators, however, a two-stranded β sheet, with amino acid side chains extending from the sheet toward the DNA, reads the information on the surface of the major groove. As in the case of a recognition α helix, this β -sheet motif can be used to recognize many different DNA sequences; the exact DNA sequence recognized depends on the sequence of amino acids that make up the β sheet. Shown is a transcription regulator that binds two molecules of S-adenosyl methionine (red). On the left is a dimer of the protein; on the right is a simplified diagram showing just the two-stranded β sheet bound to the major groove of DNA. S-adenosyl methionine is needed for this protein to bind DNA. Thus, the small molecule regulates the activity of the DNA-binding protein.

COOH NH2 V R Q H C G Zn Cys His Cys His Cys His Cys His N Cys N Cys N Cys His N Cys N Cys His Cys N Cys His Cys

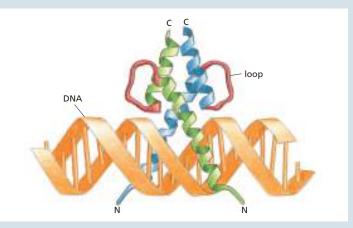

ZINC FINGER PROTEINS

This group of DNA-binding motifs includes one or more zinc atoms as structural components. All such zinc-coordinated DNA-binding motifs are called zinc fingers, referring to their appearance in early schematic drawings (left). They fall into several distinct structural groups, only one of which we consider here. It has a simple structure, in which the zinc atom holds an α helix and a β sheet together (middle). This type of zinc finger is often found in clusters with the $\boldsymbol{\alpha}$ helix of each finger contacting the major groove of the DNA, forming a nearly continuous stretch of α helices along that groove (Movie 7.3). In this way, a strong and specific DNA-protein interaction is built up through a repeating basic structural unit. Three such fingers are shown on the right.

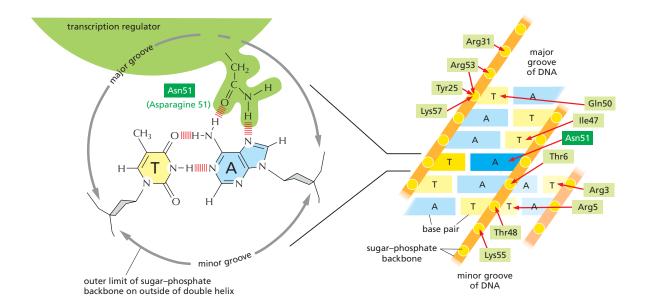

HELIX-LOOP-HELIX PROTEINS

Related to the leucine zipper, the helix–loop–helix motif consists of a short α helix connected by a loop (red) to a second, longer α helix. The flexibility of the loop allows one helix to fold back and park against the other thereby forming the dimerization surface. As shown, this two-helix structure binds both to DNA and to the two-helix structure of a second protein to create either a homodimer or a heterodimer. Two α helices that extend from the dimerization interface make specific contacts with the major groove of DNA.

MBOC7_ptr_ch07_397-474.indd 405 02/12/21 12:44 PM

use either α helices or β sheets to bind to the major groove of DNA, with amino acid side chains that extend from these motifs making their specific DNA contacts. Thus, a given structural motif can be used to recognize many different *cis*-regulatory sequences depending on the specific side chains that extend from it.

Dimerization of Transcription Regulators Increases Their Affinity and Specificity for DNA

A monomer of a typical transcription regulator recognizes about 4–8 nucleotide pairs of DNA. These proteins do not bind tightly to a single DNA sequence and reject all others; rather, each regulator recognizes a range of closely related sequences, with the affinity of the protein for the DNA varying according to how closely the DNA matches its optimal sequence. For this reason, the *cis*-regulatory sequence for a regulator is often depicted by a "logo" that displays the range of sequences recognized by that transcription regulator (**Figure 7–10**). In Chapter 6, this same type of representation was used to depict the DNA sequences recognized by bacterial RNA polymerase (see Figure 6–12).

The DNA sequence recognized by a monomer does not usually contain sufficient information to be picked out from the background of such sequences that would occur at random across the genome. For example, an exact six-nucleotide DNA sequence would be expected to occur by chance approximately once every

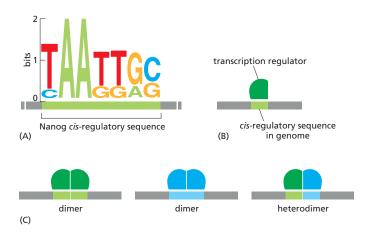

Figure 7-9 The binding of a transcription regulator to a specific DNA sequence. On the left, a single contact is shown between a transcription regulator and DNA; such contacts allow the protein to "read" the DNA sequence from the outside of the DNA double helix. On the right, the complete set of contacts between a transcription regulator (a member of the homeodomain family—see Panel 7-1) and its cis-regulatory sequence is shown. The DNA-binding portion of the protein is 60 amino acids long, and the amino acids that directly contact DNA are numbered beginning with the amino terminus. Although the interactions in the major groove are the most important, the protein also contacts both the minor groove and phosphates in the sugar-phosphate DNA backbone, as shown, (See C. Wolberger et al., Cell 67:517-528, 1991.)

Figure 7-10 Transcription regulators and cis-regulatory sequences. (A) Depiction of the cis-regulatory sequence for Nanog, a homeodomain family member that is a key transcription regulator in embryonic stem cells. This "logo" form (see Figure 6-12) shows that the protein can recognize a collection of closely related DNA sequences and gives the preferred nucleotide pair at each position. Cis-regulatory sequences are almost always "read" as doublestranded DNA, but only one strand typically is shown in a logo. (B) Representation of the cis-regulatory sequence as a green box embedded in a longer DNA molecule (gray). (C) Many transcription regulators form dimers (homodimers and heterodimers). In the example shown, three different DNAbinding specificities are formed from two transcription regulators.

MBOC7_ptr_ch07_397-474.indd 406 02/12/21 12:44 PM

4096 nucleotides (46), and the range of six-nucleotide sequences described by a typical logo would be expected to occur by chance much more often, perhaps every 1000 nucleotides. Clearly, for a bacterial genome of 4.6×10^6 nucleotide pairs, not to mention a mammalian genome of 3×10^9 nucleotide pairs, this is insufficient information to accurately control the transcription of individual genes. Additional contributions to DNA-binding specificity must therefore be present.

Many transcription regulators form dimers, with both monomers making nearly identical contacts with DNA (see Figure 7–10C). This arrangement doubles the length of the *cis*-regulatory sequence recognized and greatly increases both the affinity and the specificity of transcription regulator binding. Because the DNA sequence recognized by the protein has increased from approximately 6 nucleotide pairs to 12 nucleotide pairs, there are many fewer random occurrences of matching sequences. In many cases, heterodimers can form between two different transcription regulators, and this configuration also increases both affinity and specificity by expanding the DNA sequence recognized. Some transcription regulators can form heterodimers with more than one partner protein; in this way, the same transcription regulator can be "reused" to create several distinct DNA-binding specificities (see Figure 7–10C).

Many Transcription Regulators Bind Cooperatively to DNA

In the simplest case, the collection of noncovalent bonds that holds dimers or heterodimers together is so extensive that these structures form obligatorily and virtually never fall apart. In this case, the unit of binding is the dimer or heterodimer, and the binding curve for the transcription regulator (the fraction of DNA bound as a function of protein concentration) has a standard exponential shape (Figure 7–11A).

In many cases, however, the dimers and heterodimers are held together very weakly; they exist predominantly as monomers in solution, and yet dimers are observed on the appropriate DNA sequence. In this case, the proteins are said to bind to DNA cooperatively, and the curve describing their binding is S-shaped (Figure 7–11B). *Cooperative binding* means that, over a range of concentrations of the transcription regulator, binding is more of an all-or-none phenomenon than for noncooperative binding; that is, at most protein concentrations, the *cis*-regulatory sequence is either nearly empty or nearly fully occupied and is rarely somewhere in between. A discussion of the mathematics behind cooperative binding is given in Chapter 8 (see Figure 8–81).

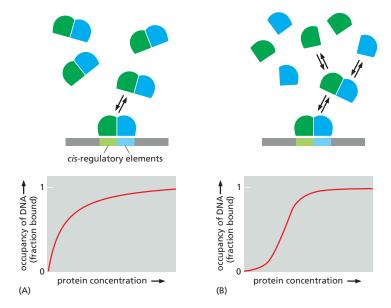

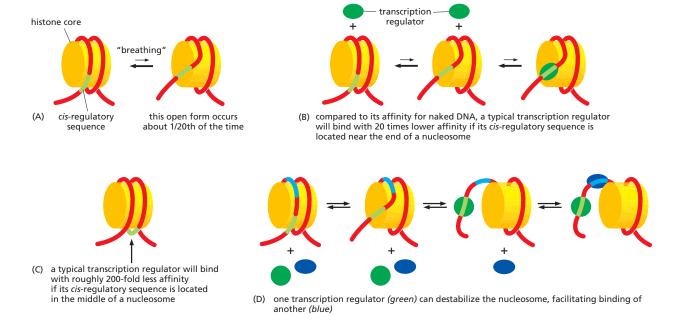

Figure 7–11 Occupancy of a cisregulatory sequence by a transcription regulator. (A) Noncooperative binding by a stable heterodimer. (B) Cooperative binding by components of a heterodimer that are predominantly monomers in solution. The shape of the curve differs from that of panel A because the fraction of protein in a form competent to bind DNA (the heterodimer) increases with increasing protein concentration.

MBOC7_ptr_ch07_397-474.indd 407 02/12/21 12:44 PM

Nucleosome Structure Promotes Cooperative Binding of Transcription Regulators

As we have just seen, cooperative binding of transcription regulators to DNA often occurs because the proteins involved have only a weak affinity for each other. However, there is a second, indirect mechanism for cooperative binding in eukaryotes, one that arises from the nucleosome structure of their chromosomes.

In general, transcription regulators bind to DNA in nucleosomes with lower affinity than they do to naked DNA. There are two reasons for this difference. First, the surface of the *cis*-regulatory sequence recognized by the transcription regulator may be facing inward on the nucleosome, toward the histone core, and therefore not be readily available to the regulatory protein. Second, even if the face of the *cis*-regulatory sequence is exposed on the outside of the nucleosome, many transcription regulators subtly alter the conformation of the DNA when they bind, and these changes are generally opposed by the tight wrapping of the DNA around the histone core. For example, many transcription regulators induce a bend or kink in the DNA when they bind.

We saw in Chapter 4 that nucleosome remodeling can alter the structure of the nucleosome, allowing transcription regulators access to the DNA. Even without remodeling, however, transcription regulators can still gain limited access to DNA in a nucleosome. The DNA at the end of a nucleosome "breathes," transiently exposing the DNA and allowing regulators to bind. This breathing occurs at a much lower rate in the middle of the nucleosome; therefore, the positions where the DNA exits the nucleosome are much easier to occupy than those in the middle of the nucleosome (Figure 7–12).

These properties of the nucleosome promote cooperative DNA binding by transcription regulators. If a transcription regulator seizes a "window of opportunity" provided by nucleosome breathing, it can enter the nucleosome by binding to the exposed DNA and prevent the DNA from tightly rewrapping around the nucleosome core. When this happens, the affinity of a second transcription regulator for a nearby *cis*-regulatory sequence can be increased simply by this loosening of the DNA from the histone core. If the two transcription regulators also interact with each other (as described earlier), the cooperative effect can be even greater. In some cases, the combined action of the regulatory proteins can eventually displace the histone core of the nucleosome altogether. Many transcription regulators, when their affinities for DNA and their concentrations are sufficiently high, can take advantage of nucleosome breathing and thereby

Figure 7–12 How nucleosomes affect the binding of transcription regulators.

MBOC7_ptr_ch07_397-474.indd 408 02/12/21 12:44 PM

"invade" nucleosomes. Moreover, as we saw in Chapter 5, passing replication forks, which transiently displace histones, offer additional windows of opportunity for transcription regulators to bind to DNA.

Although nucleosomes generally inhibit the DNA binding of transcription regulators, some regulators—if their *cis*-regulatory sequences are exposed on the nucleosome surface—can bind with nearly the same affinity as they do on naked DNA, occupying their binding sites while the DNA is still tightly wrapped around the histone core (Figure 7–13). Transcription regulators with this property are sometimes called *pioneer factors*, because they are often the first proteins to bind DNA when a previously silent gene becomes transcriptionally active. Although their binding typically destabilizes the nucleosome, pioneer factors probably exert their major effects by attracting additional proteins that alter chromatin structure, such as nucleosome remodeling complexes. If one transcription regulator binds its *cis*-regulatory sequence on a nucleosome and attracts a chromatin remodeling complex, the localized action of the remodeling complex can allow a second transcription regulator to efficiently bind nearby.

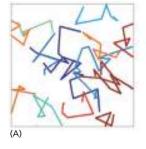

Our discussion has emphasized how transcription regulators can work together in pairs. But in reality, larger numbers often cooperate by repeated use of the same principles. It is the cooperative formation of clusters of transcription regulators on DNA that probably explains why many key regulatory sequences in eukaryotic genomes are found to be "nucleosome free."

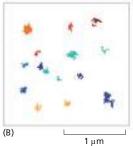

DNA-Binding by Transcription Regulators Is Dynamic

Thus far, we have treated transcription regulators as static—we have considered them as either bound to DNA or free in solution. But in reality, the situation is highly dynamic, with transcription regulator molecules in constant motion, rapidly binding and dissociating from DNA. In most cases a given transcription regulator molecule stays on its *cis*-regulatory sequence for only a short time, but it is rapidly replaced by other molecules of the same regulator. Thus, when we consider a *cis*-regulatory sequence being fully bound by its matching transcription regulator, this state is an average, over time, of many individual association and dissociation events.

By attaching a transcription regulator to a bright fluorescent tag, it is possible to follow single regulator molecules in live cells, as they diffuse randomly within the nucleus, bind to their *cis*-regulatory sequences, and then dissociate from them. In these *single-molecule tracking experiments*, different states for the regulator can be distinguished on the basis of the tagged protein's mobility over short time periods. A high-mobility regulator state is observed for the free protein diffusing in the nucleoplasm. At the other extreme, a very low-mobility state is attributed to the regulator bound to DNA, inasmuch as its restrained motions are similar to that of a histone molecule that has been labeled in the same way (Figure 7–14).

Whereas a histone remains stably bound in a nucleosome, transcription regulators remain in a low-mobility, DNA-bound state only transiently. Individual regulator molecules are observed to leave their DNA-bound state at a wide variety of rates—some molecules persist for only a fraction of a second, while others remain for minutes. How can we explain these differences? We saw earlier in the chapter (see Figure 7-10) that each transcription regulator has a preferred *cis*-regulatory sequence, but that it can also bind—albeit with lower affinity—to related

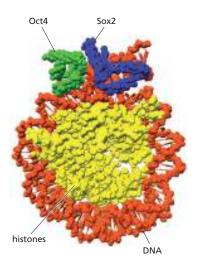

Figure 7–13 Two cooperating transcription regulators, Oct4 (green) and Sox2 (blue), bound to a nucleosome. These two transcription regulators work together and play key roles in maintaining embryonic stem cells (see Figures 7–36 and 7–37). Only the DNA-binding portion of each regulator protein is shown. (Courtesy of Nicolas H. Thomä and Alicia K. Michael. PDB code: 6790.)

Figure 7-14 Tracking single molecules of a transcription regulator in the nucleus of a living cell. By conjugating a fluorescent tag to the glucocorticoid receptor (see pp. 573-575), the behavior of this transcription regulator can be followed in living cells, using a microscope that follows its fluorescence. Computational methods then allow the observed behavior of such molecules to be classified into sets of distinct mobility groups, two of which are shown here. (A) Sample tracks observed for individual molecules of the glucocorticoid receptor in the freely diffusing mobility group. The positions illustrated were determined for a total of 10 seconds. (B) Tracks of individual molecules bound to DNA, with positions determined over a 120-second interval. (A and B, courtesy of D.A. Garcia and G.L. Hager.)

MBOC7_ptr_ch07_397-474.indd 409 02/12/21 12:44 PM

DNA sequences. Because the forward rates at which regulatory proteins "find" their *cis*-regulatory sequences are largely independent of the exact nucleotide sequence of that DNA, affinity differences are reflected in how long a protein remains bound on the DNA—the higher the affinity, the longer the protein stays bound.

Any protein, such as a transcription regulator, that binds tightly to a specific set of DNA sequences will also bind, albeit much more weakly, to any DNA sequence. This weak binding is useful because it allows a regulator to search for its target by "scanning" the DNA in the vicinity of the initial chromosomal site that it binds. Most such regulators will fail to find a matching *cis*-regulatory DNA sequence, and it is these that are thought to dissociate within seconds. The minority that persist for minutes are likely to have engaged with a matching *cis*-regulatory sequence. But because even these regulators do not remain on DNA for long periods, they need to be constantly replaced by another such molecule. Thus, as always, the static pictures in this textbook fail to do justice to the frantic state of motion that exists inside a cell (see pp. 65–66).

Summary

Transcription regulators recognize short stretches of double-helical DNA of defined sequence called cis-regulatory sequences, and they thereby determine which of the thousands of genes in a cell will be transcribed. Transcription regulators determine many cell properties, and their importance is reflected by the fact that approximately 10% of the protein-coding genes in most organisms produce them. Although each transcription regulator has unique features, most bind to DNA as homodimers or heterodimers and recognize DNA through one of a small number of structural motifs. Transcription regulators typically work in groups and bind to DNA cooperatively, a feature that is explained by several underlying mechanisms, some of which exploit the packaging of DNA in nucleosomes.

TRANSCRIPTION REGULATORS SWITCH GENES ON AND OFF

Having seen how transcription regulators bind to *cis*-regulatory sequences embedded in the genome, we can now discuss how, once bound, these proteins influence the transcription of genes. The situation in bacteria is simpler than in eukaryotes (for one thing, chromatin structure is not an issue), and we therefore discuss bacterial mechanisms before proceeding to the more complex situation in eukaryotes.

The Tryptophan Repressor Switches Genes Off

The genome of the bacterium *Escherichia coli* consists of a single, circular DNA molecule of about 4.6×10^6 nucleotide pairs that encodes approximately 4300 proteins. Only a fraction of these proteins are made at any one time. For example, all bacteria regulate the expression of many of their genes according to the food sources that are available in the environment. Thus in *E. coli*, five genes code for enzymes that manufacture the amino acid tryptophan. These genes are arranged in a cluster on the chromosome and are transcribed from a single promoter as one long mRNA molecule; such coordinately transcribed clusters are called *operons* (Figure 7–15). Such operons are common in bacteria but rare in

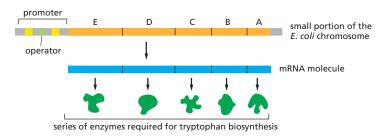

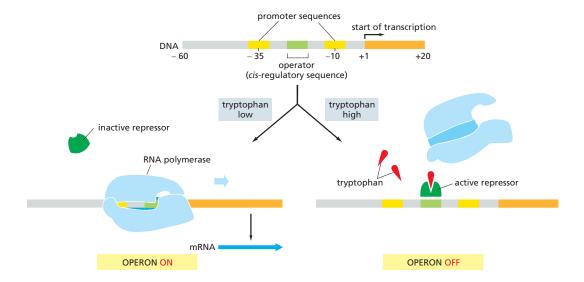

Figure 7-15 A cluster of bacterial genes can be transcribed from a single promoter. Each of these five genes encodes a different enzyme, and all of these enzymes are needed to synthesize the amino acid tryptophan from simpler molecules. The genes are transcribed as a single mRNA molecule, a feature that allows their expression to be coordinated. Clusters of genes transcribed as a single mRNA molecule are common in bacteria. Each of these clusters is called an operon because its expression is controlled by a cis-regulatory sequence called the operator (green), situated within the promoter. (In this and subsequent figures, the yellow blocks in the promoter represent DNA sequences that bind RNA polymerase; see Figure 6-12).

MBOC7_ptr_ch07_397-474.indd 410 02/12/21 12:44 PM

eukaryotes, where genes are typically transcribed and regulated individually (see Figures 6-75 and 6-90).

When tryptophan concentrations are low, the operon is transcribed; the resulting mRNA is translated to produce a full set of biosynthetic enzymes, which work in tandem to synthesize tryptophan from much simpler molecules. When tryptophan is abundant, however—for example, when the bacterium is in the gut of a mammal that has just eaten a protein-rich meal—the amino acid is imported into the cell and shuts down production of the enzymes, which are no longer needed.

We now understand exactly how this repression of the tryptophan operon comes about. Within the operon's promoter is a *cis*-regulatory sequence that is recognized by a transcription regulator. When this regulator binds to this sequence, it blocks access of RNA polymerase to the promoter, thereby preventing transcription of the operon (and thus production of the tryptophan-producing enzymes). The transcription regulator is known as the *tryptophan repressor*, and its *cis*-regulatory sequence is called the *tryptophan operator*. These components are controlled in a simple way: the repressor can bind to DNA only if it has also bound several molecules of tryptophan (**Figure 7–16**).

The tryptophan repressor is an allosteric protein, and the binding of tryptophan causes a subtle change in its three-dimensional structure so that the protein can bind tightly to the operator sequence. Whenever the concentration of free tryptophan in the bacterium drops, tryptophan dissociates from the repressor, the repressor no longer binds to DNA, and the tryptophan operon is transcribed. The repressor is thus a simple device that switches production of a set of biosynthetic enzymes on and off according to the availability of the end product of the pathway that the enzymes catalyze.

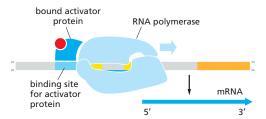

The tryptophan repressor protein itself is always present in the cell. The gene that encodes it is continually transcribed at a low level, so that a small amount of the repressor protein is always being made. Thus the bacterium can respond very rapidly to a rise or fall in tryptophan concentration.

Repressors Turn Genes Off and Activators Turn Them On

The tryptophan repressor, as its name suggests, is a *transcription repressor* protein: in its active form, it switches genes off, or *represses* them. Some bacterial transcription regulators do the opposite: they switch genes on, or *activate* them. These *transcription activator* proteins work on promoters that—in contrast to the promoter for the tryptophan operon—are only marginally able to bind and position RNA polymerase on their own. However, these poorly functioning promoters can be made fully functional by activator proteins that bind to nearby

Figure 7-16 Genes can be switched off by repressor proteins. If the concentration of tryptophan inside a bacterium is low (left), RNA polymerase (blue) binds to the promoter and transcribes the five genes of the tryptophan operon. However, if the concentration of tryptophan is high (right), the tryptophan repressor protein (dark green) becomes active and binds to the operator (light green), where it blocks the binding of RNA polymerase to the promoter. Whenever the concentration of intracellular tryptophan drops, this transcription regulator falls off the DNA allowing the polymerase to again transcribe the operon. Although not shown in the figure, the tryptophan repressor exists as a stable protein dimer.

MBOC7_ptr_ch07_397-474.indd 411 02/12/21 12:44 PM

cis-regulatory sequences and contact the RNA polymerase to help it initiate transcription (Figure 7–17).

DNA-bound activator proteins can increase the rate of transcription initiation as much as 1000-fold, a value consistent with a relatively weak and nonspecific interaction between the transcription regulator and RNA polymerase. For example, a 1000-fold change in the affinity of RNA polymerase for its promoter corresponds to a change in ΔG of $\sim \! 18$ kJ/mole, which could be accounted for by just a few weak, noncovalent bonds. Thus, many activator proteins work simply by providing a few favorable interactions that help to attract RNA polymerase to the promoter. To provide this assistance, however, the activator protein must be bound to its *cis*-regulatory sequence, and this sequence must be positioned precisely so that these favorable interactions can occur with an RNA polymerase molecule at its promoter.

Like the tryptophan repressor, activator proteins often have to interact with a second molecule to be able to bind DNA. For example, the bacterial activator protein CAP has to bind cyclic AMP (cAMP) before it can bind to DNA. Genes activated by CAP are switched on in response to an increase in intracellular cAMP concentration, which rises when glucose, the bacterium's preferred carbon source, is no longer available. CAP then drives the production of enzymes that allow the bacterium to digest other sugars.

Both an Activator and a Repressor Control the Lac Operon

The activity of a single bacterial promoter is often controlled by several different transcription regulators. The *Lac* operon in *E. coli*, for example, is controlled by both the Lac repressor and the CAP activator just discussed. The *Lac* operon encodes proteins required to import and digest the disaccharide lactose, a key nutrient in milk. In the absence of glucose (the cell's favorite energy source), the bacterium makes cAMP, which activates CAP to switch-on genes that allow the cell to utilize alternative sources of carbon—including lactose. It would be wasteful, however, for CAP to induce expression of the *Lac* operon if lactose itself were not present. Thus the Lac repressor shuts off the operon in the absence of lactose. This arrangement enables the control region of the *Lac* operon to integrate two different signals, so that the operon is highly expressed only when two conditions are met: glucose must be absent and lactose must be present (Figure 7–18). This genetic circuit thus behaves much like a switch that carries out a logic operation in a computer. When lactose is present AND glucose is absent, the cell executes the appropriate program—in this case, transcription of the genes that permit the uptake and utilization of lactose.

All transcription regulators, whether they are repressors or activators, must be bound to DNA to exert their effects. In this way, each regulatory protein acts selectively, controlling only those genes that bear a *cis*-regulatory sequence recognized by it. The logic of the *Lac* operon first attracted the attention of biologists more than 60 years ago. The way it works was uncovered by a combination of genetics and biochemistry, providing some of the first insights into how transcription is controlled in any organism.

DNA Looping Can Occur During Bacterial Gene Regulation

We have seen that transcription activators help RNA polymerase to initiate transcription and repressors hinder it. Otherwise the two types of transcription regulators are similar: both the tryptophan repressor and the CAP activator

Figure 7–17 Genes can be switched on by activator proteins. An activator protein binds to its cis-regulatory sequence on the DNA and interacts with the RNA polymerase to help it initiate transcription. Without the activator, the promoter fails to initiate transcription efficiently. In bacteria, the binding of the activator to DNA is often controlled by the interaction of a metabolite or other small molecule (red circle) with the activator protein.

MBOC7_ptr_ch07_397-474.indd 412 02/12/21 12:44 PM

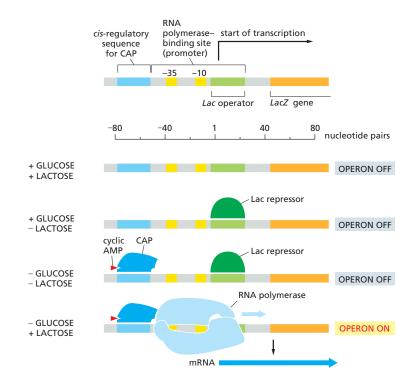

Figure 7-18 How the Lac operon is controlled by two transcription regulators, causing it to be expressed only when needed. LacZ, the first gene of the operon, encodes the enzyme β -galactosidase, which breaks down lactose to galactose and glucose. When lactose is absent, the Lac repressor binds to a cis-regulatory sequence, called the Lac operator, and shuts off expression of the operon (Movie 7.4). Addition of lactose increases the intracellular concentration of a related compound, allolactose; allolactose binds to the Lac repressor, causing it to undergo a conformational change that releases its grip on the operator DNA (not shown). This removes a block to expression of the Lac operon, but the operon can turn on only if the sugar glucose, a preferred carbon source, is absent. This is because cyclic AMP (red triangle) is produced by the cell in the absence of glucose, and this small molecule is required for CAP to bind to DNA and activate transcription.

protein must bind a small molecule to occupy their *cis*-regulatory sequences, and both recognize these DNA sequences using the same structural motif (the helix-turn-helix shown in Panel 7-1). Some proteins (for example, the CAP protein) can act either as a repressor or an activator, depending on the exact placement of a binding site relative to the promoter: if this site overlaps the promoter, CAP binding can prevent the assembly of RNA polymerase at the promoter, thus serving as a repressor.

Most bacteria have small, compact genomes, and the *cis*-regulatory sequences that control the transcription of a gene are typically located very near to the start point of transcription. But there are some exceptions to this generalization—*cis*-regulatory sequences can be located hundreds and even thousands of nucleotide pairs from the bacterial genes they control. In these cases, the intervening DNA loops out, allowing a transcription regulator bound at a distant site along the DNA to contact RNA polymerase (**Figure 7–19**). Here, the DNA is serving as a tether, enormously increasing the probability that the regulator will collide with a

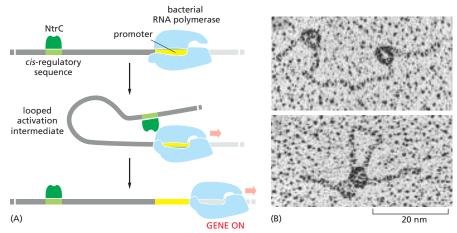

Figure 7–19 Transcriptional activation by DNA looping in bacteria. (A) The NtrC protein is a bacterial transcription regulator that activates transcription by directly contacting RNA polymerase. (B) The interaction of NtrC and RNA polymerase, with the intervening DNA looped out, can be seen in the electron microscope. (B, courtesy of Harrison Echols and Sydney Kustu.)

MBOC7_ptr_ch07_397-474.indd 413 02/12/21 12:44 PM

promoter-bound polymerase, compared with the situation where the regulator is free in solution. We will see shortly that, although the exception in bacteria, DNA looping is thought to occur in the regulation of nearly every eukaryotic gene. It has been proposed that the compact, simple genetic switches found in bacteria evolved in response to a severe competition for growth that put strong selective pressure on bacteria to maintain small genome sizes. In contrast, there appears to have been little selective pressure to "streamline" the genomes of multicellular organisms.

Complex Switches Control Gene Transcription in Eukaryotes

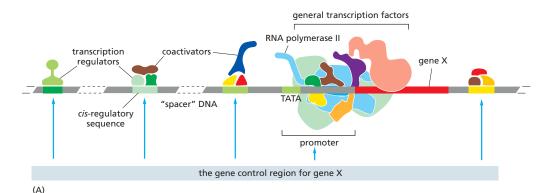

When compared to the situation in bacteria, transcription regulation in eukaryotes involves many more proteins and much longer stretches of DNA-and it often seems bewilderingly complex. Yet many of the same principles apply. As in bacteria, the time and place that each gene is to be transcribed are specified by its cis-regulatory sequences, which are "read" by the transcription regulators that bind to them. Once bound to DNA, positive transcription regulators (activators) help RNA polymerase to begin transcribing genes, and negative regulators (repressors) block this from happening. But in bacteria, most of the interactions between DNA-bound transcription regulators and RNA polymerases (whether they activate or repress transcription) are direct; that is, they contact each other. In contrast, these interactions are almost always indirect in eukaryotes: many intermediate proteins, including the histones and a large protein complex known as Mediator, act between DNA-bound transcription regulators and RNA polymerase. Moreover, in multicellular organisms, it is common for dozens of transcription regulators to control a single gene and for cis-regulatory sequences to be spread over tens of thousands of nucleotide pairs. DNA looping allows the DNA-bound regulatory proteins to interact with each other and ultimately to control RNA polymerase at the promoter. Many of the protein-protein interactions involved are of low affinity and are thought to trigger the formation of biomolecular condensates, which can facilitate reactions requiring such a large number of different components (see pp. 171-173). Finally, because nearly all of the DNA in eukaryotic organisms is organized in nucleosomes and higher-order chromatin structures, transcription initiation in eukaryotes must overcome this inherent block. In the next sections, we discuss each of these features of transcription initiation in eukaryotes, emphasizing how they provide extra levels of control not found in bacteria.

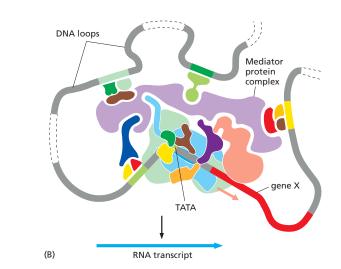

A Eukaryotic Gene Control Region Includes Many *cis-*Regulatory Sequences

In eukaryotes, RNA polymerase II transcribes all the protein-coding genes and many noncoding RNA genes. This polymerase requires five general transcription factors (with 27 subunits *in toto*; see Table 6–3, p. 333, and Figure 6–15), in contrast to bacterial RNA polymerase, which needs only a single general transcription factor (the σ subunit). As we saw in Chapter 6, the stepwise assembly of the general transcription factors at a eukaryotic promoter provides, in principle, multiple steps at which the cell can speed up or slow down the rate of transcription initiation in response to transcription regulators.

Because the many *cis*-regulatory sequences that control the expression of a typical gene are often spread over long stretches of DNA, we use the term **gene control region** to describe the whole expanse of DNA involved in regulating and initiating transcription of a eukaryotic gene. This includes the **promoter**, where the general transcription factors and the polymerase assemble, plus all of the *cis*-regulatory sequences to which transcription regulators bind to control the rate of the gene activation processes at the promoter (**Figure 7–20**). In animals and plants, it is not unusual to find the regulatory sequences of a gene dotted over stretches of DNA as large as 100,000 nucleotide pairs. For now, we can regard much of this DNA as "spacer" sequences that transcription regulators do not

MBOC7_ptr_ch07_397-474.indd 414 02/12/21 12:44 PM

directly recognize. We will see later in this chapter that some of this DNA is transcribed (but not translated) into long noncoding RNAs (lncRNAs), which have diverse functions in the cell.

In this chapter, we shall loosely use the term **gene** to refer to a segment of DNA that is transcribed into a functional RNA molecule, one that either codes for a protein or has a different role in the cell (see Table 6–1, p. 327). However, the classical view of a gene includes the gene control region as well, because mutations in it can produce an altered phenotype. Alternative RNA splicing further complicates the definition of a gene—a point we shall return to later.

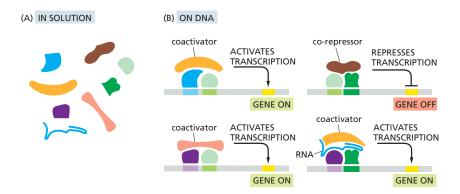

In contrast to the small number of general transcription factors, which are abundant proteins that assemble on the promoters of all genes transcribed by RNA polymerase II, there are thousands of different transcription regulators devoted to turning individual genes on and off. As we have seen, each eukaryotic gene is usually transcribed individually. Not surprisingly, the regulation of each eukaryotic gene is different in detail from that of every other gene, and it is difficult to formulate simple rules for gene regulation that apply in every case. We can, however, make some generalizations about how transcription regulators, once bound to gene control regions on DNA, set in motion the series of events that lead to gene activation or repression.

Eukaryotic Transcription Regulators Work in Groups

In bacteria, we saw that proteins such as the tryptophan repressor, the Lac repressor, and the CAP protein bind to DNA on their own and directly affect RNA polymerase at the promoter. Eukaryotic transcription regulators, in contrast, usually assemble together in groups at their *cis*-regulatory sequences. Often two

Figure 7-20 Transcription is controlled by gene control regions. (A) The gene control region of a typical eukaryotic gene depicted with the DNA arranged in a straight line. The promoter is the DNA sequence where the general transcription factors and the polymerase assemble (see Figure 6–15). The cis-regulatory sequences are binding sites for transcription regulators, whose presence on the DNA ultimately affects the rate of transcription initiation. These sequences can be located adjacent to the promoter, far upstream of it, or even within introns or entirely downstream of the gene. The broken stretches of DNA signify that the length of DNA between the cis-regulatory sequences and the start of transcription varies, sometimes reaching tens of thousands of nucleotide pairs in length. The TATA box is a DNA recognition sequence for the general transcription factor TFIID (see Figures 6-15 and 6-17). (B) DNA looping allows transcription regulators bound at many positions to "communicate" with the proteins that assemble at the promoter. As shown in this schematic diagram, many transcription regulators act through Mediator (described in Chapter 6), while some interact with the general transcription factors and RNA polymerase directly. Transcription regulators also act by recruiting proteins that alter the chromatin structure of the promoter (not shown here but discussed later in the chapter). Whereas Mediator and the general transcription factors are the same for all RNA polymerase II-transcribed genes, the transcription regulators and the locations of their binding sites relative to the promoter differ for each gene. At especially complex gene control regions, the many proteins that assemble can, by virtue of large numbers of low-specificity interactions, undergo phase transitions that further coalesce the protein and DNA components needed to initiate transcription-presumably accelerating the process.

MBOC7_ptr_ch07_397-474.indd 415 02/12/21 12:44 PM

or more regulators bind cooperatively, as discussed earlier in the chapter (see Figure 7–10). In some especially complex gene control regions, tens and even hundreds of such proteins may coassemble on DNA. In addition, a broad class of multisubunit proteins termed *coactivators* and *co-repressors* join with them. Typically, these coactivators and co-repressors do not recognize specific DNA sequences themselves; they are brought to those sequences by specific interactions with the DNA-bound transcription regulators. As their names imply, coactivators are typically involved in activating transcription and co-repressors in repressing it. In the following sections, we will see that coactivators and co-repressors can act in a variety of different ways to influence transcription once they have been localized on the genome by transcription regulators.

As shown in Figure 7-21, an individual transcription regulator can often participate in more than one type of regulatory complex. A protein might function, for example, in one case as part of a complex that activates transcription and in another case as part of a complex that represses transcription. Thus, individual eukaryotic transcription regulators function as regulatory parts that are used to build complexes whose function depends on the final assembly of all of the individual components. Each eukaryotic gene is therefore regulated by a "committee" of proteins, all of which must be present to express the gene at its proper level. Often the protein-protein interactions between transcription regulators and between regulators and coactivators are too weak for them to assemble in solution; however, the appropriate combination of cis-regulatory sequences can "crystallize" the assembly of these complexes on DNA. In very large and complex gene control regions, this assembly may be accompanied by a phase transition to form a biomolecular condensate, whereby all the components are held together even more efficiently by keeping them in rough proximity even when individual proteins disassociate from DNA.

Activator Proteins Promote the Assembly of RNA Polymerase at the Start Point of Transcription

The *cis*-regulatory sequences to which eukaryotic transcription activator proteins bind were originally called *enhancers* because their presence "enhanced" the rate of transcription initiation. It initially came as a surprise when it was discovered that these sequences could be found tens of thousands of nucleotide pairs away from the promoter; as we have seen, DNA looping, which was not widely appreciated at the time, can now explain this initially puzzling observation.

Once bound to DNA, how do assemblies of activator proteins increase the rate of transcription initiation? At most genes, several mechanisms work in concert. Their ultimate function is to attract and position RNA polymerase II at the promoter and to release it so that transcription can begin.

Some activator proteins bind directly to one or more of the general transcription factors, accelerating their assembly on a promoter that has been brought in proximity—through DNA looping—to that activator. Most transcription activators, however, attract coactivators that then perform the biochemical tasks needed to initiate transcription. As we have seen, one of the most prevalent coactivators is

Figure 7–21 Eukaryotic transcription regulators assemble into complexes on DNA. (A) Seven different proteins and an RNA molecule are shown. The nature and function of the complex they form depend on the specific cis-regulatory sequences that seed their assembly. (B) Some assembled complexes activate gene transcription, while another represses transcription. Note that the light green and dark green proteins are shared by both activating and repressing complexes. Proteins that do not themselves bind DNA but assemble on other DNA-bound transcription regulators are termed coactivators or co-repressors. In some cases (lower right), long, noncoding RNA molecules are also found in these assemblies. As described later in this chapter, these RNAs often act as scaffolds to hold groups of proteins together.

MBOC7_ptr_ch07_397-474.indd 416 02/12/21 12:44 PM

the large *Mediator* protein complex, composed of more than 30 subunits. About the same size as RNA polymerase itself, Mediator serves as a bridge between DNA-bound transcription activators, RNA polymerase, and the general transcription factors, facilitating their assembly at the promoter (see Figure 7–20).

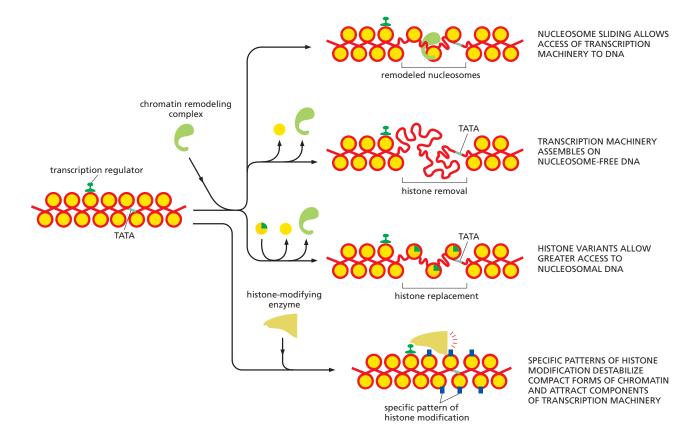

Eukaryotic Transcription Activators Direct the Modification of Local Chromatin Structure

The eukaryotic general transcription factors and RNA polymerase are unable, on their own, to assemble on a promoter that is packaged in nucleosomes. Thus, in addition to directing the assembly of the transcription machinery at the promoter, eukaryotic transcription activators—once bound to their *cis*-regulatory sequences—promote transcription by triggering changes to the chromatin structure of the promoters, rendering the underlying DNA more accessible. The enzymes that alter chromatin structure are usually carried as subunits of coactivators, which are typically multiprotein complexes, with different subunits carrying out different functions. For example, such a coactivator might carry one subunit that associates with specific DNA-bound transcription regulators, another that associates with one of the general transcription factors, and several more that alter chromatin structure in different ways.

The most important ways of locally altering chromatin are through covalent histone modifications, nucleosome remodeling, nucleosome removal, and histone replacement (all discussed in Chapter 4). Eukaryotic transcription activators use all four of these mechanisms: thus they attract coactivators that include histone modification enzymes, ATP-dependent chromatin remodeling complexes, and histone chaperones. These proteins often act cooperatively to alter the chromatin structure of promoters, providing greater access to the DNA (Figure 7-22).

Often a series of individual events, ultimately directed by transcription regulators, must occur before RNA polymerase can be assembled onto a promoter,

Figure 7–22 Eukaryotic transcription activator proteins direct local alterations in chromatin structure. Nucleosome remodeling, nucleosome removal, histone replacement, and certain types of histone modifications favor transcription initiation (see Table 4–2, p. 210). As illustrated, some of these changes are driven by different types of ATP-dependent chromatin remodeling complexes (see Figures 4–26 and 4–27); most also involve histone chaperones (not shown). Such alterations increase the accessibility of DNA and facilitate the binding of RNA polymerase and the general transcription factors.

MBOC7_ptr_ch07_397-474.indd 417 02/12/21 12:44 PM

Figure 7–23 Successive histone modifications during transcription initiation. In this example, taken from the human interferon-β gene promoter, a transcription activator binds to DNA packaged into chromatin and attracts a histone acetyl transferase that acetylates lysine 9 of histone H3 and lysine 8 of histone H4 (see Figure 4–35). Next, a histone kinase, part of a different coactivator attracted by the same transcription activator, phosphorylates serine 10 of histone H3, but it can only do so after lysine 9 has been acetylated. This serine modification signals the original histone acetyl transferase to acetylate position K14 of histone H3. Next, the general transcription factor TFIID and a chromatin remodeling complex come into play to promote the subsequent steps of transcription initiation. TFIID and the remodeling complex both recognize acetylated histone tails through a *bromodomain*, a protein domain specialized to read this particular mark on histones; a bromodomain is carried in a subunit of each protein complex. Binding of TFIID causes a sharp bend in the DNA (not shown but see Figure 6–17), which facilitates sliding of the nucleosome to a new position, thereby freeing the start site of transcription for binding by RNA polymerase II.

The histone acetyl transferase, the histone kinase, and the chromatin remodeling complex are all subunits of coactivators. The order of events shown applies to a specific promoter; at other genes, the steps may occur in a different order or individual steps may be omitted altogether. (Adapted from T. Agalioti et al., *Cell* 111:381–392, 2002.)

with details that depend on the gene being regulated. In the example illustrated in Figure 7-23, a series of specific histone tail modifications is triggered by a transcription activator; these modifications then attract additional proteins to the promoter, including both a chromatin remodeling complex and a general transcription factor. Those proteins can in turn recruit additional proteins to the promoter, while also destabilizing adjacent nucleosomes.

Because the local chromatin changes directed by one transcription regulator often allow the binding of additional proteins—both directly (see Figure 7-12) and indirectly as just described—a cascade of events typically takes place on the control regions of eukaryotic genes to regulate their transcription.

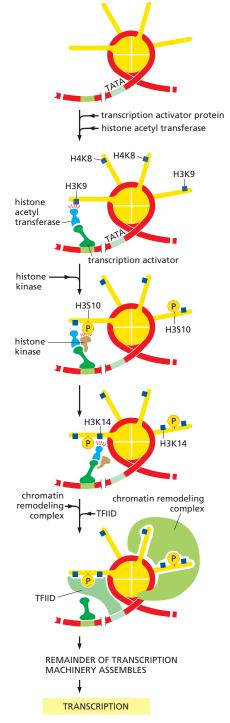

As RNA polymerase II transcribes through a gene a different type of chromatin modification occurs. The histones just ahead of the polymerase are acetylated by enzymes carried by the polymerase, removed by histone chaperones, and deposited behind the moving polymerase. These histones are then rapidly deacetylated and methylated, also by complexes that are carried by the polymerase, leaving behind nucleosomes that are especially resistant to transcription. This remarkable process seems to prevent spurious transcription reinitiation behind a moving polymerase, which, in essence, must clear a path through chromatin as it transcribes. Later in this chapter, when we discuss *RNA interference*, the potential dangers to the cell of such inappropriate transcription will become especially obvious.

Some Transcription Activators Work by Releasing Paused RNA Polymerase

Thus far, we have emphasized how transcription regulators—once bound to DNA—can assemble multiple components and stimulate transcription initiation. But for some genes, a key regulatory step occurs after this point (Figure 7–24). In the most common of these cases, the RNA polymerase halts after transcribing about 50 nucleotides of RNA, and further elongation requires a new transcription activator to bind to the gene's control region (see Figure 7–24C).

The release of a paused RNA polymerase can occur in several ways. In some cases, the new activator brings in a chromatin remodeling complex that removes a nucleosome block to the elongating RNA polymerase. In other cases, the activator communicates with RNA polymerase (typically through a coactivator), signaling it to forge ahead. Finally, as we saw in Chapter 6, RNA polymerase requires *elongation factors* to effectively transcribe through chromatin (Figure 6–19). In some cases, the key step in gene activation is the delayed loading of these factors onto RNA polymerase, directed by DNA-bound transcription activators. Once loaded, these factors allow the polymerase to move through blocks imposed by chromatin structure to begin transcribing the gene effectively.

Paused polymerases are common in humans, where a significant fraction of genes that are not being transcribed have a paused polymerase located just

MBOC7_ptr_ch07_397-474.indd 418 02/12/21 12:44 PM

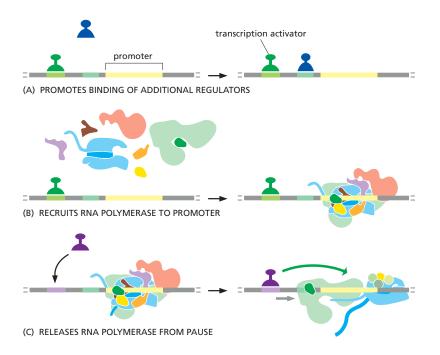

Figure 7-24 Different transcription regulators can act at different steps. (A) As described earlier in this chapter (see Figure 7-12), a DNA-bound transcription activator can promote DNA binding by additional transcription regulators. (B) As shown in more detail in Figures 7-20 and 7-22, most transcription activators direct assembly of RNA polymerase at promoters; this can occur by a variety of mechanisms. (C) Some other transcription activators, once bound to DNA, release RNA polymerase molecules that are paused after transcribing about 50 nucleotides of RNA. For simplicity, many of the additional proteins required for transcription initiation are not shown.

downstream from the promoter. Having RNA polymerase already poised on a promoter in the beginning stages of transcription bypasses the step of assembling many components at the promoter, which is often slow. This mechanism is therefore thought to allow cells to begin transcribing a gene in rapid response to an extracellular signal.

Transcription Activators Work Synergistically

We have seen that complexes of transcription activators and coactivators assemble cooperatively on DNA. We have also seen that these assemblies can promote different steps in transcription initiation. In general, where several factors work together to enhance a reaction rate, the joint effect is not merely the sum of the enhancements that each factor alone contributes, but the product of them. If, for example, factor A lowers the free-energy barrier for a reaction by a certain amount and thereby speeds up the reaction 100-fold, and factor B, by acting on that reaction, does likewise, then A and B acting in parallel can lower the energy barrier by a double amount and speed up the reaction 10,000-fold. Even if A and B work simply by attracting the same protein, the affinity of that protein for the reaction site increases multiplicatively. Thus, transcription activators often exhibit transcriptional synergy, where several DNA-bound activator proteins working together produce a transcription rate that is much higher than the sum of their transcription rates working alone (Figure 7-25).

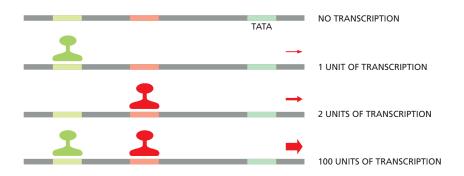

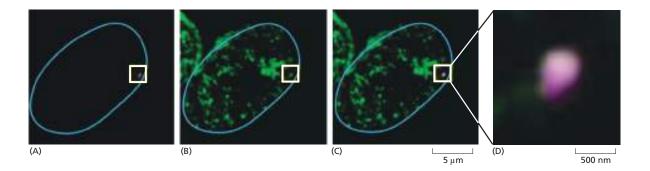

Figure 7-25 Transcriptional synergy. This experiment compares the rate of transcription produced by three experimentally constructed regulatory regions in a eukaryotic cell and reveals transcriptional synergy, a greater than additive effect of multiple activators working together. Such transcriptional synergy is not only observed between different transcription activators from the same organism: it is also seen between activator proteins from different eukaryotic species when they are experimentally introduced into the same cell. This last observation reflects the high degree of conservation of the machinery responsible for eukaryotic transcription initiation.

MBOC7_ptr_ch07_397-474.indd 419 02/12/21 12:44 PM

As a result, the rate of transcription of a gene ultimately depends on the spectrum of regulatory proteins that are bound upstream and downstream of its transcription start site, along with the coactivator proteins they bring to the DNA.

Condensate Formation Likely Increases the Efficiency of Transcription Initiation

We have discussed in broad, conceptual terms the many different types of proteins that must assemble for transcription of a typical gene to begin. For especially complex gene control regions, such as those of key human genes that orchestrate development, several hundred individual subunits are involved and, as they begin to assemble on DNA, they become involved in networks that create phase transitions, forming small biomolecular condensates. As described in Chapter 3, such condensates hold their proteins in loose proximity, such that, when one disassociates from the assembly, it can be retained nearby by a network of fluctuating weak interactions (see pp. 171–173). Consistent with this idea, many transcription regulators, coactivators, and co-repressors contain the type of low-complexity, unstructured regions that help to drive condensate formation.

How might this aid transcription? At least some of these transcription condensates contain additional copies of key proteins, including the Mediator complex (Figure 7–26). The presence of these extra copies in the same condensate is proposed to make transcription initiation an efficient but highly dynamic process, with proteins within the condensate rapidly exchanging on and off DNA. According to this view, Figure 7–20B represents only a frozen moment in transcription initiation. Whether such condensates form on most eukaryotic genes that are being transcribed—or on just those whose regulation is especially complex—remains to be determined.

Eukaryotic Transcription Repressors Can Inhibit Transcription in Several Ways

Although the "default" state of eukaryotic DNA packaged into nucleosomes is resistant to transcription, eukaryotes nonetheless use transcription regulators to repress the transcription of individual genes. These transcription repressors can rapidly turn off a gene that is being actively transcribed, and they can depress the rate of transcription even below that of the very low default value. Like the transcription activators discussed earlier, transcription repressors often work on a gene-by-gene basis. But unlike the bacterial repressors discussed earlier in this chapter, eukaryotic repressors do not directly compete with the RNA polymerase for access to the DNA. Instead, they use a variety of other mechanisms, some of which are illustrated in Figure 7-27. Like transcription activation, transcription repression can act through more than one mechanism at a given target gene, thereby ensuring especially efficient repression.

The different mechanisms of repression depicted in Figure 7–27 have different consequences for the ease with which a repressed gene can be reactivated. For most of the strategies, the repressed state is relatively easy to rapidly reverse, for

Figure 7-26 Condensate formation at the transcription control region of the Nanog gene in a mouse embryonic stem cell. The cell was fixed, and in (A) the Nanog gene was identified by hybridizing a complementary nucleotide sequence attached to a red fluorophore. according to a procedure known as FISH (see Figure 8-32). Nanog is a key transcription regulator in embryonic stem cells (see Figure 7-10), and its own regulatory region is one of the most complex in the mouse genome. The nucleus is indicated by the blue oval. (B) A subunit of Mediator fused to a green fluorescent protein (see Figure 9-16) was visualized. (C) The two preceding images have been merged, and in (D) the portion of the image in the white square is magnified tenfold. The size and diffuse nature of the "blob" suggest a condensate containing a large number of proteins. Note that additional condensates of Mediator are visible throughout the nucleus and may represent condensates at other enhancers. These condensates are much smaller than those of the nuclear "organelles," such as the nucleolus, discussed in Chapter 6, (From B.R. Sabari et al., Science 361:eaar3958, 2018. With permission from AAAS.)

MBOC7_ptr_ch07_397-474.indd 420 02/12/21 12:44 PM

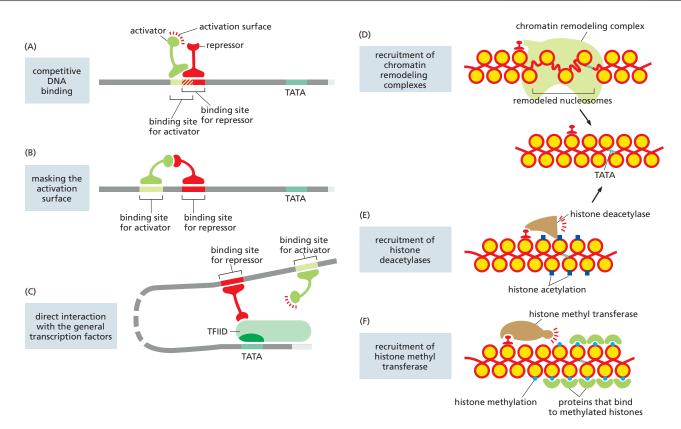

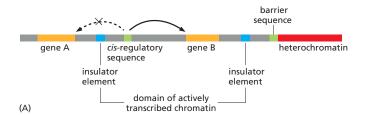

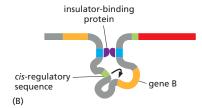

Figure 7–27 Six of the ways in which eukaryotic repressor proteins can operate. (A) A repressor protein outcompetes activator proteins for binding to the same regulatory DNA sequence. (B) Both activator and repressor proteins bind close to each other on DNA, and the repressor "quenches" the activator, preventing it from functioning (for example, by blocking the recruitment of its coactivators). (C) The repressor "poisons" assembly of the general transcription factors by binding to and stabilizing an intermediate. (D) The repressor recruits a chromatin remodeling complex that restores the nucleosomal state of the promoter region to its pre-transcriptional, default form. (E) The repressor attracts a histone deacetylase to the promoter, removing the histone acetylation needed for transcription initiation (see Figure 7–23). (F) Heterochromatin formation is triggered when a repressor attracts a specific histone methyl transferase that trimethylates either lysine 9 or lysine 27 on histone H3, thereby creating either H3K9me3- or H3K27me3-marked nucleosomes. "Read-write" mechanisms then spread each type of methylated nucleosome for thousands of nucleotide pairs along the DNA; they also help the methylation pattern to be inherited across cell divisions (see Figures 4–40 and 4–44). The final step in heterochromatin formation occurs when each type of modified nucleosome attracts additional proteins that condense the DNA and maintain it in a transcriptionally silent form.

example, by simply inactivating the repressor. But, the last mechanism—a directed methylation of specific histone amino acids that creates an unusually highly condensed form of chromatin, known as heterochromatin—is self-reinforcing and can propagate even when the initiating signal is no longer present (see Figure 4–44). As discussed in Chapter 4, chromatin that is marked by H3K9me3 (trimethylation of the lysine at position 9 of histone H3) appears to be the most difficult to transcribe. Typically located around centromeres and repeated DNA sequences such as inactive transposons, this type of heterochromatin strongly suppresses both genetic recombination and transcription. A different histone H3 modification (H3K27me3) is associated with a second form of heterochromatin that is also resistant to transcription. Although apparently easier to activate than the H3K9me3 form, this form of chromatin is also self-propagating and can persist across cell divisions, after the initiating signal has disappeared.

These two types of heterochromatin are used to tightly repress genes active in early development, presumably to make sure that these genes are not expressed in the mature organism. Tight, heritable gene repression is especially important to animals and plants whose growth depends on elaborate and complex developmental programs. Misexpression of a single gene at a critical time can have

MBOC7_ptr_ch07_397-474.indd 421 02/12/21 12:44 PM

disastrous consequences for the individual. For this reason, many of the genes encoding the most important developmental regulatory proteins are kept tightly repressed, often by multiple mechanisms.

Insulator DNA Sequences Prevent Eukaryotic Transcription Regulators from Influencing Distant Genes

We have seen that all genes have control regions, which dictate at which times, under what conditions, and in what tissues the gene will be expressed. We have also seen that eukaryotic transcription regulators can act across very long stretches of DNA, with the intervening DNA looped out. How, then, are control regions of different genes kept from interfering with one another? For example, what keeps a transcription regulator bound on the control region of one gene from looping in the wrong direction and inappropriately influencing the transcription of an adjacent gene? And, if complex regulatory regions form biomolecular condensates, what keeps all of the control regions from forming a giant condensate where the regulatory information would become scrambled?

To avoid such cross-talk between control regions, several types of DNA elements compartmentalize the genome into discrete regulatory domains. In Chapter 4, we discussed *barrier sequences* that prevent the spread of heterochromatin into genes that need to be expressed (see Figure 4-41). A second type of DNA element, called an *insulator*, prevents *cis*-regulatory sequences from running amok and activating inappropriate genes (Figure 7-28). As we saw in Chapter 4, insulator sequences function by forming loops of chromatin, an effect mediated by specialized proteins that recognize them (see Figures 4-57 and 7-28B). The loops are thought to keep a gene and its control region in rough proximity and help to prevent the control region from "spilling over" to adjacent genes. More generally, the distribution of insulators and barrier sequences in a genome helps to divide it into independent domains of gene regulation and chromatin structure (see pp. 223-225).

The distribution of the more than 10,000 loops on the collection of mammalian chromosomes can change as cells differentiate or as they respond to changes in their environment. In addition, these loops formed by insulators are not static; rather, they undergo a continual process of loop extrusion and release that is driven by cohesion protein rings (see Figure 4–57). It has been proposed that the extrusion process itself helps to juxtapose enhancers with their matching promoters by sliding them past one another, while helping to break up inappropriate enhancer–promoter connections by physically separating them.

Although chromosomes are dynamically organized into domains that discourage control regions from acting indiscriminately, there are special circumstances where a control region located on one chromosome has been found to deliberately activate a gene located on a different chromosome. Although there is much we do not understand about this mechanism, it reflects the extreme versatility of transcription regulation strategies.

Summary

Transcription regulators switch the transcription of individual genes on and off in cells. In prokaryotes, these proteins typically bind to specific DNA sequences close to the RNA polymerase start site and, depending on the nature of the

Figure 7–28 Schematic diagram summarizing the properties of insulators and barrier sequences. (A) Insulators directionally block the action of enhancers, whereas barrier sequences prevent the spread of heterochromatin. How barrier sequences likely function is depicted in Figure 4–41. (B) Insulator-binding proteins (purple) hold chromatin in loops that favor "correct" enhancer–promoter associations. Thus, gene B is properly regulated, and gene B's cis-regulatory sequences can be prevented from influencing the transcription of gene A. The major insulator-binding protein in mammals is denoted CTCF.

MBOC7_ptr_ch07_397-474.indd 422 02/12/21 12:44 PM

regulatory protein and the precise location of its binding site relative to the start site, either activate or repress transcription of the gene. The flexibility of the DNA helix, however, also allows transcription regulators bound at distant sites to affect the RNA polymerase at the promoter by the looping out of the intervening DNA. The regulation of higher eukaryotic genes is much more complex, commensurate with a larger genome size and the large variety of cell types that are formed. A single eukaryotic gene is typically controlled by many transcription regulators bound to sequences that can be tens or even hundreds of thousands of nucleotide pairs from the promoter that directs transcription of the gene. Eukaryotic activators and repressors act by a wide variety of mechanisms—generally both altering chromatin structure and controlling the assembly of the general transcription factors and RNA polymerase at the promoter. They do this by attracting coactivators and co-repressors, protein complexes that perform the necessary biochemical reactions. The time and place that each gene is transcribed, as well as its rates of transcription under different conditions, are determined by the particular spectrum of transcription regulators present in the cell that bind to the control region of the gene.

MOLECULAR GENETIC MECHANISMS THAT CREATE AND MAINTAIN SPECIALIZED CELL TYPES

Although all cells must be able to switch genes on and off in response to changes in their environments, the cells of multicellular organisms have evolved this capacity to an extreme degree. In particular, once a cell in a multicellular organism becomes committed to differentiate into a specific cell type, the cell maintains this choice through many subsequent cell generations, which means that it remembers the changes in gene expression involved in the choice. This phenomenon of *cell memory* is a prerequisite for the creation of organized tissues and for the maintenance of stably differentiated cell types. In contrast, other changes in gene expression in eukaryotes, as well as most such changes in bacteria, are only transient. The tryptophan repressor, for example, switches off the tryptophan genes in bacteria only in the presence of tryptophan; as soon as tryptophan is removed from the medium, the genes are switched back on, and the descendants of the cell will have no memory that their ancestors had been exposed to tryptophan.

In this section, we shall examine some specific examples that illustrate how cell types are specified and maintained and how simple gene regulatory devices can be combined to create the "logic circuits" through which cells integrate signals and remember events in their past. We begin by considering one such complex gene control region that has been studied in great detail.

Complex Genetic Switches That Regulate *Drosophila* Development Are Built Up from Smaller Modules

We have seen that transcription regulators can be positioned at multiple sites along long stretches of DNA and that these proteins can bring into play coactivators and co-repressors that ultimately position and activate RNA polymerase to begin transcription. Here, we discuss how the numerous transcription regulators that bind to the control region of a gene can integrate external information, so as to cause the gene to be transcribed at the proper place and time.

The expression of the *Drosophila Even-skipped* (*Eve*) gene plays an important part in the development of the *Drosophila* embryo. If this gene is inactivated by mutation, many parts of the embryo fail to form, and the embryo dies early in development. At the stage of development when *Eve* begins to be expressed, the embryo is a single giant cell containing multiple nuclei in a common cytoplasm. This cytoplasm contains a mixture of transcription regulators that are distributed unevenly along the length of the embryo, thus providing *positional information* that distinguishes one part of the embryo from another

MBOC7_ptr_ch07_397-474.indd 423 02/12/21 12:44 PM

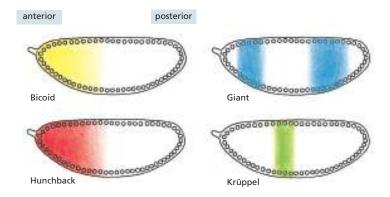

Figure 7–29 The nonuniform distribution of transcription regulators in an early *Drosophila* embryo. At this stage, the embryo is a syncytium; that is, multiple nuclei are contained in a common cytoplasm. Although the nuclei are shown in only a slice of the embryo, in reality, they are arranged in three dimensions around the inner surface of the giant cell.

(Figure 7–29). Although the nuclei are initially identical, they rapidly begin to express different genes because they are exposed to different transcription regulators: the nuclei near the anterior end of the developing embryo are exposed to a set of transcription regulators that is different from the set present at the middle and that present at the posterior end of the embryo.

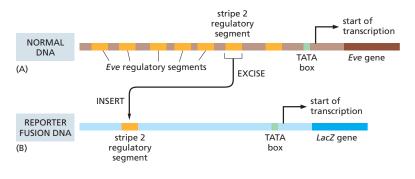

The regulatory DNA sequences that control the *Eve* gene have evolved to "read" the concentrations of transcription regulators at each position along the length of the embryo, so as to cause the *Eve* gene to be expressed in seven precisely positioned stripes, each initially five to six nuclei wide. How is this remarkable feat of information processing carried out? Although there is still much to learn, several general principles have emerged from studies of *Eve* and other genes that are similarly regulated.

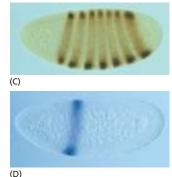

The control region of the *Eve* gene is very large (approximately 20,000 nucleotide pairs). It is formed from a series of relatively simple regulatory modules, each of which contains multiple *cis*-regulatory sequences and is responsible for specifying a particular stripe of *Eve* expression along the embryo. This modular organization of the *Eve* gene control region was revealed by experiments in which a particular regulatory module (say, that specifying stripe 2) is removed from its normal setting upstream of the *Eve* gene, placed in front of a reporter gene, and reintroduced into the *Drosophila* genome. When developing embryos derived from flies carrying this genetic construct are examined, the reporter gene is found to be expressed in precisely the position of stripe 2 but not in the other normal stripe positions (**Figure 7–30**). Similar experiments reveal the existence of other regulatory modules, which specify other stripes.

The Drosophila Eve Gene Is Regulated by Combinatorial Controls

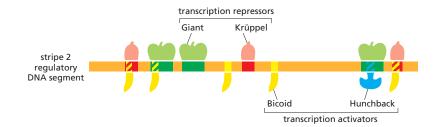

A detailed study of the stripe 2 regulatory module has provided insights into how it reads and interprets positional information. The module contains recognition sequences for two transcription regulators that activate *Eve* transcription (Bicoid and Hunchback) and for two that repress it (Krüppel and Giant) (Figure 7–31).

Figure 7–30 Experiment demonstrating the modular construction of the Eve gene regulatory region. (A) A 480nucleotide-pair section of the Eve regulatory region was removed and (B) inserted upstream of a test promoter that directs the synthesis of the enzyme β-galactosidase (the product of the E. coli LacZ gene-see Figure 7-18). (C, D) When this artificial construct was reintroduced into the genome of Drosophila embryos. the embryos (D) expressed β-galactosidase (detectable by histochemical staining) precisely in the position of the second of the seven Eve stripes. (C) The complete set of Eve stripes was detected using antibodies directed against the Eve protein. β-Galactosidase is simple to detect and thus provides a convenient way to monitor the expression specified by a gene control region. As used here, β-galactosidase is said to serve as a reporter, because it "reports" the activity of a gene control region. (C and D, courtesy of Stephen Small and Michael Levine.)

MBOC7_ptr_ch07_397-474.indd 424 02/12/21 12:44 PM

The relative concentrations of these four proteins determine whether the protein complexes that form at the stripe 2 module activate transcription of the *Eve* gene. **Figure 7-32** shows the distributions of the four transcription regulators across the region of a *Drosophila* embryo where stripe 2 forms. It is thought that either of the two repressor proteins, when bound to the DNA, will turn off the stripe 2 module, whereas both Bicoid and Hunchback must bind for this module's maximal activation. This simple regulatory scheme suffices to turn on the stripe 2 module (and therefore the expression of the *Eve* gene) only in those nuclei located where the levels of both Bicoid and Hunchback are high and both Krüppel and Giant are absent—a combination that occurs in only one region of the early embryo. It is not known exactly how these four transcription regulators interact with coactivators and co-repressors to specify the final level of transcription across the stripe, but the outcome very likely relies on competition between activators and repressors that act by the mechanisms outlined in Figures 7-21, 7-22, and 7-27.

The stripe 2 element is autonomous, inasmuch as it specifies stripe 2 when isolated from its normal context (see Figure 7–30). The other stripe regulatory modules are thought to be constructed similarly, reading positional information provided by other combinations of transcription regulators. The entire *Eve* gene control region binds more than 20 different transcription regulators. Seven combinations of regulators—one combination for each stripe—specify *Eve* expression, while many other combinations (all those found in the interstripe regions of the embryo) keep all the stripe elements silent. A large and complex control region is thereby built from a series of smaller modules, each of which consists of a unique arrangement of short *cis*-regulatory sequences recognized by specific transcription regulators.

The *Eve* gene itself encodes a transcription regulator, which, after its pattern of expression is set up in seven stripes, controls the expression of other *Drosophila* genes. As development proceeds, the embryo is thus subdivided into finer and finer regions that eventually give rise to the different body parts of the adult fly, as discussed in Chapter 21.

Eve exemplifies the complexity of transcription control regions in plants and animals. As this example shows, control regions can respond to many different inputs, integrate this information, and produce a complex spatial and temporal output as

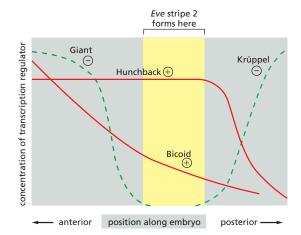

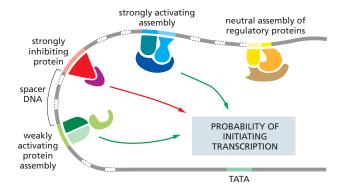

Figure 7-31 The Eve stripe 2 unit. The segment of the Eve gene control region identified in Figure 7-30 contains cisregulatory sequences for four transcription regulators. It is known from genetic experiments that these four regulatory proteins are responsible for the proper expression of Eve in stripe 2. Flies that are deficient in the two gene activators Bicoid and Hunchback, for example, fail to efficiently express Eve in stripe 2. In flies deficient in either of the two gene repressors, Giant and Krüppel, stripe 2 expands and covers an abnormally broad region of the embryo. As indicated, in some cases the binding sites for the transcription regulators overlap, and the proteins can compete for binding to the DNA. For example, binding of Krüppel and binding of Bicoid to the site at the far right is mutually exclusive.

Figure 7-32 Distribution of the transcription regulators responsible for ensuring that Eve is expressed in stripe 2. The distributions of these proteins were visualized by staining a developing Drosophila embryo with antibodies directed against each of the four proteins, and a graph of the staining intensities is shown. The expression of Eve in stripe 2 occurs only at the position where the two activators (Bicoid and Hunchback) are present and the two repressors (Giant and Krüppel) are absent. In fly embryos that lack Krüppel, for example, stripe 2 expands posteriorly. Likewise, stripe 2 expands posteriorly if the DNAbinding sites for Krüppel in the stripe 2 module are inactivated by mutation (see also Figure 7-31).

MBOC7_ptr_ch07_397-474.indd 425 02/12/21 12:44 PM

development proceeds. However, exactly how all these mechanisms work together to produce the final output is understood only in broad outline (Figure 7–33).

Transcription Regulators Are Brought into Play by Extracellular Signals

The above example from *Drosophila* clearly illustrates the power of combinatorial control, but this case is unusual in that the nuclei are exposed directly to positional cues in the form of concentrations of transcription regulators. In embryos of most other organisms and in all adults, individual nuclei are in separate cells, and extracellular information (including positional cues) must be passed across the plasma membrane so as to generate signals in the cytosol that cause different transcription regulators to become active in different cell types. Some of the different mechanisms that are known to be used to activate transcription regulators are diagrammed in **Figure 7–34**; in Chapter 15, we discuss how extracellular signals trigger these changes.

Like the fly example discussed earlier, mammalian enhancers are also modular. An example is the control region responsible for regulating the α -globin gene, which codes for one of the subunits of hemoglobin (see Figure 3–20). Here, five

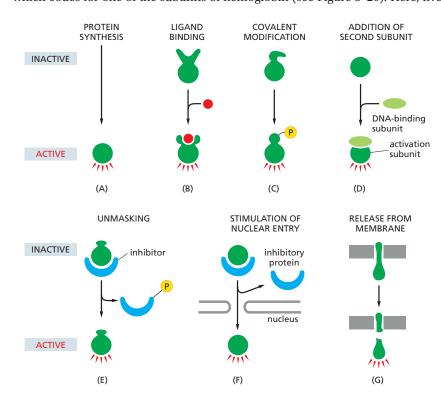

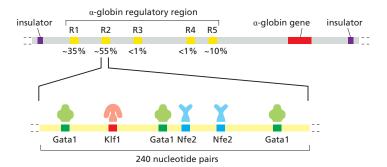

Figure 7-33 The integration of multiple inputs at a promoter. Multiple sets of transcription regulators, coactivators, and co-repressors can work together to influence transcription initiation at a promoter, as they do in the Eve stripe 2 module illustrated in Figure 7-31. It is not yet understood in detail how the cell achieves integration of multiple inputs, but it is likely that the final transcriptional activity of the gene results from competitions between activators and repressors that act by the mechanisms summarized in Figures 7-21, 7-22, and 7-27. As we saw earlier, for especially complex gene control regions, it has been proposed that these competitions take place and are "summed up" in localized biomolecular condensates formed by networks of weak interactions.

Figure 7-34 Some ways in which the activity of transcription regulators is controlled inside eukaryotic cells. (A) The protein is synthesized only when needed. (B) Activation by ligand binding. (C) Activation by covalent modification; phosphorylation is shown here, but many other modifications are possible (see Table 3-4, p. 175). (D) Formation of a complex between a DNA-binding protein and a separate protein with a transcriptionactivating domain. (E) Unmasking of an activation domain by the phosphorylation of an inhibitor protein. (F) Stimulation of nuclear entry by removal of an inhibitory protein that otherwise keeps the regulatory protein from entering the nucleus. (G) Release of a transcription regulator from a membrane bilayer by regulated proteolysis.

MBOC7_ptr_ch07_397-474.indd 426 02/12/21 12:44 PM

different modules are spread out over about 25,000 nucleotide pairs (Figure 7–35). Each of the five modules, when experimentally separated from the other four, can act as an independent enhancer to specify production of α -globin; but they do so only in erythroid cells, the precursors to red blood cells, because only erythroid cells express the appropriate transcription regulators. Red blood cells, which contain high concentrations of hemoglobin, are unusual in that they lack DNA and rely on their precursor cells to synthesize this protein.

Combinatorial Gene Control Creates Many Different Cell Types

We have seen that transcription regulators usually act in combination to control the expression of an individual gene. It is also generally true that each transcription regulator in an organism contributes to the control of many genes. This point is illustrated schematically in Figure 7-36, which shows how combinatorial gene

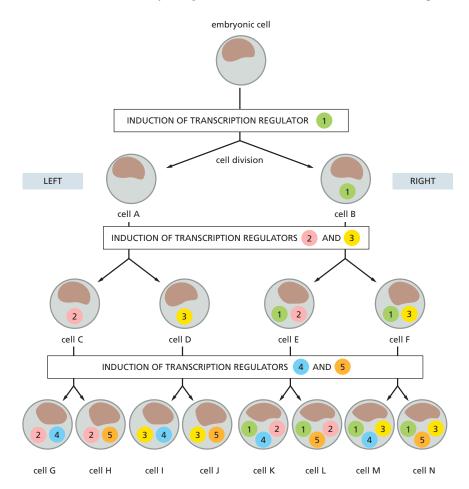

Figure 7-35 Modular structure of the control region for the mouse α -globin gene. Each of the five modules (R1-R5) can independently act as an enhancer, that is, they can each activate transcription of a reporter construct (see Figure 7-30B) However, the patterns of expression in a developing embryo are somewhat different for different modules. As indicated by the percentage designations, each module differs in the quantitative contributions it makes to the overall transcription rate in erythroid cells, with the total amount of mRNA being roughly equal to that of the sum of that produced by the individual modules. The additive properties of this control region suggest that the modules all affect the same step in transcription.

The combination of transcription regulators that recognize the R2 module, the most active of the five, is shown in the expanded view. These three transcription regulators are made in erythroid cells and are absent in most other cell types, explaining why expression of the globin gene occurs only in erythroid cells. Most of these same proteins also bind to the other α -globin regulatory modules, consistent with the modules working additively. As shown, insulator sequences flank the gene (including its control region), allowing the α -globin gene to be regulated independently of other genes on the same chromosome (see Figure 7-28). It is thought that modules R3 and R4 make no significant contribution to the overall transcription of the α -globin gene, but are once-functional modules that are in the slow evolutionary process of disappearing due to a gradual accumulation of mutations. (Courtesy of Helena Francis and Douglas Higgs.)

Figure 7-36 The importance of combinatorial gene control for development. Combinations of a few transcription regulators can generate many cell types during development. In this simple, idealized scheme, a "decision" to make one of a pair of different transcription regulators (shown as numbered circles) is made after each cell division. Sensing its relative position in the embryo, the daughter cell toward the left side of the embryo is always induced to synthesize the even-numbered protein of each pair, while the daughter cell toward the right side of the embryo is induced to synthesize the odd-numbered protein. The production of each transcription regulator is assumed to be self-perpetuating once it has become initiated (see Figure 7-42). In this way, through cell memory, the final combinatorial specification is built up step by step. In this purely hypothetical example, five different transcription regulators have created eight final cell types (G-N).

MBOC7_ptr_ch07_397-474.indd 427 02/12/21 12:44 PM

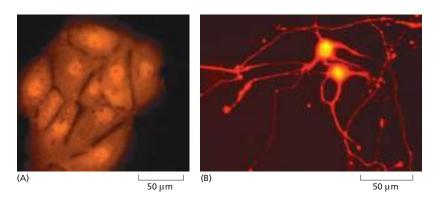

Figure 7–37 A small set of transcription regulators can convert one differentiated cell type into another. In this experiment, liver cells grown in culture (A) were converted into neuronal cells (B) by the artificial expression of three neuron-specific transcription regulators. (Both types of cells express a red fluorescent protein, which helps to visualize them.) This conversion involves the activation of many neuron-specific genes as well as the repression of many liver-specific genes. (From S. Marro et al., Cell Stem Cell 9:374–382, 2011. With permission from Elsevier.)

control makes it possible to generate a great deal of biological complexity even with relatively few transcription regulators.

Because of such combinatorial control, a given transcription regulator need not have a single, simply definable function as commander of a particular battery of genes or specifier of a particular cell type. Rather, transcription regulators can be likened to the words of a language: they are used with different meanings in a variety of contexts and rarely alone; it is the well-chosen combination that conveys the information that specifies a gene regulatory event.

Because of combinatorial gene control, the effect of adding a new transcription regulator to a cell will depend on that cell's past history, inasmuch as this history determines the transcription regulators already present. Thus, during embryonic development, a cell can accumulate a series of transcription regulators that may not initially alter gene expression. Only the addition of the final members of a requisite combination of transcription regulators will complete the regulatory message, leading to large changes in gene expression.

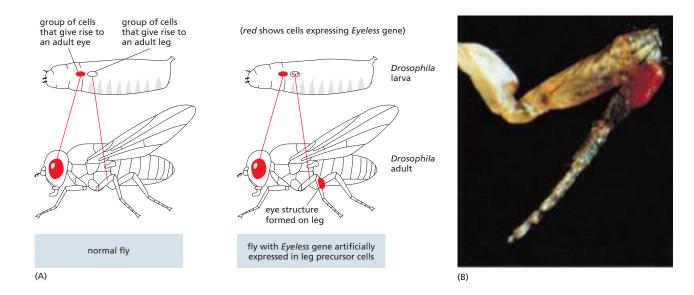

The importance of a combination of transcription regulators for the specification of cell types is most easily demonstrated by their ability—when expressed artificially in a specific combination—to convert one type of cell to another. For example, the artificial expression of three neuron-specific transcription regulators in liver cells can convert the liver cells into functional nerve cells (Figure 7–37). In some cases, expression of even a single transcription regulator is sufficient to convert one cell type to another: when the gene encoding the transcription regulator MyoD is artificially introduced into fibroblasts cultured from skin connective tissue, the fibroblasts form muscle-like cells. As discussed in Chapter 22, fibroblasts, which are derived from the same broad class of embryonic cells as muscle cells, have already accumulated many of the other necessary transcription regulators required for the combinatorial control of the muscle-specific genes, and the addition of MyoD completes the unique combination required to direct the cells to become muscle.

An even more striking example is seen by artificially expressing, early in development, a single *Drosophila* transcription regulator (Eyeless) in groups of cells that would normally go on to form leg parts. Here, this abnormal gene expression change causes eye-like structures to develop in the legs (**Figure 7–38**).

Specialized Cell Types Can Be Experimentally Reprogrammed to Become Pluripotent Stem Cells

Artificial manipulation of transcription regulators can also coax various differentiated cells to *de-differentiate* into pluripotent stem cells that are capable of giving rise to the different cell types in the body, as discussed in Chapter 22. Thus, when three specific transcription regulators are artificially expressed in cultured mouse fibroblasts, a number of cells become **induced pluripotent stem cells (iPS cells)**—cells that look and behave like the pluripotent embryonic stem

MBOC7_ptr_ch07_397-474.indd 428 02/12/21 12:44 PM

(ES) cells that are derived from embryos (Figure 7–39). This approach has been adapted to produce iPS cells from a variety of specialized cell types, including cells taken from humans. Such human iPS cells can then be directed to generate a population of differentiated cells for use in the study or treatment of disease, a topic discussed in detail in Chapter 22.

Although it was once thought that cell differentiation was irreversible, it is now clear that by manipulating combinations of transcription regulators, cell types and differentiation pathways can be readily reversed and otherwise altered.

Combinations of Master Transcription Regulators Specify Cell Types by Controlling the Expression of Many Genes

As we saw in the introduction to this chapter, different cell types of multicellular organisms differ enormously in the proteins and RNAs they express. For example, only muscle cells express special types of actin and myosin that form the contractile apparatus, while nerve cells must make and assemble all the proteins needed to form dendrites and synapses. We have seen that these patterns of cell-type-specific expression are orchestrated by a combination of so-called **master transcription regulators**. In many cases, these proteins bind directly to *cis*-regulatory sequences of the genes particular to that cell type. Thus, MyoD binds directly to *cis*-regulatory sequences located in the control regions of the muscle-specific genes. In other cases, the master regulators control the

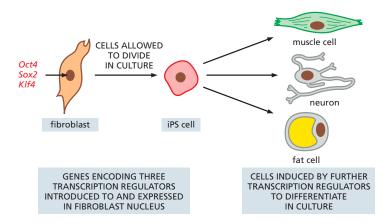

Figure 7-38 Expression of the Drosophila Eyeless gene in precursor cells of the fly leg triggers the development of an eye on the leg. (A) Simplified diagrams showing the result when a fruit fly larva contains either the normally expressed Eyeless gene (left) or an Eyeless gene that is additionally expressed artificially in cells that normally give rise to leg tissue (right). (B) Photograph of an abnormal leg that contains a misplaced eye (see also Figure 21-2). The transcription regulator was named Eyeless because its inactivation in otherwise normal flies causes the loss of eyes (see Figure 21-32). (B, courtesy of Walter Gehring.)

Figure 7-39 A combination of transcription regulators can induce a differentiated cell to de-differentiate into a pluripotent cell. The artificially induced expression of a set of three genes, each of which encodes a transcription regulator, can reprogram a fibroblast into a pluripotent cell with embryonic stem (ES) cell-like properties. Like ES cells, such induced pluripotent stem (iPS) cells can proliferate indefinitely in culture and can be stimulated by appropriate extracellular signal molecules to differentiate into almost any cell type found in the body. Transcription regulators such as Oct4, Sox2, and Klf4 are often called master transcription regulators because their expression is sufficient to trigger a change in cell identity. How two of these transcription regulators interact with DNA in a nucleosome is shown in Figure 7-13.

MBOC7_ptr_ch07_397-474.indd 429 02/12/21 12:44 PM

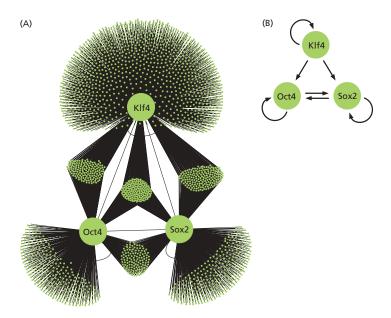

Figure 7-40 A portion of the transcription network specifying embryonic stem cells. (A) The three master transcription regulators in Figure 7–39 are shown as large circles. Genes whose cis-regulatory sequences are bound by each regulator in embryonic stem cells are indicated by a small green dot (representing the gene) connected by a thin line (representing the binding interaction). Note that many of the target genes are bound by more than one of the regulators. (B) The master regulators control their own expression. As shown here, the three transcription regulators bind to their own control regions (indicated by feedback loops), as well as those of the other master regulators (indicated by straight arrows). (Courtesy of Trevor Sorrells, based on data from J. Kim et al., Cell 132:1049-1061, 2008.)

expression of "downstream" transcription regulators that, in turn, bind to the control regions of other cell-type-specific genes and control their synthesis.

The specification of a particular cell type typically involves changes in the expression of several thousand genes. Genes whose protein products are required in the cell type are expressed at high levels, while those not needed are typically down-regulated. As might be imagined, the pattern of binding between the master regulators and all of the regulated genes can be extremely elaborate (**Figure 7–40**). When we consider that many of these regulated genes have control regions that span tens of thousands of nucleotide pairs, commensurate with the *Eve* example discussed earlier, we can begin to appreciate the enormous complexity of cell-type specification.

An outstanding question in biology is how the information in a genome is used to specify a multicellular organism. Although we have the general outline of the answer, we are far from understanding how a single cell type is completely specified, let alone a whole organism.

Specialized Cells Must Rapidly Turn Some Genes On and Off

Although they generally maintain their identities, specialized cells must constantly respond to changes in their environment. Among the most important changes are signals from other cells that coordinate the behavior of the whole organism. Many of these signals induce transient changes in gene transcription, and we discuss the nature of these signals in detail in Chapter 15. Here, we consider how specialized cell types rapidly and decisively switch groups of genes on and off in response to their environment. Even though control of gene expression is combinatorial, the effect of a single transcription regulator can still be decisive in switching any particular gene on or off, simply by completing the combination needed to maximally activate or repress that gene. This situation is analogous to dialing in the final number of a combination lock: the lock will spring open with only this simple addition if all of the other numbers have been previously entered. And just as the same number can complete the combination for many different locks, the addition of a particular protein can turn on many different genes.

An example is the rapid control of gene expression by the human glucocorticoid receptor protein. To bind to its *cis*-regulatory sequences in the genome, this transcription regulator must first form a complex with a molecule of a glucocorticoid steroid hormone, such as cortisol (see Figures 15–65 and 15–66). The body releases this hormone during times of starvation and intense physical activity,

MBOC7_ptr_ch07_397-474.indd 430 02/12/21 12:44 PM

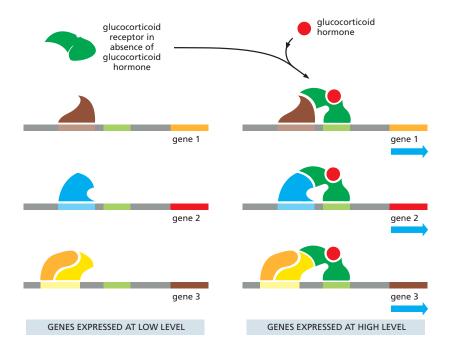

Figure 7-41 A single transcription regulator can coordinate the expression of many different genes. The action of the glucocorticoid receptor is illustrated schematically. On the left is a series of genes, each of which has various transcription regulators bound to its regulatory region. However, these bound proteins are not sufficient on their own to fully activate transcription. On the right is shown the effect of adding an additional transcription regulator—the glucocorticoid receptor in a complex with glucocorticoid hormone—that has a cisregulatory sequence in the control region of each gene. The glucocorticoid receptor completes the combination of transcription regulators required for maximal initiation of transcription, and the genes are now maximally switched on as a set. When the hormone is no longer present, the alucocorticoid receptor dissociates from DNA, and the genes return to their prestimulated levels.

and among its other activities, it stimulates liver cells to increase the production of glucose from amino acids and other small molecules. To respond in this way, liver cells increase the expression of many different genes that code for metabolic enzymes, such as tyrosine aminotransferase, as we discussed earlier in this chapter (see Figure 7–3). Although these genes all have different and complex control regions, their maximal expression depends on the binding of the hormone–glucocorticoid receptor complex to its *cis*-regulatory sequence, which is present in the control region of each gene. When the body has recovered and the hormone is no longer present, the expression of each of these genes drops to its normal level in the liver. In this way, a single transcription regulator can rapidly control the expression of many different genes (Figure 7–41).

The effects of the glucocorticoid receptor are not confined to cells of the liver. In other cell types, activation of this transcription regulator by hormone also causes changes in the expression levels of many genes; the genes affected, however, are usually different from those affected in liver cells. As we have seen, each cell type has an individualized set of transcription regulators, and because of combinatorial control, these critically influence the action of the glucocorticoid receptor. Because the receptor is able to assemble with different sets of cell-type-specific transcription regulators, switching it on with hormone produces a different spectrum of effects in each cell type.

Differentiated Cells Maintain Their Identity

Once a cell has become differentiated into a particular cell type, it will generally remain differentiated, and all its progeny cells will remain that same cell type. Some highly specialized cells, including skeletal muscle cells and neurons, never divide again once they have differentiated; that is, they are *terminally differentiated* (as discussed in Chapter 17). But many other differentiated cells—such as fibroblasts, smooth muscle cells, and liver cells—will divide many times in the life of an individual. When they do, these specialized cell types give rise only to cells like themselves: smooth muscle cells do not give rise to liver cells, nor liver cells to fibroblasts.

For a proliferating cell to maintain its identity—a property called **cell memory**—the patterns of gene expression responsible for that identity must be remembered and passed on to its daughter cells through subsequent cell divisions. Thus, in the model we discussed in Figure 7-36, the production of each

MBOC7_ptr_ch07_397-474.indd 431 02/12/21 12:44 PM

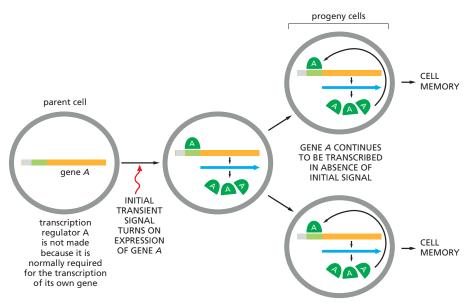

Figure 7–42 A positive feedback loop can create cell memory. Protein A is a master transcription regulator that activates the transcription of its own gene—as well as other cell-type-specific genes (not shown). All of the descendants of the original cell will therefore "remember" that the progenitor cell had experienced a transient signal that initiated the production of protein A.

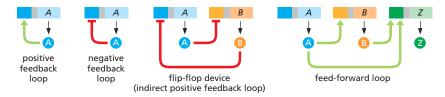

transcription regulator, once begun, has to be continued in the daughter cells of each cell division. How is such perpetuation accomplished?

Cells have several ways of ensuring that their daughters "remember" what kind of cells they are. One of the simplest and most important is through a positive feedback loop, where a master cell-type transcription regulator activates transcription of its own gene, in addition to that of the other cell-type-specific genes needed to maintain the cell type. Each time a cell divides, the regulator is distributed to both daughter cells, where it continues to stimulate the positive feedback loop, making more of itself and the cell-type proteins it controls each division. Positive feedback is crucial for establishing "self-sustaining" circuits of gene expression that allow a cell to commit to a particular fate—and then to transmit that information to its progeny (Figure 7–42).

As was previously indicated in Figure 7-40B, the master regulators needed to maintain the pluripotency of iPS cells bind to *cis*-regulatory sequences in their own control regions, providing examples of this type of positive feedback loop. In addition, most of these pluripotent stem cell regulators also activate transcription of other master regulators, resulting in a complex series of indirect feedback loops. For example, if A activates B, and B activates A, this forms a positive feedback loop where A activates its own expression, albeit indirectly. The series of direct and indirect feedback loops observed in the iPS circuit is typical of other specialized cell circuits. Such a network structure strengthens cell memory, increasing the probability that a particular pattern of gene expression is transmitted through successive generations. For example, if the level of A drops below the critical threshold to stimulate its own synthesis, regulator B can rescue it. By successive application of this mechanism, a complex series of positive feedback loops among multiple transcription regulators can stably maintain a differentiated state through many cell divisions.

Positive feedback loops formed by transcription regulators are probably the most prevalent way of ensuring that daughter cells remember what kind of cells they are meant to be, and they are found in all species on Earth. For example, many bacteria and single-cell eukaryotes form different types of cells, and positive feedback loops lie at the heart of mechanisms that maintain their cell types through many rounds of cell division. Plants and animals also make extensive use of transcription feedback loops; but as we saw in Chapter 4 and shall discuss again later in the chapter, they have additional, more specialized mechanisms for making cell memory even stronger (see, for example, Figure 4–44). We will return

MBOC7_ptr_ch07_397-474.indd 432 02/12/21 12:44 PM

to these additional mechanisms later in the chapter, but first, we consider how combinations of transcription regulators and *cis*-regulatory sequences can be combined to create other useful logic devices for the cell.

Transcription Circuits Allow the Cell to Carry Out Logic Operations

Simple gene regulatory switches can be combined to create all sorts of control devices, just as simple electronic switching elements in a computer can be linked to perform different types of operations. An analysis of gene regulatory circuits reveals that certain simple types of arrangements (called *network motifs*) are found over and over again in cells from widely different species. For example, positive and negative feedback loops are common in all cells (Figure 7-43). Whereas the former provides a simple memory device (see Figure 7-42), the latter is often used to keep the expression of a gene close to a standard level despite the variations in biochemical conditions inside a cell. Suppose, for example, that a transcription repressor protein binds to the regulatory region of its own gene and exerts a strong negative feedback, such that transcription falls to a very low rate when the concentration of the repressor protein is above some critical value (determined by its affinity for its DNA-binding site). The concentration of the protein can then be held close to the critical value, because any circumstance that causes a fall below that value can lead to a steep increase in synthesis, and any that causes a rise above that value will lead to synthesis being switched off. Such adjustments will, however, take time, so that an abrupt change of conditions will cause a disturbance of gene expression that is strong but transient. If there is a delay in the feedback loop, the result may be spontaneous oscillations in the expression of the gene (see Figure 15-18). The different types of behavior produced by a feedback loop will depend on the details of the system; for example, how tightly the transcription regulator binds to its cis-regulatory sequence, its rate of synthesis, and its rate of decay. We discuss these issues in quantitative terms and in more detail in Chapter 8.

With two or more transcription regulators, the possible range of circuit behaviors becomes more complex. Some bacterial viruses contain a common type of two-gene circuit that can flip-flop between expression of one gene and expression of the other (see Figure 7-43). Another common circuit arrangement is called a *feed-forward* loop; such a loop can serve as a filter, responding to input signals that are prolonged but disregarding those that are brief (Figure 7-44). Although

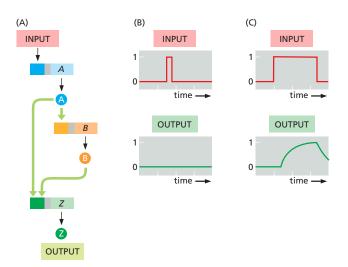

Figure 7–43 Common types of network motifs in transcription circuits. A and B represent transcription regulators, *green arrows* indicate positive transcription control, while *red lines with bars* depict negative transcription control. In the feed-forward loop, A and B represent transcription regulators that *both* activate the transcription of target gene *Z* (see also Figure 8–88).

Figure 7-44 How a feed-forward loop can measure the duration of a signal. (A) In this theoretical example, transcription regulators A and B must both be present on the DNA for transcription of gene Z, and gene A becomes active only when an input signal is present. (B) If the input signal to gene A is brief, it does not stay active long enough for transcription regulator B to accumulate, and gene Z is not transcribed. (C) If the signal to gene A persists, transcription regulators A and B both accumulate, and gene Z is transcribed. This arrangement allows the cell to ignore rapid fluctuations of the input signal and respond only to persistent levels. This strategy could be used, for example, to distinguish between random noise and a true signal

The behavior shown here was computed for one particular set of parameter values describing the quantitative properties of transcription regulators A and B, as well as the product of gene Z, along with their syntheses. With different values of these parameters, feed-forward loops can in principle perform other types of "calculations." Many feed-forward loops have been discovered in cells. As explained in Chapter 8, theoretical analyses are needed to help researchers to discernand subsequently test-the different ways in which these circuits function (see Figures 8-87 and 8-88). (Adapted from S.S. Shen-Orr et al., Nat. Genet. 31:64-68, 2002.)

MBOC7_ptr_ch07_397-474.indd 433 02/12/21 12:44 PM

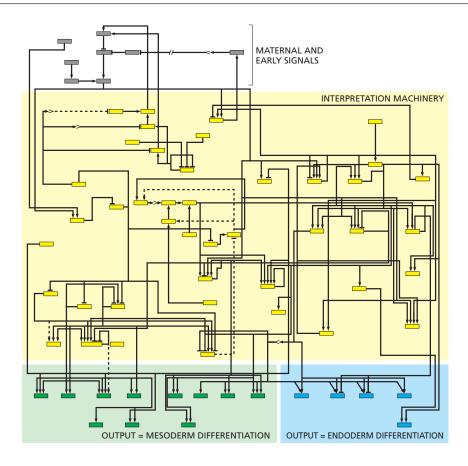

Figure 7–45 The exceedingly complex gene circuit that specifies a portion of the developing sea urchin embryo. Each colored small box represents a different gene. Those in yellow code for transcription regulators, and those in green and blue code for proteins that give cells of the mesoderm and endoderm, respectively, their specialized characteristics. Genes depicted in grav are largely active in the mother and provide the egg with cues needed for proper development. As in Figure 7-43, arrows depict instances in which a transcription regulator activates the transcription of another gene, and lines ending in bars indicate examples of gene repression. (From I.S. Peter and E.H. Davidson, Nature 474:635-639, 2011. With permission from Springer Nature.)

they arose as products of evolution, without advance planning or design, these various network motifs resemble some of the miniature logic devices found in electronic circuits. And, like circuits designed by humans, they can process information in surprisingly sophisticated ways.

The simple types of devices just illustrated are often found joined together, creating exceedingly complex circuits (Figure 7-45). Each cell in a developing multicellular organism is equipped with similarly complex control machinery, and it must, in effect, use its intricate system of interlocking transcription switches to "compute" how it should behave at each time point in response to the many different past and present inputs received. We are only beginning to understand how to study such complex intracellular control networks. Indeed, without new approaches, coupled with quantitative information that is far more precise and complete than we now possess, it will be impossible to predict the behavior of a system such as that shown in Figure 7-45. As explained in Chapter 8, a circuit diagram by itself is insufficient to deeply understand biological mechanisms.

Summary

The many types of cells in animals and plants are created largely through mechanisms that cause different sets of genes to be transcribed in different cells. The transcription of any particular gene is generally controlled by a combination of transcription regulator proteins. Each type of cell in a higher eukaryotic organism contains a specific set of transcription regulators that ensures the expression of only those genes appropriate to that type of cell. A given transcription regulator may be active in a variety of circumstances, and it is typically involved in the regulation of many different genes.

Because specialized animal cells can maintain their unique character through many cell-division cycles, and even when grown in culture, there must exist

MBOC7_ptr_ch07_397-474.indd 434 02/12/21 12:44 PM

mechanisms to ensure this cell memory. Direct or indirect positive feedback loops, which enable transcription regulators to perpetuate their own synthesis, provide one of the simplest mechanisms for producing a cell memory. Transcription circuits also provide the cell with the means to carry out many other types of logic operations. Simple transcription circuits combined into large regulatory networks drive highly sophisticated programs of embryonic development that will require new approaches to fully decipher.

MECHANISMS THAT REINFORCE CELL MEMORY IN PLANTS AND ANIMALS

Thus far in this chapter, we have emphasized the regulation of gene transcription by proteins that associate either directly or indirectly with DNA. However, DNA itself can be covalently modified, and, as we saw in Chapter 4, certain types of chromatin states can be inherited. In this section, we shall see how these phenomena provide additional opportunities for the regulation of gene expression, particularly in mammals. Near the end of this section, we discuss how a whole chromosome can be transcriptionally shut down using such mechanisms, and how this state can be maintained through many cell divisions.

Patterns of DNA Methylation Can Be Inherited When Vertebrate Cells Divide

In vertebrate cells, the methylation of cytosine provides one mechanism through which gene expression patterns can be passed on to progeny cells. The methylated form of cytosine, 5-methylcytosine (5-methyl C), has the same relation to cytosine that thymine has to uracil, and the modification likewise has no effect on base-pairing (Figure 7-46). DNA methylation in vertebrate DNA occurs on cytosine (C) nucleotides largely in the sequence CG, which is base-paired to exactly the same sequence (in opposite orientation) on the other strand of the DNA helix. Consequently, a simple mechanism permits the existing pattern of DNA methylation to be inherited directly by the daughter DNA strands. An enzyme called *maintenance methyl transferase* acts preferentially on those CG sequences that are base-paired with a CG sequence that is already methylated. As a result, the pattern of DNA methylation on the parent DNA strand serves as a template for the methylation of the daughter DNA strand, causing this pattern to be inherited directly after DNA replication (Figure 7-47).

Although DNA methylation patterns can be maintained in differentiated cells by the mechanism shown in Figure 7–47, methylation patterns are dynamic during mammalian development. Shortly after fertilization, there is a genome-wide wave of demethylation, when the vast majority of methyl groups are lost from the

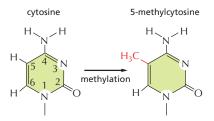

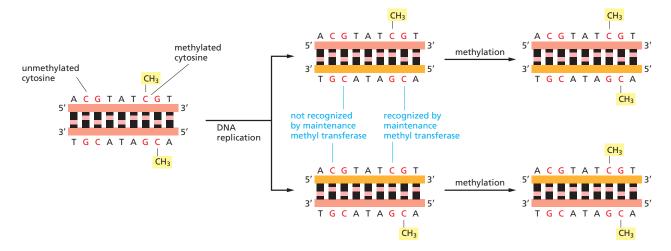

Figure 7–46 Formation of 5-methylcytosine occurs by methylation of a cytosine base in the DNA double helix. In vertebrates, this event is largely confined to selected cytosine (C) nucleotides located in the sequence CG. CG sequences are sometimes denoted as CpG sequences, where the p indicates a phosphate linkage to distinguish it from a CG base pair. In this chapter, we will continue to use the simpler nomenclature CG to indicate this dinucleotide.

Figure 7–47 How DNA methylation patterns are faithfully inherited. In vertebrate DNA, a large fraction of the cytosine nucleoticles in the sequence CG is methylated (see Figure 7–46). Because of the existence of a methyldirected methylating enzyme (the maintenance methyl transferase), once a pattern of DNA methylation is established, that pattern of methylation is inherited in the progeny DNA, as shown.

MBOC7_ptr_ch07_397-474.indd 435 02/12/21 12:44 PM

DNA. This demethylation may occur either by suppression of maintenance DNA methyl transferase activity, resulting in the passive loss of methyl groups during each round of DNA replication, or by *DNA demethylases* that actively remove methyl groups from DNA. Later in development, several *de novo DNA methyl transferases* come into play and methylate about 70% of the CG sequences in the genome. This extensive methylation occurs largely indiscriminately, although proteins that are bound to specific sequences on the genome can block the methylation of those sequences. In addition, some sequence-specific DNA-binding proteins direct DNA methylases to specific locations in genomes, resulting in very high local densities of methylation in the neighborhoods of those DNA-bound proteins. Conversely, DNA demethylases can also be directed to certain regions of the genome, resulting in loss of methyl groups in those regions. Despite these selective mechanisms, the patterns of overall methylation across differentiated cell types are broadly similar, and many methylated positions—on their own—appear to have little or no impact on gene expression.

DNA methylation has several uses in the vertebrate cell. A very important role of dense methylation is to work in conjunction with other gene expression control mechanisms to establish a particularly efficient form of gene repression. This combination of mechanisms enables unneeded eukaryotic genes to be repressed to a very high degree. The rate at which a vertebrate gene is transcribed can vary 10^6 -fold between one tissue and another, and unexpressed vertebrate genes are much less "leaky" in terms of transcription than bacterial genes, in which the largest known differences in transcription rates between expressed and unexpressed gene states are only about 1000-fold.

Dense DNA methylation helps to repress transcription in several ways. The methyl groups on methylated cytosines lie in the major groove of DNA and interfere directly with the binding of some proteins (transcription regulators as well as the general transcription factors) required for transcription initiation. In addition, the cell contains a repertoire of proteins that bind specifically to methylated DNA. The best characterized of these also associate with histone-modifying enzymes, leading to a repressive, heterochromatin state where chromatin structure and DNA methylation act synergistically (Figure 7–48).

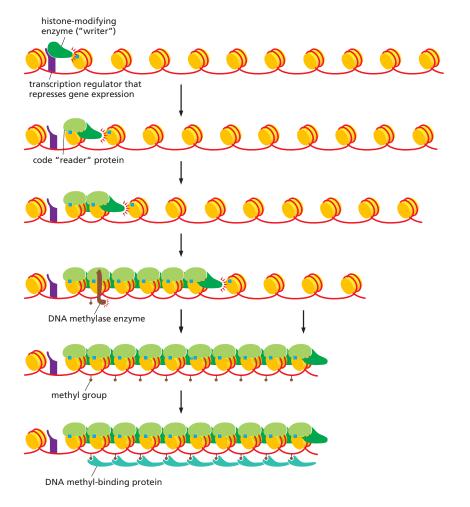

Many genes that are needed only in differentiated cells are tightly repressed in this way in embryonic cells. As differentiation proceeds, they become activated, although this process typically requires many steps, often involving "pioneer factors" (see Figure 7–13), histone demethylases, and DNA demethylases. The latter enzymes convert 5-methyl C to 5-hydroxymethyl C, which is later replaced by C either through DNA repair (see Figure 5–41A) or, passively, through multiple rounds of DNA replication. In addition, many genes active in embryonic tissues become repressed during differentiation by the mechanisms shown in Figure 7-48. The reactivation of these genes is one of the key steps in converting differentiated cells back into stem cells, as explained in Chapter 22.

CG-Rich Islands Are Associated with Many Genes in Mammals

Because of the way in which DNA repair enzymes work, methylated C nucleotides in the vertebrate genome tend to be eliminated in the course of evolution. Accidental deamination of an unmethylated C gives rise to U (see Figure 5–38B), which is not normally present in DNA and thus is recognized easily by the DNA repair enzyme uracil DNA glycosylase. The deamination product is thereby excised and replaced with a C, as discussed in Chapter 5. But accidental deamination of a 5-methyl C cannot be repaired in this way, for the deamination product is a T and so is indistinguishable from the other, nonmutant T nucleotides in the DNA. Although a special repair system exists to remove some of these incorrect T nucleotides, many of the deaminations escape detection, so that those C nucleotides in the genome that are methylated tend to mutate to T over evolutionary time.

During the course of evolution, more than three out of every four CGs have been lost in this way, leaving vertebrates with a remarkable deficiency of this dinucleotide. This ratio probably reflects a balance between methylated CG loss

MBOC7_ptr_ch07_397-474.indd 436 02/12/21 12:44 PM

by DNA repair and CG gain by random mutation. The CG sequences that remain are very unevenly distributed in the genome; they are present at 10 times their average density in selected regions, called **CG islands**, which average 1000 nucleotide pairs in length. The human genome contains roughly 20,000 CG islands, and they usually include promoters of genes. For example, 60% of human proteincoding genes have promoters embedded in CG islands, and these include virtually all the promoters of the so-called *housekeeping genes*—those genes that code for the many proteins that are essential for cell viability and are therefore expressed in nearly all cells (**Figure 7-49**). Over evolutionary time scales, the CG

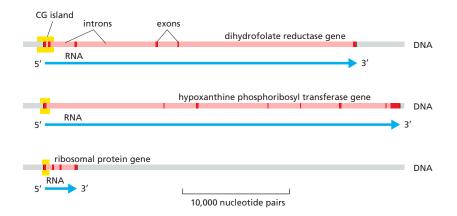

Figure 7-48 Multiple mechanisms can produce especially stable gene repression. In this schematic example, histone reader and writer proteins (discussed in Chapter 4), triggered by transcription regulators, establish a repressive form of chromatin whose nucleosomes are marked by the trimethylation of specific lysine amino acids in histones (see Figure 4-35, as well as Figure 7-27F). An additional layer of repression can occur when a de novo DNA methylase is attracted by the modified histones and methylates nearby cytosines in DNA; and these are, in turn, bound by DNA methyl-binding proteins. During DNA replication, some of the modified (blue dot) histones will be inherited by one daughter chromosome, some by the other, and in each daughter they can induce reconstruction of the same pattern of chromatin modifications (see Figure 4-44). At the same time, the mechanism shown in Figure 7-47 will cause both daughter chromosomes to inherit the same methylation pattern. This makes the two mechanisms for inheriting a repressed gene mutually reinforcing, accounting for the inheritance by daughter cells of both the histone and the DNA modifications. It can also explain the tendency of some chromatin modifications to spread along a chromosome (see Figure 4-39). This type of heterochromatin is assembled and disassembled on different genes as mammalian development proceeds, depending on whether the gene product is needed. For example, when endoderm precursor cells differentiate into the hepatocytes of the liver, an estimated 6000 genes are unpackaged from this repressive form of chromatin and become actively transcribed. At roughly the same time, about 1600 genes active in endoderm cells become packaged into this type of chromatin and are thereby tightly repressed in hepatocytes.

Figure 7–49 The CG islands surrounding the promoter in three mammalian housekeeping genes. The *yellow boxes* show the extent of each island. As for most genes in mammals, the exons *(dark red)* are very short relative to the introns *(light red)*. (Adapted from A.P. Bird, *Trends Genet*. 3:342–347, 1987.)

MBOC7_ptr_ch07_397-474.indd 437 02/12/21 12:44 PM

Figure 7–50 A mechanism to explain both the marked overall deficiency of CG sequences and their clustering into CG islands in vertebrate genomes. The vertical white lines mark the location of CG dinucleotides in the DNA sequences, while red circles indicate the presence of a methyl group on the CG dinucleotide. CG sequences that lie in regulatory sequences of genes that are transcribed in germ cells are unmethylated and therefore tend to be retained in evolution. Methylated CG sequences, on the other hand, tend to be lost through deamination of 5-methyl C to T, unless the CG sequence is critical for survival.

islands were spared the accelerated mutation rate of bulk CG sequences because they remained unmethylated in the germ line (Figure 7–50).

CG islands remain unmethylated in most somatic tissues whether or not the associated gene is expressed. The unmethylated state is maintained by a group of proteins that bind specifically to unmethylated CG sequences in the genome and modify the neighboring nucleosomes by methylating histone H3 (on the lysine at position 4; see Figure 4-35). These modified nucleosomes somehow repel the de novo methylases, and the unmethylated state is thereby continually maintained. Unmethylated CG islands have several properties that make them particularly suitable for promoters. For example, some of the same proteins that protect them from methylation recruit additional histone-modifying enzymes that decompress the chromatin, making the islands particularly "promoter friendly." As a result, RNA polymerase is often found bound to promoters within CG islands, even when the associated gene is not being actively transcribed. At unmethylated CG islands, the competition between polymerase binding and nucleosome assembly at promoters is thus always tipped toward the former. However, additional steps are needed for the final "push" to transcribe the adjacent gene; these are directed by transcription regulators that bind to cis-regulatory sequences of DNA, often well upstream from the CG islands.

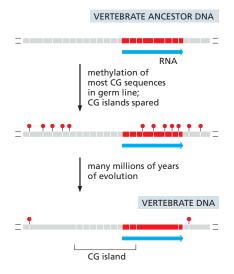

Genomic Imprinting Is Based on DNA Methylation

Mammalian cells are diploid, containing one set of genes inherited from the father and one set from the mother. The expression of a small minority of genes depends on which parent they came from: when the paternally inherited gene copy is active, the maternally inherited gene copy is silent, or vice versa. This phenomenon is called **genomic imprinting**.

Roughly 300 genes are imprinted in humans. Because only one copy of an imprinted gene is expressed, imprinting can "unmask" harmful mutations that would normally be covered by the other, functional copy. For example, Angelman syndrome, a disorder of the nervous system in humans that causes reduced mental ability and severe speech impairment, results from a gene deletion on one chromosomal homolog and the silencing, by imprinting, of the intact gene on the other homolog.

The *insulin-like growth factor-2* (*Igf2*) gene in the mouse provides a well-studied example of imprinting. Mice that do not express *Igf2* at all are born half the size of normal mice. However, only the paternal copy of *Igf2* is transcribed, and only this gene copy matters for the phenotype. As a result, mice with a mutated paternally derived *Igf2* gene are stunted, while mice with a mutated maternally derived *Igf2* gene are normal.

In the early embryo, genes subject to imprinting are marked by methylation according to whether they were derived from a sperm or an egg chromosome. In this way, DNA methylation is used as a mark to distinguish two copies of a gene that can be otherwise identical (Figure 7–51). Such imprinted genes are somehow protected from the wave of DNA demethylation that takes place shortly after fertilization (see pp. 435–436), enabling the somatic cells produced during embryonic development to "remember" the parental origin of each of the two copies of the gene and to regulate their expression accordingly. In most cases, the methyl imprint silences nearby gene expression. In some cases, however, it can activate expression of a gene. In the case of *Igf2*, for example, methylation of an insulator element on the paternally derived chromosome blocks its function and allows distant *cis*-regulatory sequences to activate transcription of the *Igf2* gene.

MBOC7_ptr_ch07_397-474.indd 438 02/12/21 12:45 PM

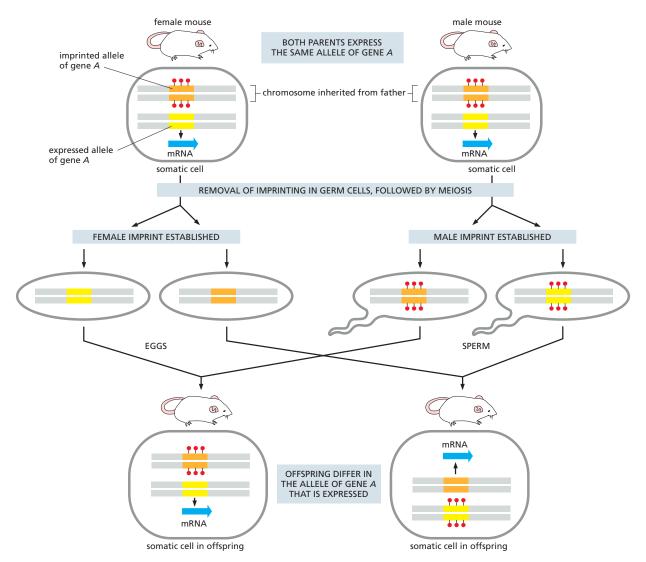

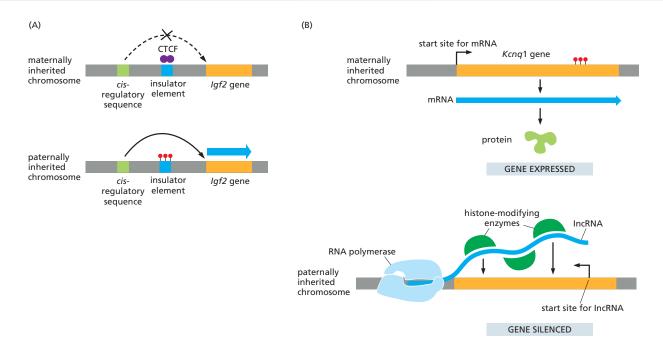

Figure 7–51 How imprinting can cause a non-Mendelian pattern of inheritance. The *top* portion of the figure shows a pair of homologous chromosomes in the somatic cells of two adult mice, one male and one female. In this example, both mice have inherited the top homolog from their father and the bottom homolog from their mother, and the paternal copy of a gene subject to imprinting (indicated in *orange*) is methylated, preventing its expression. The maternally derived copy of the same gene (*yellow*) is expressed. The remainder of the figure shows the outcome of a cross between these two mice. During germ-cell formation, but before meiosis, the imprints are erased and then, much later in germ-cell development, they are reimposed in a sex-specific pattern (*middle* portion of figure). In eggs produced from the female, neither allele of the *A* gene is methylated. In sperm from the male, both alleles of gene *A* are methylated. Shown at the *bottom* of the figure are two of the possible imprinting patterns inherited by the progeny mice; the mouse on the *left* has the same imprinting pattern as each of the parents, whereas the mouse on the *right* has the opposite pattern. If the two alleles of gene *A* are distinct (for example, if one codes for a mutant protein), the different imprinting patterns can cause phenotypic differences in the progeny mice, even though they carry exactly the same DNA sequences of the two *A* gene alleles.

Imprinting provides an important exception to classical "Mendelian" genetic behavior, and several hundred mouse genes are thought to be affected in this way. However, the majority of mouse genes are not imprinted, and therefore the rules of Mendelian inheritance apply to most of the mouse genome.

On the maternally derived chromosome, the insulator is not methylated, and the *Igf2* gene is therefore not transcribed (**Figure 7–52A**).

Other cases of imprinting are also based on DNA methylation, but they employ different "downstream" mechanisms. Some involve *long noncoding RNAs* (*lncRNAs*), which are defined as RNA molecules more than 200 nucleotides in length that do not code for proteins. We discuss lncRNAs broadly at the end of this chapter; here, we focus on the role of a specific lncRNA in imprinting. In the case

MBOC7_ptr_ch07_397-474.indd 439 02/12/21 12:45 PM

of the *Kcnq1* gene, which codes for a voltage-gated calcium channel needed for proper heart function, the lncRNA is made only from the paternal allele (which is unmethylated), and it is not released by the RNA polymerase, remaining instead at its site of synthesis on the DNA template. This RNA in turn recruits the histone-modifying and DNA-methylating enzymes that direct the formation of repressive chromatin, which silences the protein-coding gene associated on the paternally derived chromosome (Figure 7–52B). The maternally derived gene, on the other hand, is immune to these effects because its imprinted methylation blocks the synthesis of the lncRNA but allows transcription of the adjacent protein-coding gene. Thus, like *Igf2*, the specificity of *Kcnq1* imprinting arises from an inherited methylation pattern; the difference lies in the way these patterns cause the differential gene expression.

Why imprinting should exist at all is a mystery. In vertebrates, it is restricted to mammals that develop within the mother, and many of the imprinted genes are involved in fetal development. One idea is that imprinting reflects a middle ground in the evolutionary struggle between males to produce larger offspring and females to limit offspring size by "halving" the dosage of certain gene products that might accelerate growth. Whatever its purpose might be, imprinting provides startling evidence that features of DNA other than its sequence of nucleotides can be inherited.

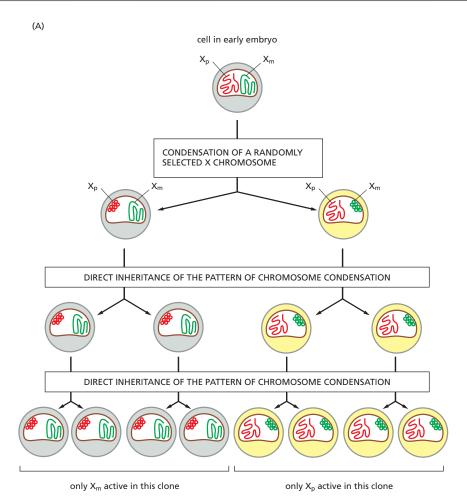

A Chromosome-wide Alteration in Chromatin Structure Can Be Inherited

We have seen that DNA methylation and certain types of chromatin structure can be heritable, preserving patterns of gene expression across cell generations. Perhaps the most striking example of this effect occurs in mammals, in which an alteration in the chromatin structure of an entire chromosome can modulate the levels of expression of most genes on that chromosome.

Males and females differ in their *sex chromosomes*. Females have two X chromosomes, whereas males have one X and one Y chromosome. In humans, the X and Y sex chromosomes differ radically in gene content: the X chromosome is three times larger and contains about 900 protein-coding genes compared to the Y chromosome's 55 protein-coding genes. Mammals have evolved a *dosage compensation* mechanism to ensure that the same amount of most of the

Figure 7-52 Some mechanisms of imprinting. (A) On chromosomes inherited from the female, the CTCF protein binds to an insulator (see Figure 7-28), blocking communication between cis-regulatory sequences (green) and the Igf2 gene (orange). Igf2 is therefore not expressed from the maternally inherited chromosome. Because of imprinting, the insulator on the male-derived chromosome is methylated (red circles): this inactivates the insulator by blocking the binding of the CTCF protein and allows the cis-regulatory sequences to activate transcription of the Igf2 gene. In other examples of imprinting, methylation simply blocks gene expression by interfering with the binding of proteins required for a gene's transcription. (B) Imprinting of the mouse Kcnq1 gene. On the maternally derived chromosome, synthesis of the IncRNA is blocked by methylation of the DNA (red circles) and the Kcnq1 gene is expressed. On the paternally derived chromosome, the IncRNA is synthesized, remains in place, and by directing alterations in chromatin structure blocks expression of the Kcna1 gene. Although shown as directly binding to IncRNA, the histone-modifying enzymes are likely to be recruited indirectly, through additional proteins.

MBOC7_ptr_ch07_397-474.indd 440 02/12/21 12:45 PM

(B)

Figure 7–53 X-inactivation. (A) The clonal inheritance in female mammals of a condensed, inactive X chromosome. (B) A calico cat, whose patches of color reflect the random nature of the X-inactivation process. (B, bluecaterpillar/Deposit photos.)

X-chromosome gene products is made in both male and female cells, despite the fact that females contain twice as many X-chromosome genes. Mutations that interfere with this dosage compensation are generally lethal.

Mammals achieve dosage compensation by the transcriptional inactivation of one of the two X chromosomes in female somatic cells, a process known as **X-inactivation**. As a result of X-inactivation, two X chromosomes can coexist within the same nucleus, be exposed to the same diffusible transcription regulators, and yet differ entirely in their expression.

Early in the development of a female embryo, when it consists of a few hundred cells, one of the two X chromosomes in each cell becomes highly condensed into a type of heterochromatin. In placental mammals, the initial choice of which X chromosome to inactivate—the maternally inherited one (X_m) or the paternally inherited one (X_p) —appears to be random. And once either X_p or X_m has been inactivated, it remains silent throughout all subsequent cell divisions of that cell and its progeny, indicating that the inactive state is faithfully maintained through many cycles of DNA replication and mitosis. Because X-inactivation is random and takes place after several hundred cells have already formed in the embryo, every female is a mosaic of clonal groups of cells in which either X_p or X_m is silenced (Figure 7–53), distributed in small clusters in the adult animal because sister cells tend to remain close together during later stages of development (Figure 7–54).

X-inactivation creates the orange and black coat coloration of some female cats (see Figure 7-53B). In these "calico" cats, one X chromosome carries a gene that produces orange hair color, and the other X chromosome carries an allele

MBOC7_ptr_ch07_397-474.indd 441 02/12/21 12:45 PM

Figure 7-54 Photoreceptor cells in the retina of a female mouse showing patterns of X-inactivation. Using genetic engineering techniques (described in Chapter 8), the germ line of a mouse was modified so that one copy of the X chromosome (if active) makes a green fluorescent protein and the other (if active) a red fluorescent protein. Both proteins concentrate in the nucleus, and, in the field of cells shown here, it is clear that only one of the two X chromosomes is active in each cell. If both chromosomes were active, the nuclei would fluoresce both red and green, and therefore appear yellow. (From H. Wu et al., Neuron 81:103-119, 2014. With permission from Elsevier.)

of the same gene that results in black hair color; it is the random X-inactivation that produces patches of cells of two distinctive colors. In contrast, male cats of this genetic stock are either solid orange or solid black, depending on which X chromosome they have inherited from their mothers. Although X-inactivation is maintained over thousands of cell divisions, it is reversed during germ-cell formation, so that all the haploid oocytes contain an active X chromosome and can express X-linked gene products.

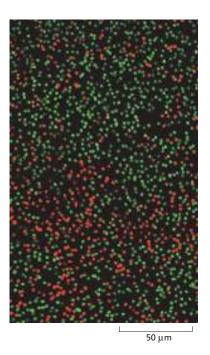

The Mammalian X-Inactivation in Females Is Triggered by the Synthesis of a Long Noncoding RNA

How is an entire chromosome transcriptionally inactivated? In humans, the chromosome-wide inactivation process begins with the synthesis of a long noncoding RNA, called Xist, whose gene lies on the X chromosome. This transcript (about 20,000 nucleotides in length) is synthesized by only one of the two X chromosomes in females, and exactly how this seemingly random choice is made remains to discovered. Once an Xist RNA molecule is synthesized, it does not leave the X chromosome from which it was made; rather, it diffuses along only that chromosome. Ultimately, about 2000 molecules of Xist are synthesized per X chromosome, and they eventually coat the chromosome that produces it. The spread of Xist across the chromosome does not itself cause transcriptional silencing; this long RNA contains binding sites for many different proteins that carry out the actual gene silencing. These include DNA methylases, histone-modifying enzymes, and structural components specific to the inactive X chromatin. As a result, extensive methylation of the inactive X occurs (including at CG islands), and the chromosome is folded into compact structures that are generally resistant to transcription (Figure 7-55). These multiple layers, each of which can be self-propagating (see Figure 7-48), ensure that the randomly chosen X chromosome remains inactive through multiple cell divisions.

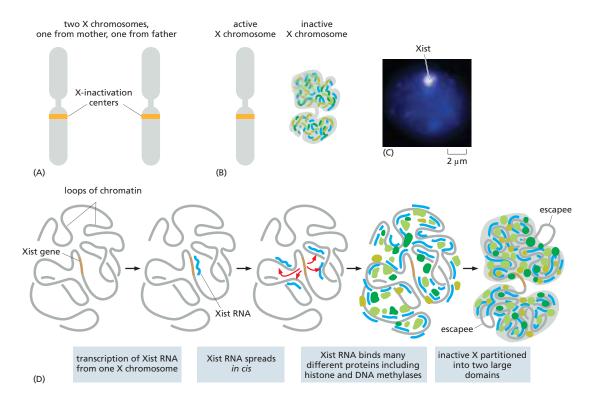

Not every gene on the inactive X chromosome is transcriptionally silenced. Of the approximately 900 protein-coding genes on the human X chromosome, 15-20% remain actively expressed after the chromosome-wide inactivation process has been completed. And for many of these genes, both copies—one from the active X and one from the inactive X—must be expressed to obtain sufficient levels of their gene products for proper development to occur.

How do select genes escape silencing after the majority of the X chromosome is rendered transcriptionally inactive? As we saw in Chapter 4 and earlier in this chapter, transcriptionally active genes generally occur in DNA loops that are held in place by insulator proteins such as CTCF (see Figure 7-28), and this is the case for the "escapees" of the inactive X chromosome. These loops are believed to extend from the bulk of the tightly packaged chromosome. In contrast, most of the inactive genes lie in the interior of the inactive X chromosome, which is depleted for CTCF. It has been proposed that X-inactivation is accompanied by the formation of a specialized biomolecular condensate, where the proteins and RNAs needed for gene repression are kept at high local concentrations; according to this model, the loops of active genes would extend outward, beyond the boundary of the condensate.

We have described the way that placental mammals deal with dosage compensation on the X chromosome, but the details of this process differ from those in most other animals in important ways. For example, in marsupials, the choice of which X chromosome to inactivate is not random; instead, the X chromosome inherited from the father is automatically silenced. And in flies, dosage

MBOC7 ptr ch07 397-474.indd 442 02/12/21 12:45 PM

compensation takes place in the male, where the single X chromosome is upregulated approximately twofold to match the female dose. Finally, in nematode worms, the hermaphrodites reduce gene expression by roughly half on both X chromosomes to match the single X-chromosome dosage in males.

The fundamentally different mechanisms of dosage compensation among animals suggest that it has been a relatively recent evolutionary innovation. We have some clues for its origin in humans. Some of the key components in X-inactivation also function to repress the many transposons in the human genome, a process we discuss later in the chapter. It has been proposed that Xist evolved from multiple transposons that inserted into our X chromosome, eventually "tricking" the cell into inactivating the whole chromosome.

Stable Patterns of Gene Expression Can Be Transmitted to Daughter Cells

Imprinting and X-inactivation are examples of **monoallelic gene expression**, where only one of the two copies of a gene is expressed in a diploid genome. In addition to the silenced genes on the X chromosome and the 300 or so genes that are imprinted, there are another 1000–2000 human genes that exhibit monoallelic expression. Like X-inactivation (but unlike imprinting), the choice of which copy of the gene is expressed and which is silenced appears random. Yet once the choice is made, it can persist for many cell divisions. Because the choice is often made relatively late in development, cells of the same tissue in the same individual can express different copies of a given gene. In other words, somatic tissues are often mosaics, where different clones of cells have subtly different patterns of gene expression. The mechanisms responsible for this type of monoallelic expression and its memory through cell divisions are not known in detail, and its general purpose—if any—is poorly understood. However, several different mechanisms are known that may contribute to such inheritance, as we now discuss.

In considering the general question of cell memory, it is useful to return to our discussion of the different cell types in an organism. As we have seen, once a cell in an organism differentiates into a particular cell type, it generally remains

Figure 7-55 Mammalian X-inactivation.

The two X chromosomes in a female mammal (A) before and (B) after X-inactivation. (C) At an early stage of X-chromosome inactivation, mouse chromosomes have been hybridized with a fluorescent probe that is complementary to the Xist RNA, which coats only the inactive X chromosome; the remaining DNA has been stained blue with a dye. (D) A schematic illustration of how the continuing synthesis of Xist RNA at the Xist locus moves Xist molecules outward. across the chromosome. As Xist molecules coat the chromosome, they begin to associate with a variety of structural proteins and enzymes that modify histones and DNA. [Although some of these proteins are bound to the chromosome prior to Xist spreading (not shown), most are brought in by direct association with Xist.] The two major chromosome domains that are created at the completion of the inactivation process have been proposed to be biomolecular condensates. Genes that escape the inactivation process are shown as loops, extending from the compact domains. (B and D, based on a figure supplied by Agnese Loda and Edith Heard; C, from L. Giorgetti et al., Nature 535:575-579, 2016. Reproduced with permission from SNCSC.)

MBOC7_ptr_ch07_397-474.indd 443 02/12/21 12:45 PM

444

specialized in that way; if it divides, its daughters inherit the same specialized character. Perhaps the simplest way for a cell to remember its identity is through a positive feedback loop in which a key transcription regulator activates, either directly or indirectly, the transcription of its own gene (see Figure 7-42). As we discussed earlier in this chapter, interlocking positive feedback loops of the type shown in Figure 7-40B provide greater stability by buffering the circuit against fluctuations in the level of any one transcription regulator. Because transcription regulators are synthesized in the cytosol and diffuse throughout the nucleus, feedback loops based on this mechanism will affect both copies of a gene in a diploid cell. However, as discussed earlier, the expression pattern of a gene on one chromosome can differ from that of the copy of the same gene on the other chromosome (as in X-inactivation or in imprinting). Such differences can also be inherited through many cell divisions, and they cannot be explained by this type of transcription feedback loop.

The ability of a daughter cell to retain a memory of the gene expression patterns that were present in the parent cell is an example of **epigenetic inheritance**, which we define as a heritable alteration in a cell or organism's phenotype that does not result from changes in the nucleotide sequence of DNA. In **Figure 7–56**, we illustrate four mechanisms that can produce epigenetic inheritance, contrasting those self-propagating mechanisms that work *in cis*, affecting only one chromosomal copy, with self-propagating mechanisms that work *in trans*, affecting both chromosomal copies of a gene.

It is important to note that many of the changes in gene expression that occur in cells are transient and depend on the continued presence of a signal that is

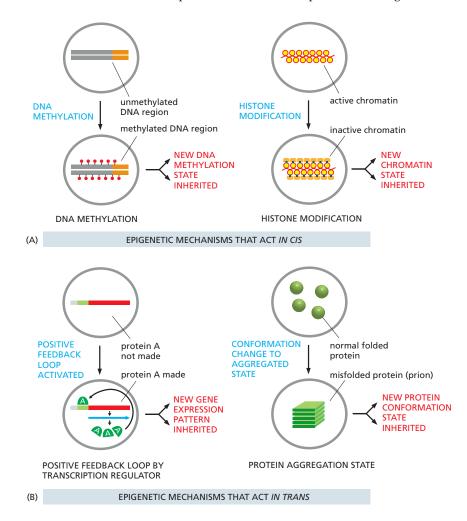

Figure 7-56 Four distinct mechanisms that can produce an epigenetic form of inheritance in an organism. (A) Two epigenetic mechanisms that act in cis. As discussed in this chapter, a maintenance methylase can propagate specific patterns of cytosine methylation (see Figure 7-47). Alternatively, as discussed in Chapter 4, a histone-modifying enzyme that replicates the same covalent modification that attracts it to chromatin can result in a chromatin structure being self-propagating (see Figure 4-44). Note that the term epigenetic is sometimes misused to refer to all covalent modifications of histones, whether or not they are self-propagating. But many histone modifications are erased each time a cell divides, and they therefore do not fit our definition. (B) Two epigenetic mechanisms that act in trans. Positive feedback loops formed by transcription regulators are found in all species and are probably the most common form of cell memory. As discussed in Chapter 3, some proteins can form self-propagating prions (see Figure 3-33). When these proteins are involved in gene expression, prions can transmit a particular pattern of gene expression to daughter cells.

MBOC7_ptr_ch07_397-474.indd 444 02/12/21 12:45 PM

external to the cell. When the signal disappears, so does the new gene expression pattern; in other words, the pattern is not directly heritable (see Chapter 15). Gene expression changes of both types—both heritable and non-heritable—are crucial for the function of all cells on earth. And the discovery more than 60 years ago that gene expression can be regulated by cells ranks as one of the fundamental principles of biology.

Summary

In addition to the positive feedback loops created by transcription regulators, eukaryotic cells can use both inherited forms of DNA methylation and inherited states of chromatin condensation as mechanisms for generating a cell memory of gene expression patterns. An especially dramatic case that involves chromatin condensation is the inactivation of an entire X chromosome in female mammals. DNA methylation underlies the phenomenon in mammals of genomic imprinting, in which the expression of a gene depends on whether that gene was inherited from the mother or the father. All of these mechanisms allow cells to pass on gene expression patterns to their progeny cells, contributing to the epigenetic inheritance that makes complex multicellular life possible.

POST-TRANSCRIPTIONAL CONTROLS

In principle, every step required for the process of gene expression can be controlled. Indeed, one can find examples of each type of regulation, and many genes are known to be regulated by multiple mechanisms. As we have seen, controls on the initiation of gene transcription are one critical form of regulation for all genes. But other, equally important controls often act later in the pathway from DNA to protein to change the amount of gene product that is made—and in some cases, even to alter the amino acid sequence of a protein product. These **post-transcriptional controls**, which operate after RNA polymerase has bound to the gene's promoter and has begun its RNA synthesis, are crucial for the regulation of many genes.

In the following sections, we consider the varieties of post-transcriptional regulation in a temporal order, following the sequence of events that an RNA molecule might experience after its transcription has begun (Figure 7–57).

Transcription Attenuation Causes the Premature Termination of Some RNA Molecules

It has long been known that the expression of some genes is inhibited by premature termination of transcription, a phenomenon called *transcription attenuation*. In some of these cases, the nascent RNA chain adopts a structure that causes it to interact with the RNA polymerase in such a way as to abort its transcription. When the gene product is required, regulatory proteins bind to the nascent RNA chain to remove the attenuation, allowing the transcription of a complete RNA molecule.

A well-studied example of transcription attenuation occurs during the life cycle of HIV, the human immunodeficiency virus that is the causative agent of acquired immune deficiency syndrome, or AIDS. Once the HIV genome has been integrated into the host genome, the viral DNA is transcribed by the cell's RNA polymerase II (see Figure 5–61). However, this polymerase usually terminates transcription after synthesizing transcripts of several hundred nucleotides and thus fails to efficiently transcribe the entire viral genome. But when conditions for viral growth are optimal, a virus-encoded protein called Tat, which binds to a specific stem-loop structure in the nascent RNA that contains a "bulged base," prevents this premature termination (see Figure 6–92). Once bound to this specific RNA structure (called TAR), Tat assembles several host-cell proteins that allow the RNA polymerase to continue transcribing. The normal role of at least some of these proteins is to prevent pausing and premature termination by RNA polymerase when it transcribes normal cell genes. A normal cell mechanism has

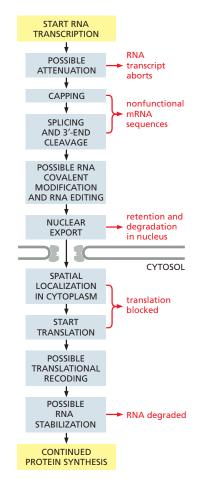

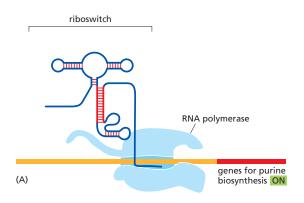

Figure 7–57 Post-transcriptional controls of gene expression. The final synthesis rate of a protein can, in principle, be controlled at any of the steps listed in capital letters, although only a few of the steps depicted here are likely to be critical for the regulation of any one particular protein. As we shall discuss, the 3' end cleavage, splicing, editing, and translation recoding steps also make it possible for the cell to produce more than one protein variant from the same gene.

MBOC7_ptr_ch07_397-474.indd 445 02/12/21 12:45 PM

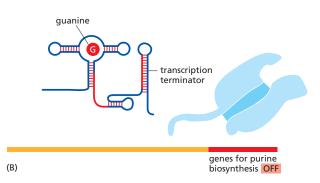

Figure 7–58 A riboswitch that responds to guanine. In this example from bacteria, the riboswitch controls expression of the purine biosynthetic genes. (A) When guanine levels in cells are low, an elongating RNA polymerase transcribes the purine biosynthetic genes, and the enzymes needed for guanine synthesis are therefore expressed. (B) When guanine is abundant, it binds the riboswitch, causing it to undergo a conformational change that forces the RNA polymerase to terminate transcription (see Figure 6–11). (C) Guanine (red) bound to the riboswitch. Only those nucleotides that form the guanine-binding pocket are shown. Many other riboswitches exist, including those that recognize S-adenosylmethionine, coenzyme B₁₂, flavin mononucleotide, adenine, lysine, and glycine. (A and B, adapted from M. Mandal and R.R. Breaker, Nat. Rev. Mol. Cell Biol. 5:451–463, 2004; and C.K. Vanderpool and S. Gottesman, Mol. Microbiol. 54:1076–1089, 2004; C, adapted from A. Serganov et al., Chem. Biol. 11:1729–1741, 2004. PDB code: 1Y27.)

apparently been highjacked by HIV to permit transcription of its genome to be controlled by a single viral protein.

Riboswitches Probably Represent Ancient Forms of Gene Control

In Chapter 6, we discussed the idea that, before modern cells arose on Earth, RNA played the role of both DNA and proteins, storing hereditary information and catalyzing chemical reactions (see pp. 389–393). The discovery of *riboswitches* shows that RNA can also form control devices. Riboswitches are short sequences of RNA that change their conformation when they bind a specific small molecule, such as a metabolite. Riboswitches are often located near the 5' end of mRNAs, and they fold while the mRNA is being synthesized, blocking or permitting progress of the RNA polymerase according to whether the regulatory small molecule is bound (Figure 7–58).

Riboswitches are particularly common in bacteria, where they sense key small metabolites in the cell and adjust gene expression accordingly. Each recognizes only the appropriate small molecule with high specificity. In many cases, every chemical feature of the small molecule is read by the RNA, and the binding affinities observed are as tight as those typically observed between small molecules and proteins (see Figure 7–58C).

Riboswitches are perhaps the most economical examples of gene control devices, inasmuch as they completely bypass the need for regulatory proteins. In the example illustrated (see Figure 7–58), the riboswitch controls transcription elongation, but riboswitches can also regulate other steps in gene expression, as we shall see later in this chapter. The fact that highly sophisticated gene control devices can be made from short sequences of RNA provides important support for the early "RNA world" hypothesis.

Alternative RNA Splicing Can Produce Different Forms of a Protein from the Same Gene

As discussed in Chapter 6, RNA splicing shortens the transcripts of many eukaryotic genes by removing the intron sequences from mRNA precursors. A cell can splice an RNA transcript differently and thereby make different

MBOC7_ptr_ch07_397-474.indd 446 02/12/21 12:45 PM

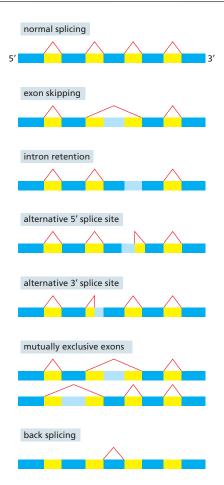

Figure 7–59 Patterns of alternative RNA splicing. Dark blue boxes mark exon sequences that are retained in spliced mRNAs. Light blue boxes mark possible exon sequences that are included only in the indicated mRNAs. The boxes are joined by red lines to indicate where intron sequences (yellow) are removed. In back splicing (discussed later in the chapter), a single exon is removed as a circular RNA molecule. (Adapted from H. Keren et al., Nat. Rev. Genet. 11:345–355, 2010.)

polypeptide chains from the same gene—a process called **alternative RNA splicing** (Figure 7–59; see also Figure 6–27). Many animal genes produce multiple proteins in this way.

When different splicing possibilities exist at several positions in the transcript, a single gene can produce dozens of different proteins. In one extreme case, a single *Drosophila* gene can, in principle, produce as many as 38,000 different proteins through alternative splicing (**Figure 7–60**), although only a fraction of these forms have thus far been experimentally observed. Considering that the *Drosophila* genome has approximately 14,000 protein-coding genes, it is clear that the protein complexity of an organism can greatly exceed the number of its genes. This example also illustrates the perils in equating gene number with an organism's complexity. For example, alternative splicing is rare in single-celled budding yeasts but very common in flies. Budding yeast has about 6200 genes, only about 300 of which are subject to splicing, and nearly all of these have only a single intron. The fact that flies have only 2–3 times as many genes as yeasts greatly underestimates the difference in complexity of these two genomes.

In some cases, alternative RNA splicing occurs because there is an *intron sequence ambiguity*: the standard spliceosome mechanism for removing intron sequences (discussed in Chapter 6) is unable to distinguish clearly between two or more alternative pairings of 5' and 3' splice sites, so that different choices are made by chance on different individual transcripts. Where such *constitutive* alternative splicing occurs, several versions of the protein encoded by the gene are made in all cells in which the gene is expressed.

In many cases, however, alternative RNA splicing is regulated. In the simplest examples, regulated splicing is used to switch from the production of a

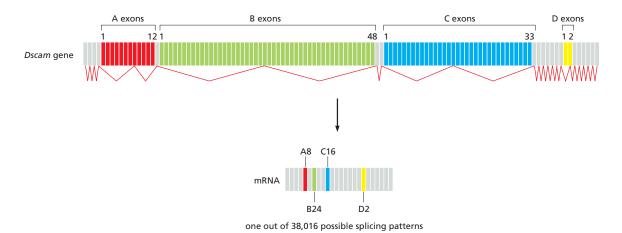

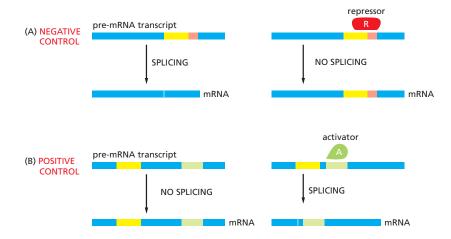

Figure 7–60 Alternative splicing of RNA transcripts of the *Drosophila Dscam* gene. Dscam proteins have several different functions. In cells of the fly immune system, they mediate the phagocytosis of bacterial pathogens. In cells of the nervous system, they are needed for proper wiring of neurons. Each mature mRNA contains 24 exons, four of which (denoted A, B, C, and D) are present in the *Dscam* gene as arrays of alternative exons. Each RNA contains 1 of 12 alternatives for exon A (red), 1 of 48 alternatives for exon B (green), 1 of 33 alternatives for exon C (blue), and 1 of 2 alternatives for exon D (yellow). This figure shows only one of the many possible splicing patterns (indicated by the red line and by the mature mRNA below it). Each variant Dscam protein folds into roughly the same structure (predominantly a series of extracellular immunoglobulin-like domains linked to a membrane-spanning region; see Figure 24–48), but the amino acid sequences of the domains vary according to the splicing pattern. The diversity of Dscam variants contributes to the plasticity of the immune system, as well as to the formation of complex neural circuits. (Adapted from D.L. Black, *Cell* 103:367–370, 2000. With permission from Elsevier.)

MBOC7_ptr_ch07_397-474.indd 447 02/12/21 12:45 PM

nonfunctional protein to the production of a functional one (or the other way around). The transposase that catalyzes the transposition of the *Drosophila* P element, for example, is produced in a functional form in germ cells and a nonfunctional form in somatic cells of the fly, allowing the P element to spread throughout the genome of the fly without causing damage in somatic cells (see Figure 5–59 and Table 5–4, p. 308). This difference in transposon activity has been traced to the presence of an intron sequence in the transposase RNA that is removed only in germ cells.

In addition to enabling switching from the production of a functional protein to the production of a nonfunctional one (or vice versa), the regulation of RNA splicing can generate different versions of a protein in different cell types, according to the needs of the cell. Tropomyosin, for example, is produced in specialized forms in different types of cells (see Figure 6–27). Cell-type-specific forms of many other proteins are produced in the same way.

RNA splicing can be regulated either negatively, by a regulatory molecule that prevents the splicing machinery from gaining access to a particular splice site on the RNA, or positively, by a regulatory molecule that helps direct the splicing machinery to an otherwise overlooked splice site (Figure 7-61).

Because of the plasticity of RNA splicing, the blocking of a "strong" splicing site will often expose a "weak" site and result in a different pattern of splicing. Thus, the splicing of a pre-mRNA molecule can be thought of as a delicate balance between competing splice sites—a balance that can easily be tipped by the effects on splicing of RNA-bound regulatory proteins.

The Definition of a Gene Has Been Modified Since the Discovery of Alternative RNA Splicing

The discovery that eukaryotic genes usually contain introns and that their coding sequences can be assembled in more than one way raised new questions about the definition of a gene. A gene was first clearly defined in molecular terms in the early 1940s from work on the biochemical genetics of the fungus *Neurospora*. Until then, a gene had been defined as a region of the genome that segregates as a single unit during meiosis and gives rise to a definable phenotypic trait—such as a red or a white eye in *Drosophila* or a round or wrinkled seed in peas. The *Neurospora* findings revealed that most genes correspond to a region of the genome that directs the synthesis of a single enzyme, leading to the view that each gene encodes one polypeptide chain. As more was learned about the mechanism of gene expression in the 1960s, a gene became identified as that stretch of DNA that was transcribed into the RNA coding for either a single polypeptide chain or a single structural RNA such as a tRNA or an rRNA molecule. The discovery of introns in the late 1970s could be readily accommodated by

Figure 7-61 Negative and positive control of alternative RNA splicing. (A) In negative control, a repressor protein binds to a specific sequence in the premRNA transcript and blocks access of the splicing machinery to a splice junction. This often results in the use of a secondary splice site, thereby producing an altered pattern of splicing (see Figure 7-59). (B) In positive control, the splicing machinery is unable to remove a particular intron sequence efficiently without assistance from an activator protein. Because an RNA molecule is flexible, the nucleotide sequences that bind these activators can be located many nucleotide pairs from the splice junctions they control, and they are often called splicing enhancers, by analogy with the transcription enhancers mentioned earlier in this chapter.

MBOC7_ptr_ch07_397-474.indd 448 02/12/21 12:45 PM

the original definition of a gene, provided that a single polypeptide chain was specified by the RNA transcribed from any one DNA sequence. But now that it is clear that many DNA sequences in eukaryotic cells can produce a set of distinct (but related) proteins by means of alternative RNA splicing, how should a gene be defined?

It is relatively rare that a single transcription unit produces two very different eukaryotic proteins, and in those cases, the two proteins are considered to be produced by distinct genes that overlap on the chromosome. It seems unnecessarily complex, however, to consider most of the protein variants produced by alternative RNA splicing as being derived from overlapping genes. A more sensible alternative is to modify the original definition to consider any DNA sequence that is transcribed as a single unit and encodes a set of closely related polypeptide chains (protein isoforms) as a single protein-coding gene. This definition of a **gene** also accommodates those DNA sequences that encode protein variants produced by post-transcriptional processes other than RNA splicing, such as the transcript cleavage and RNA editing discussed shortly.

Back Splicing Can Produce Circular RNA Molecules

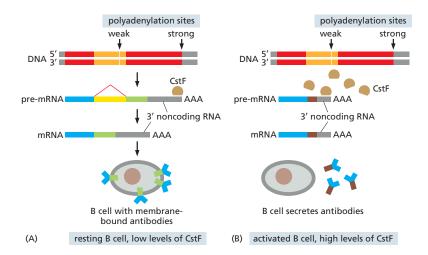

We have seen that pre-mRNA splicing is remarkably plastic, and recent discoveries have revealed a new surprise. Some pre-mRNAs undergo what is termed "back splicing" where a 3' splice site is joined to a downstream 5' splice site, thereby reversing the normal joining order (see Figure 7-59). This process typically releases a single exon sequence as a covalently closed, circular RNA molecule. These unusual RNAs are exported from the nucleus but are rarely translated into protein. Instead, they have been proposed to "soak up" complementary RNAs as well as RNA-binding proteins and to provide scaffolds for multisubunit RNA-protein complexes. Because they lack free ends, which are the normal substrates for RNA-degrading enzymes, these circular RNAs are much more stable than typical mRNAs. Although usually made in small amounts, their stability can allow them to accumulate to high concentrations in cells, and several specific circular RNAs are especially prominent in cells of the mammalian brain and immune systems. Although we still have much to learn about these peculiar RNAs, they attest to the many surprises that RNA biology has in store for us. We shall revisit this general issue at the end of the chapter, when we discuss the diversity of noncoding RNAs.

A Change in the Site of RNA Transcript Cleavage and Poly-A Addition Can Change the C-terminus of a Protein

We saw in Chapter 6 that the 3′ end of a eukaryotic mRNA molecule is not formed by the termination of RNA synthesis by the RNA polymerase, as it is in bacteria. Instead, it results from an RNA cleavage reaction that is catalyzed by additional proteins while the transcript is elongating (see Figure 6–36). A cell can control the site of this cleavage so as to change the C-terminus of the resultant protein. In the simplest cases of alternate cleavage and polyadenylation, one protein variant is simply a truncated version of the other; in many other cases, however, the alternative cleavage and polyadenylation sites lie within intron sequences, and the pattern of splicing is thereby altered. This process can produce two closely related proteins that differ only in the amino acid sequences at their C-terminal ends. An analysis of RNAs produced from the human genome in a variety of cell types indicates that as many as half of all human protein-coding genes produce mRNA species with more than one site of polyadenylation.

A well-studied example of regulated polyadenylation is the switch from the synthesis of membrane-bound to secreted antibody molecules that occurs during the development of B lymphocytes (see Figure 24–22). Early in the life history of a B lymphocyte, the antibody it produces is anchored in the plasma membrane, where it serves as a receptor for antigen. Antigen stimulation causes B lymphocytes to multiply and to begin secreting their antibody. The secreted form of the

MBOC7_ptr_ch07_397-474.indd 449 02/12/21 12:45 PM

antibody is identical to the membrane-bound form except at the extreme C-terminus. In this part of the protein, the membrane-bound form has a long string of hydrophobic amino acids that traverses the lipid bilayer of the membrane, whereas the secreted form has a much shorter string of hydrophilic amino acids. The switch from membrane-bound to secreted antibody is generated through a change in the site of RNA cleavage and polyadenylation, as shown in Figure 7–62.

The change is caused by an increased concentration of a subunit of a protein (CstF) that promotes RNA cleavage (see Figure 6–36). The first cleavage/poly-A addition site that a transcribing RNA polymerase encounters is suboptimal and is usually skipped in unstimulated B lymphocytes, leading to production of the longer RNA transcript. But when activated to produce antibodies, the B lymphocyte produces more CstF; as a result, cleavage now occurs at the suboptimal site, and the shorter transcript is produced. In this way, a change in concentration of a general RNA-processing factor can have a dramatic effect on the expression of a specific gene.

Nucleotides in mRNA Can Be Covalently Modified

In the previous chapter, we saw how specialized proteins modify the 5' and 3' ends of eukaryotic mRNAs and how a complex assembly of proteins and RNA molecules removes intron sequences. However, mRNA molecules are subject to more than 100 additional kinds of covalent changes, predominantly chemical modifications of individual bases, a few of which are shown in Figure 7-63. The reasons for most of these modifications of individual mRNAs remain a mystery. We do not know what they might do or even if they are biologically meaningful, inasmuch as many of them may simply represent "spillover" from the processes that modify the highly abundant tRNA and rRNA molecules (see Figures 6-43 and 6-57).

One of the most prominent and best understood mRNA modifications is the methylation of the amino group on adenine to produce N^6 -methyladenosine

Figure 7-62 Regulation of the site of RNA cleavage and poly-A addition determines whether an antibody molecule is secreted or remains membrane-bound. (A) In unstimulated B lymphocytes, a long RNA transcript is produced, and the intron sequence (yellow) near its 3' end is removed by RNA splicing to provide an mRNA molecule that codes for a membrane-bound antibody molecule. Only a portion of the antibody gene is shown in the figure; the actual gene and its mRNA would extend further to the left of the diagram. (B) After antigen stimulation, the RNA transcript is cleaved and polyadenylated upstream from the intron's 3' splice site. As a result, some of the intron sequence remains as a coding sequence in the short transcript, specifying the hydrophilic C-terminal portion of the secreted antibody molecule (brown). (Adapted from D. Di Giammartino et al., Mol. Cell 43:853-866, 2011.)

Figure 7–63 Four of the most prominent of the many types of covalent base modifications found in mRNA. Differences from the normal nucleosides are indicated in *red*. Each base is joined to a ribose sugar (not shown) by the indicated bond to form the nucleoside.

MBOC7_ptr_ch07_397-474.indd 450 02/12/21 12:45 PM

(see Figure 7–63). This addition is constantly being removed by protein complexes that contain demethylases, or "erasers," making the modification temporary. The methylases responsible for this modification typically act as the RNA is being transcribed; they recognize short sequences in the emerging RNA (often with the help of other proteins) and methylate the adenosines adjacent to these sequences.

In humans an average of 1–3 N^6 -methyladenosine modifications occur on each mRNA molecule. What are their consequences? One effect is the destabilization of the hairpin helices that are formed by intramolecular base-pairing. This modification can thereby change the secondary structure of mRNA, which in some cases alters the splicing pattern of transcripts. In other cases, the modification promotes destruction of mRNAs through "reader" proteins that attract the RNA degradation machinery. A rapid destruction of certain mRNAs is especially important during cell differentiation, when the mRNAs produced earlier need to be cleared out. Finally, other specific N^6 -methyladenosine modifications are known to promote translation of the modified mRNA. In this case, reader proteins that attract the translation machinery come into play. The many other mRNA modifications, some of which are shown in Figure 7–63, are more poorly understood, but some may likewise help to determine exactly how each mRNA is to be handled by the cell.

RNA Editing Can Change the Meaning of the RNA Message

The molecular mechanisms used by cells are providing scientists with a continual source of surprises. An example is a covalent modification of mRNA that alters its nucleotide sequence and thereby changes the coded message it carries—a process known as RNA editing.

In animals, two principal types of such RNA editing occur: the deamination of adenine to produce inosine (A-to-I editing) and, less frequently, the deamination of cytosine to produce uracil (C-to-U editing; see Figure 5–43). Because these chemical modifications alter the pairing properties of the bases (I pairs with C, and U pairs with A), they can have profound effects on the meaning of the RNA. If the edit occurs in a coding region, it can either change the amino acid sequence of the protein or produce a truncated protein by creating a premature stop codon. Edits that occur outside coding sequences can affect the pattern of pre-mRNA splicing, the transport of mRNA from the nucleus to the cytosol, the efficiency with which the RNA is translated, or the base-pairing between microRNAs (miRNAs) and their mRNA targets, a form of gene regulation that will be discussed later in the chapter.

The process of A-to-I editing is particularly prevalent in humans, where it occurs for approximately 1000 genes. Enzymes called *ADARs* (*adenosine deaminases acting on RNA*) perform this type of editing; these enzymes recognize a double-strand RNA structure that is formed through base-pairing between the site to be edited and a complementary sequence located elsewhere on the same RNA molecule, typically in an intron (Figure 7–64). The structure of

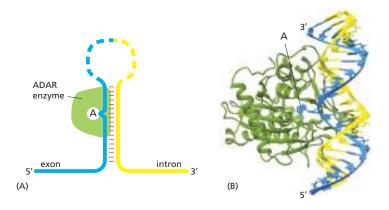

Figure 7-64 Mechanism of A-to-I RNA editing in mammals. (A) Typically, a sequence complementary to the position of the edit is present in an intron, and the resulting double-strand RNA structure attracts an A-to-I editing enzyme (ADAR). In the case illustrated, the edit is made in an exon; in most cases, however, it occurs in noncoding portions of the mRNA. Editing by ADAR takes place in the nucleus, before the pre-mRNA has been fully processed. Mice and humans have two ADAR genes: ADR1 is expressed in many tissues and is required in the liver for proper red blood cell development; ADR2 is expressed only in the brain, where it is required for proper brain development. (B) The human ADR2 enzyme bound to double-stranded RNA. The adenine to be edited is seen to be flipped out of the RNA double helix and buried deep in the catalytic pocket of the enzyme. Base flipping, which allows the enzyme access to the entire base, is also observed in enzymes that repair DNA (see Figure 5-42). (PDB code: 5ED1.)

MBOC7_ptr_ch07_397-474.indd 451 02/12/21 12:45 PM

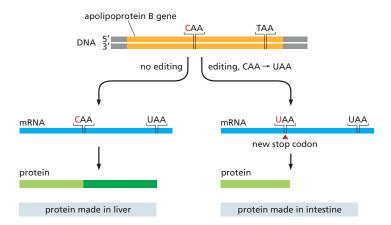

Figure 7–65 C-to-U RNA editing produces a truncated form of apolipoprotein B. As indicated, a tissue-specific edit in the middle of a coding sequence creates a truncated version of this protein in the intestine.

the double-stranded RNA specifies whether the mRNA is to be edited, and if so, where the edit should be made. An especially important example of A-to-I editing takes place in the mRNA that codes for a transmitter-gated ion channel in the brain. A single edit changes a glutamine to an arginine; the affected amino acid lies on the inner wall of the channel, and the editing change alters the Ca²⁺ permeability of the channel. Mutant mice that cannot make this edit are prone to epileptic seizures and die during or shortly after weaning, showing that editing of the ion channel RNA is normally crucial for proper brain development.

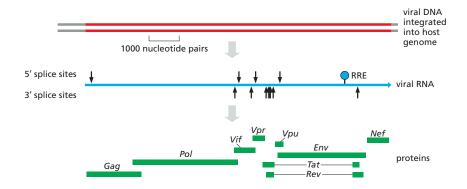

C-to-U editing, which is carried out by a different set of enzymes, is also important in mammals. For example, in certain cells of the gut, the mRNA for apolipoprotein B undergoes a C-to-U edit that creates a premature stop codon and therefore produces a shorter form of the protein. In cells of the liver, the editing enzyme is not expressed, and the full-length apolipoprotein B is produced. The two protein isoforms have different properties, and each plays a role in lipid metabolism that is specific to the organ that produces it (Figure 7–65).

Why RNA editing exists at all is a mystery. One idea is that it arose in evolution to correct "mistakes" in the genome. Another is that it arose as a somewhat slapdash way for the cell to produce subtly different proteins from the same gene. A third possibility is that RNA editing originally evolved as a defense mechanism against retroviruses and retrotransposons and was only later adapted by the cell to change the meanings of certain mRNAs. The last explanation receives support from the fact that RNA editing plays important roles in cell defense. The RNA genomes of some retroviruses, including HIV, are extensively edited after they infect cells. This hyperediting creates many harmful mutations in the viral RNA genome and also causes viral mRNAs to be retained in the nucleus, where they are eventually degraded. Although some modern retroviruses can protect themselves against this defense mechanism, RNA editing presumably helps to hold many viruses in check.

The Human AIDS Virus Illustrates How RNA Transport from the Nucleus Can Be Regulated

It has been estimated that in mammals only about one-twentieth of the total mass of RNA that is synthesized ever leaves the nucleus. We saw in Chapter 6 that most mammalian RNA molecules undergo extensive processing and that the "leftover" RNA fragments (excised introns and RNA sequences 3' to the cleavage/poly-A site) are degraded in the nucleus. Incompletely processed and otherwise damaged RNAs are also eventually degraded as part of the quality-control system that acts on RNA production.

MBOC7_ptr_ch07_397-474.indd 452 02/12/21 12:45 PM

As described in Chapter 6, the export of RNA molecules from the nucleus is delayed until processing has been completed. However, mechanisms that deliberately override this control point can be used to regulate gene expression. This strategy forms the basis for one of the best-understood examples of regulated nuclear transport of mRNA, which occurs in the human AIDS virus, HIV.

As we saw in Chapter 5, HIV, once inside the cell, directs the formation of a double-strand DNA copy of its single-strand RNA genome, which is then inserted into the genome of the host (see Figure 5–61). Once inserted, the viral DNA can be transcribed as one long RNA molecule by the host cell's RNA polymerase II. This transcript is then spliced in many different ways to produce more than 30 different species of mRNA, which in turn are translated into a variety of different proteins (Figure 7–66). In order to make progeny virus, entire unspliced viral transcripts must be exported from the nucleus to the cytosol, where they are packaged into viral capsids and serve as the viral genome. This large transcript, as well as certain alternatively spliced HIV mRNAs that are needed to produce viral proteins, still carry complete introns. The host cell's normal block to the nuclear export of unspliced RNAs therefore presents a special problem for HIV.

The block is overcome by a viral-coded protein (called Rev) that binds to a specific RNA sequence (called the Rev response element; RRE) located within a viral intron. The Rev protein interacts with a nuclear export receptor (Crm1), which directs the movement of viral RNAs through nuclear pores into the cytosol despite the presence of intron sequences. (How export receptors function is discussed in detail in Chapter 12.) The regulation of nuclear export by Rev has several important consequences for HIV growth and pathogenesis. In addition to ensuring the nuclear export of specific unspliced RNAs, it divides the viral infection into an early phase (in which Rev is translated from a fully spliced RNA, and all of the intron-containing viral RNAs are retained in the nucleus and degraded) and a late phase (in which unspliced RNAs are exported because of Rev function). This timing helps the virus replicate by providing the gene products in roughly the order in which they are needed (Figure 7–67).

Regulation by Rev and by Tat, the HIV protein that counteracts premature transcription termination (see pp. 445–446), allows the virus to achieve latency, a condition in which the HIV genome has become integrated into the host-cell genome, but the production of viral proteins has temporarily ceased. If, after the virus's initial entry into a host cell, conditions are unfavorable for viral replication, Rev and Tat are made at levels too low to promote transcription and export of unspliced RNA. This stalls the viral growth cycle until conditions improve, whereupon Rev and Tat levels increase and the virus enters the replication cycle.

mRNAs Can Be Localized to Specific Regions of the Cytosol

Once a newly made eukaryotic mRNA molecule has passed through a nuclear pore and entered the cytosol, it is typically met by ribosomes, which translate it into a polypeptide chain. Once the first round of translation "passes" the

Figure 7-66 The compact genome of HIV, the human AIDS virus. The positions of the nine HIV genes are shown in green. The red double line indicates a DNA copy of the viral genome that has become integrated into the host DNA (gray). Note that the coding regions of many HIV genes overlap, and that those for Tat and Rev are split by introns. The blue line in the middle of the figure represents the pre-mRNA transcript of the viral DNA and shows the locations of all the possible splice sites (arrows). There are many alternative ways of splicing the viral transcript; for example, the Env mRNAs retain the intron that has been spliced out of the Tat and Rev mRNAs. The Rev response element (RRE) is indicated by a blue ball and stick. It is a 234-nucleotide-long stretch of RNA that folds into a defined structure; Rev recognizes a particular hairpin within this larger structure.

The Gag gene codes for a protein that is cleaved into several smaller proteins that form the viral capsid. The Pol gene codes for a protein that is cleaved to produce reverse transcriptase (which transcribes RNA into DNA), as well as the integrase involved in integrating the viral genome (as double-stranded DNA) into the host genome. The Env gene codes for the envelope proteins (see Figure 5-61). Tat, Rev, Vif, Vpr, Vpu, and Nef are small proteins with a variety of functions. As discussed in the text, Rev regulates nuclear export (see Figure 7-67), and Tat regulates the elongation of transcription across the integrated viral genome (see pp. 445–446).

MBOC7_ptr_ch07_397-474.indd 453 02/12/21 12:45 PM

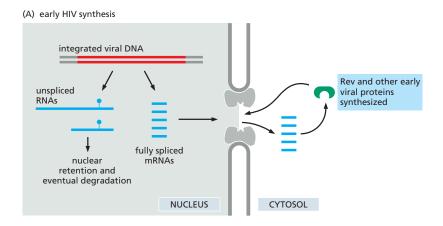

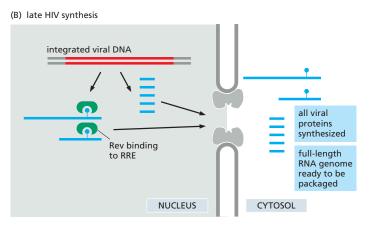

Figure 7–67 Regulation of nuclear export by the HIV Rev protein. (A) Early in HIV infection, only the fully spliced RNAs (which contain the coding sequences for Rev, Tat, and Nef) are exported from the nucleus and translated. (B) Once sufficient Rev protein has accumulated and been transported into the nucleus, unspliced viral RNAs can be exported from the nucleus. Many of these RNAs are translated into protein, and the full-length transcripts are packaged into new viral particles.

nonsense-mediated decay test (see Figure 6–80), the mRNA is usually translated in earnest. If the mRNA encodes a protein that is destined to be secreted or expressed on the cell surface, a signal sequence at the protein's N-terminus will direct it to the endoplasmic reticulum (ER). In this case, as discussed in Chapter 12, components of the cell's protein-sorting apparatus recognize the signal sequence as soon as it emerges from the ribosome and direct the entire complex of ribosome, mRNA, and nascent protein to the membrane of the ER, where the remainder of the polypeptide chain is synthesized. In other cases, free ribosomes in the cytosol synthesize the entire protein, and signals in the completed polypeptide chain may then direct the protein to other sites in the cell.

Many mRNAs are themselves directed to specific intracellular locations before their efficient translation begins, allowing the cell to position its mRNAs close to the sites where the encoded protein is needed. RNA localization has been observed in many organisms, including unicellular fungi, plants, and animals, and it appears to be a common mechanism that cells use to concentrate high-level production of proteins at specific sites. This strategy also provides the cell with other advantages. For example, it allows the establishment of asymmetries in the cytosol of the cell, a key step in many stages of development.

The localization of mRNA, coupled with translational control, also allows the cell to regulate gene expression independently in different regions. This feature is particularly important in large, highly polarized cells such as neurons; in those cells, specific mRNAs are transported for long distances along axons and dendrites to synapses, and the translation of the mRNAs that become localized there is often controlled by synaptic activity.

The mechanisms for mRNA localization that have been discovered all require specific signals in the mRNA itself (Figure 7-68). These signals are usually

MBOC7_ptr_ch07_397-474.indd 454 02/12/21 12:45 PM

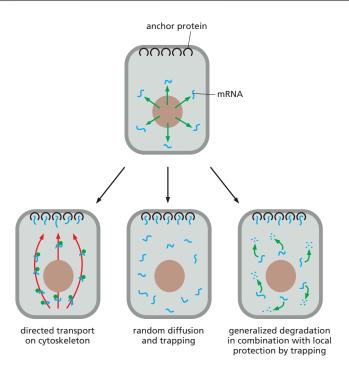

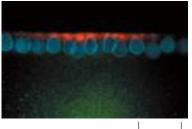

Figure 7-68 Mechanisms for the localization of mRNAs. The mRNA to be localized leaves the nucleus through nuclear pores (top). Some localized mRNAs (left diagram) travel to their destination by associating with cytoskeletal motors, which use the energy of ATP hydrolysis to move the mRNAs unidirectionally along filaments in the cytoskeleton (red) (see Chapter 16). At their destination, the mRNAs are held in place by anchor proteins (black). Other mRNAs randomly diffuse through the cytosol and are simply trapped by anchor proteins at their sites of localization (center diagram). As an additional feature, many mRNAs (right diagram) are degraded in the cytosol unless they have bound, through random diffusion, a localized anchor protein complex that protects the mRNA from degradation (black). These mechanisms require specific signals on the mRNA, which are typically located in the 3' UTR. In all cases, other RNA-bound components block the translation of the mRNA until it is properly localized. Even then, additional signals are often needed to begin translation. (Adapted from H.D. Lipshitz and C.A. Smibert, Curr. Opin. Genet. Dev. 10:476-488, 2000.)

concentrated in the 3' *untranslated region* (*UTR*), the region of RNA that extends from the stop codon that terminates protein synthesis to the start of the poly-A tail (**Figure 7–69**). As in neurons, mRNA localization is usually coupled with translational controls to ensure that the localized mRNA remains quiescent until it is needed.

The *Drosophila* egg provides an especially striking example of mRNA localization. The mRNA encoding the Bicoid transcription regulator is localized by attachment to the cytoskeleton at the anterior tip of the developing egg. When fertilization triggers the translation of this mRNA, it generates a gradient of the Bicoid protein that plays a crucial part in directing the development of the anterior part of the embryo (see Figures 7–29 and 21–19). Many mRNAs in somatic cells are also localized in a similar way. The mRNA that encodes actin, for example, is localized to the actin-filament-rich cell cortex in mammalian fibroblasts by means of a 3' UTR signal.

We saw in Chapter 6 that mRNA molecules exit from the nucleus bearing numerous markings in the form of RNA modifications (the 5' cap and the 3' poly-A tail) and bound proteins (exon junction complexes, for example) that signify the successful completion of the different pre-mRNA processing steps. As just described, the 3' UTR of an mRNA can be thought of as a "ZIP code" that directs mRNAs to different places in the cell. Shortly, we will see that mRNAs also carry information specifying their average lifetime in the cytosol and the efficiency with

Figure 7–69 An experiment demonstrating the importance of the 3' UTR in localizing mRNAs to specific regions of the cytoplasm. For this experiment, two different fluorescently labeled RNAs were prepared by transcribing DNA *in vitro* in the presence of fluorescently labeled derivatives of ribonucleoside triphosphates. One RNA (labeled with a *red* fluorochrome) contains the coding region for the *Drosophila* Hairy protein and includes the adjacent 3' UTR. The other RNA (labeled *green*) contains the Hairy coding region with the 3' UTR deleted. The two RNAs were mixed and injected into a *Drosophila* embryo at a stage of development when multiple nuclei reside in a common cytoplasm (see Figure 7–29). When the fluorescent RNAs were visualized 10 minutes later, the full-length *hairy* RNA (*red*) was localized to the apical side of nuclei (*blue*), whereas the transcript missing the 3' UTR (*green*) failed to localize and is seen as a diffuse cloud. Hairy is one of many transcription regulators that specify positional information in the developing *Drosophila* embryo, and the localization of its mRNA (shown in this experiment to depend on its 3' UTR) is critical for proper fly development. 456

which they are translated into protein. In a broad sense, the untranslated regions of eukaryotic mRNAs resemble the transcriptional control regions of genes: their nucleotide sequences contain information specifying the way the RNA is to be used, and proteins interpret this information by binding specifically to these sequences. Thus, in addition to the specification of amino acid sequences, mRNA molecules are rich with other types of information.

Untranslated Regions of mRNAs Control Their Translation

Once an mRNA has been synthesized, one of the most common ways of regulating the levels of its protein product is to control the step that initiates translation. Even though the details of translation initiation differ between eukaryotes and bacteria (as we saw in Chapter 6), they each use some of the same basic regulatory strategies.

In bacterial mRNAs, a conserved stretch of nucleotides—the *Shine-Dalgarno sequence*—is always found a few nucleotides upstream of the initiating AUG codon, and it is required to start protein synthesis (see Figure 6-75). The control of bacterial translation generally involves either exposing or blocking this critical sequence (Figure 7-70).

Eukaryotic mRNAs do not contain such a sequence. Instead, as discussed in Chapter 6, the selection of an AUG codon as a translation start site is largely determined by its proximity to the cap at the 5' end of the mRNA molecule, which is the site at which the small ribosomal subunit binds to the mRNA and begins

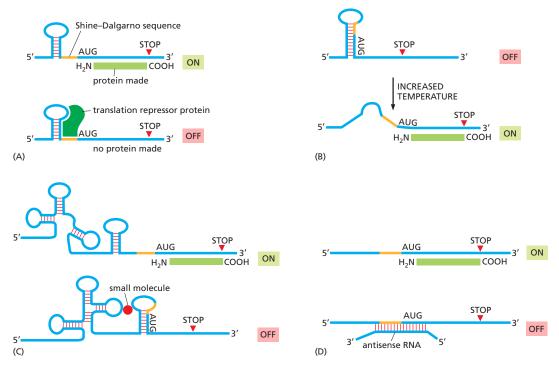

Figure 7–70 Mechanisms of translational control. Although these examples are from bacteria, many of the same principles operate in eukaryotes. (A) Sequence-specific RNA-binding proteins repress translation of specific mRNAs by blocking access of the ribosome to the Shine–Dalgarno sequence (orange). For example, some ribosomal proteins repress translation of their own mRNA. This negative feedback mechanism allows the cell to maintain balanced quantities of the various components needed to form ribosomes. (B) An RNA "thermosensor" permits efficient translation initiation only at elevated temperatures at which the stem–loop structure has been melted. An example occurs in the human pathogen Listeria monocytogenes, in which the translation of its virulence genes increases at 37°C, the temperature of the host. (C) Binding of a small molecule to a riboswitch causes a major rearrangement of RNA structure, creating a different set of stem–loop structures. In the bound structure, the Shine–Dalgarno sequence (orange) is sequestered, and translation initiation is thereby blocked. In many bacteria, S-adenosylmethionine acts in this manner to block production of the enzymes that synthesize it. (D) An "antisense" RNA produced from elsewhere in the genome base-pairs with a specific mRNA and blocks its translation. Many bacteria regulate expression of iron-storage proteins in this way.

MBOC7_ptr_ch07_397-474.indd 456 02/12/21 12:45 PM

scanning for an initiating AUG codon. In eukaryotes, translational repressors can bind to the 5' end of the mRNA and thereby inhibit translation initiation (see Figure 7–74). A particularly important type of translational control in eukaryotes relies on small RNAs (termed *microRNAs*, or *miRNAs*) that bind to mRNAs and reduce protein output, as described later in this chapter.

The Phosphorylation of an Initiation Factor Regulates Protein Synthesis Globally

Eukaryotic cells decrease their overall rate of protein synthesis in response to a variety of situations, including deprivation of growth factors or nutrients, infection by viruses, and sudden increases in temperature. (This response is coordinated by the TOR signaling pathway, which is described in Chapter 17; see Figure 17–61.) Much of the decrease in translation is caused by the phosphorylation of the translation initiation factor eIF2 by specific protein kinases that respond to the changes in conditions

The normal function of eIF2 was outlined in Chapter 6 (see Figure 6–74). It forms a complex with GTP and mediates the binding of the methionyl initiator tRNA to the small ribosomal subunit, which then binds to the 5' end of the mRNA and begins scanning along the mRNA. When an AUG codon is recognized, the eIF2 protein hydrolyzes the bound GTP to GDP, causing a conformational change in the protein and releasing it from the small ribosomal subunit. The large ribosomal subunit then joins the small one to form a complete ribosome that begins protein synthesis.

Because eIF2 binds very tightly to GDP, a guanine nucleotide exchange factor (see p. 880) designated eIF2B is required to release the GDP from eIF2 so that a new GTP molecule can bind—as required for eIF2 reuse (Figure 7–71A). When eIF2 is phosphorylated, it binds to eIF2B unusually tightly, inactivating this exchange factor. Because there is more eIF2 than eIF2B in cells, even a fraction of phosphorylated eIF2 can trap nearly all of the eIF2B. Without this exchange factor, GDP remains bound to nearly all of the nonphosphorylated eIF2, greatly slowing protein synthesis (Figure 7–71B).

Regulation of the level of active eIF2 is especially important in mammalian cells. As described in Chapter 17, eIF2 down-regulation is part of the mechanism that allows these cells to enter a nonproliferating, resting state (called G_0) in which the rate of total protein synthesis is reduced to about one-fifth the rate in proliferating cells.

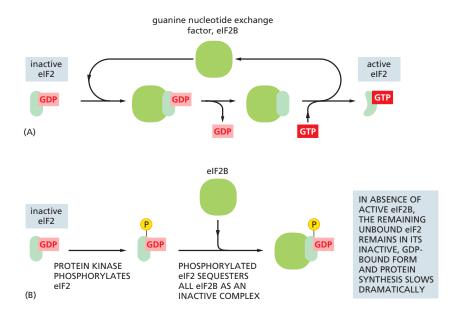

Figure 7–71 The eIF2 cycle. (A) The recycling of used eIF2 by a guanine nucleotide exchange factor (eIF2B). (B) How eIF2 phosphorylation controls protein synthesis rates by sequestering eIF2B.

MBOC7_ptr_ch07_397-474.indd 457 02/12/21 12:45 PM

Initiation at AUG Codons Upstream of the Translation Start Can Regulate Eukaryotic Translation Initiation

We saw in Chapter 6 that eukaryotic translation typically begins at the first AUG downstream of the 5' end of the mRNA, which is the first AUG encountered by a scanning small ribosomal subunit. But, as we have seen, the nucleotides immediately surrounding the AUG also influence the efficiency of translation initiation. If the recognition site is poor enough, scanning ribosomal subunits will sometimes ignore the first AUG codon in the mRNA and skip to the second or third AUG codon instead. This phenomenon, known as "leaky scanning," is a strategy frequently used to produce two or more closely related proteins, differing only in their N-termini, from the same mRNA. A particularly important use of this mechanism is the production of the same protein with and without a signal sequence attached at its N-terminus. This allows the protein to be directed to two different locations in the cell (for example, to both mitochondria and the cytosol). Cells can regulate the relative abundance of the protein isoforms produced by leaky scanning; for example, a cell-type-specific increase in the abundance of the initiation factor eIF4F favors the use of the AUG closest to the 5' end of the mRNA, even if it is surrounded by nonoptimal nucleotides.

Another type of control found in eukaryotes uses one or more short *open reading frames*—short stretches of DNA that begin with a start codon (ATG) and end with a stop codon, with no stop codons in between—that lie between the 5' end of the mRNA and the beginning of a gene. Often, the amino acid sequences coded by these upstream open reading frames (uORFs) are not important; instead, the uORFs serve a purely regulatory function. A uORF present on an mRNA molecule will generally decrease translation of the downstream gene by trapping a scanning ribosome initiation complex and causing the ribosome to translate the uORF and dissociate from the mRNA before it reaches the bona fide protein-coding sequence.

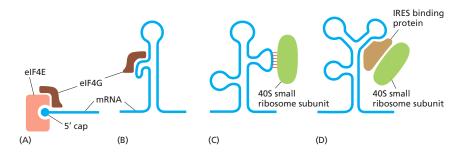

When the activity of a general translation factor (such as eIF2 discussed earlier) is reduced, one might expect that the translation of all mRNAs would be reduced equally. Contrary to this expectation, however, the phosphorylation of eIF2 can have selective effects, even enhancing the translation of specific mRNAs that contain uORFs. This can enable cells, for example, to adapt to starvation for specific nutrients by shutting down the synthesis of all proteins except those that are required for synthesis of the missing nutrients. The details of this mechanism have been worked out for the yeast mRNA that encodes a protein called Gcn4, a transcription regulator that activates many genes that encode proteins that are important for amino acid synthesis.

The *Gcn4* mRNA encodes several short uORFs, and when amino acids are abundant, ribosomes translate the uORFs and generally dissociate before they reach the *Gcn4* coding region. But a global decrease in eIF2 activity brought about by amino acid starvation makes it more likely that a scanning small ribosomal subunit will move across the uORFs (without translating them) before it acquires a molecule of eIF2. This ribosomal subunit is then free to initiate translation on the actual *Gcn4* sequences, and the increased level of this transcription regulator increases the production of amino acid biosynthetic enzymes. Thus, when cells encounter "hard times," phosphorylation of eIF2 globally decreases translation while increasing synthesis of those proteins most needed by the cell to cope with the new conditions.

Internal Ribosome Entry Sites Also Provide Opportunities for Translational Control

Although most eukaryotic mRNAs are translated beginning with the first AUG downstream from the 5' cap, certain AUGs, as we just saw, can be skipped over during the scanning process. There is a second way that cells can initiate translation at positions distant from the 5' end of the mRNA, using a specialized

MBOC7_ptr_ch07_397-474.indd 458 02/12/21 12:45 PM

type of RNA sequence called an **internal ribosome entry site** (IRES). In some cases, two distinct protein-coding sequences are carried in tandem on the same eukaryotic mRNA; translation of the first occurs by the usual scanning mechanism utilizing the first AUG encountered, and translation of the second occurs by means of an IRES located much further into the mRNA. IRESs are typically several hundred nucleotides in length, and they fold into specific structures that bypass the need for a 5' cap and the translation factor that recognizes it, eIF4E (Figure 7–72).

It is estimated that 10% of all mammalian mRNAs contain an IRES. Some of these protein synthesis start sites are specifically activated by external signals such as stress. But the best-understood examples occur with viruses, which use IRESs as part of a strategy to get their own mRNA molecules translated while blocking the normal 5' cap-dependent translation of host mRNAs. On infection, these viruses produce a protease (encoded in the viral genome) that cleaves the host-cell translation factor eIF4G, rendering it unable to bind to eIF4E, the cap-binding complex (see Figure 6–74). This shuts down most of the host cell's translation and effectively diverts the translation machinery to the IRES sequences present on the viral mRNAs. (The truncated eIF4G remains competent to initiate translation at these internal sites.)

The many ways in which viruses manipulate their host's protein-synthesis machinery for their own advantage continue to surprise cell biologists. Studying the many results of this evolutionary "arms race" between humans and pathogens has led to many fundamental insights into the workings of the cell, and we revisit this topic in Chapter 23.

Changes in mRNA Stability Can Control Gene Expression

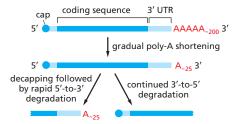

Most mRNAs in a bacterial cell are very unstable, having half-lives of less than a couple of minutes. Exonucleases, which degrade in the 3'-to-5' direction, are usually responsible for the rapid destruction of these mRNAs. Because its mRNAs are both rapidly synthesized and rapidly degraded, a bacterium can adapt quickly to environmental changes.

As a general rule, the mRNAs in eukaryotic cells are more stable. Some, such as that encoding β -globin, have half-lives of more than 10 hours. But most are considerably less stable, with half-lives of less than 30 minutes. The mRNAs that code for proteins such as growth factors and transcription regulators, whose production rates need to change rapidly in cells, are especially short-lived.

We saw in Chapter 6 that the cell has several mechanisms that rapidly destroy incorrectly processed RNAs. But now we focus on the ultimate fate of a typical "normal" eukaryotic mRNA molecule. Two general mechanisms exist for eventually destroying it, both of which begin with a gradual shortening of the poly-A tail by an exonuclease, a process that starts as soon as the mRNA reaches the cytosol. In a broad sense, this poly-A shortening acts as a timer that counts down the lifetime of each mRNA. Once the poly-A tail is reduced to a critical length (about 25 nucleotides in humans), the two destruction pathways converge. In one, the 5' cap is removed (a process called decapping), and the "exposed" mRNA is rapidly degraded from its 5' end. In the other, the mRNA continues to

Figure 7-72 Internal ribosome entry sites (IRESs) can promote translation initiation by a variety of mechanisms. (A) The normal cap-dependent mechanism requires eIF4G binding to the cap to begin assembly of the other translation components (see Figure 6-74). (B) The cap and eIF4E are bypassed by direct binding of eIF4G to a specific RNA structure formed by the IRES. (C) The small ribosome subunit binds directly to the IRES through base-pairing between sequences in the IRES and the I8S rRNA, positioning it to begin translation. (D) Specialized proteins bind to an IRES and then attract the small ribosome subunit.

MBOC7_ptr_ch07_397-474.indd 459 02/12/21 12:45 PM

be degraded from the 3' end, through the poly-A tail into the coding sequences (Figure 7-73).

Nearly all mRNAs are subject to both types of decay, which can occur simultaneously on the same mRNA molecule. Specific nucleotide sequences determine how fast each step occurs and therefore how long each mRNA will persist in the cell and be able to produce protein. The 3' UTR sequences are especially important in controlling mRNA lifetimes, and they often carry binding sites for specific proteins that increase or decrease the rates of poly-A shortening, decapping, or 3'-to-5' degradation. The half-life of an mRNA is also affected by how efficiently it is translated. Poly-A shortening and decapping compete directly with the machinery that translates the mRNA; therefore, any factors that increase the translation efficiency for an mRNA will tend to reduce its degradation.

Although poly-A shortening controls the half-life of most eukaryotic mRNAs, some mRNAs can be degraded by a specialized mechanism that bypasses this step altogether. In these cases, specific endonucleases cleave the mRNA internally, effectively decapping one end and removing the poly-A tail from the other, so that both halves are rapidly degraded. The mRNAs that are destroyed in this way carry specific nucleotide sequences—often in their 3' UTRs—that serve as recognition sequences for these endonucleases. This strategy makes it simple to tightly regulate the stability of these mRNAs by blocking or exposing the endonuclease site in response to extracellular signals. For example, the addition of iron to cells decreases the stability of the mRNA that encodes the receptor protein that binds the iron-transporting protein transferrin, causing less of this receptor to be made. This effect is mediated by the iron-sensitive RNA-binding protein aconitase. During iron starvation, aconitase binds the 3' UTR of the transferrin receptor mRNA and increases receptor production by blocking endonucleolytic cleavage of the mRNA (Figure 7–74A). On the addition of iron, aconitase is released from

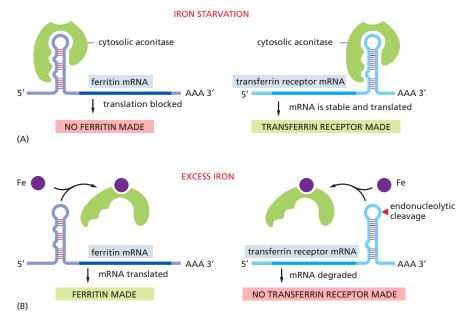

Figure 7–73 Two mechanisms of eukaryotic mRNA decay. Once a mature mRNA is exported to the cytosol, enzymes known as deadenylases gradually shorten its poly-A tail. When a critical threshold of poly-A tail length occurs, the two degradation mechanisms shown are triggered, probably by loss of the poly-A-binding proteins. Although 5'-to-3' and 3'-to-5' degradation are shown here on separate RNA molecules, these two processes can occur together on the same molecule. (Adapted from C.A. Beelman and R. Parker, *Cell* 81:179–183, 1995.)

Figure 7-74 Two post-translational controls mediated by iron. (A) During iron starvation, the binding of aconitase to the 5' UTR of the ferritin mRNA blocks translation initiation; its binding to the 3' UTR of the transferrin receptor mRNA blocks an endonuclease cleavage site and thereby stabilizes the mRNA. (B) In response to an increase in iron concentration in the cytosol, a cell increases its synthesis of ferritin in order to bind the extra iron and decreases its synthesis of transferrin receptors in order to import less iron across the plasma membrane. Both responses are mediated by the same iron-responsive regulatory protein, aconitase, which recognizes common features in a stem-loop structure in the mRNAs encoding ferritin and the transferrin receptor. Aconitase dissociates from the mRNA when it binds iron. But because the transferrin receptor and ferritin are regulated by different types of mechanisms, their levels respond oppositely to iron concentrations even though they are regulated by the same iron-responsive regulatory protein. (Adapted from M.W. Hentze et al., Science 238:1570-1573, 1987; and J.L. Casey et al., Science 240:924-928, 1988.)

MBOC7_ptr_ch07_397-474.indd 460 02/12/21 12:45 PM

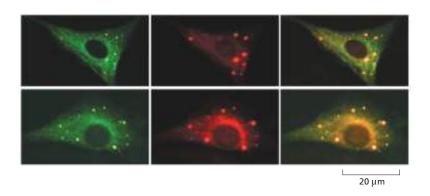

Figure 7–75 Visualization of P-bodies. Human cells were stained with antibodies to a component of the mRNA decapping enzyme Dcp1a (left panels) and to the Argonaute protein (middle panels). As described later in this chapter, Argonaute is a key component of RNA interference pathways and both it and the decapping enzyme destabilize mRNAs. The merged images (right panels) show that the two proteins co-localize to P-bodies in the cytoplasm. (Adapted from J. Liu et al., Nat. Cell Biol. 7:719–723, 2005. Reproduced with permission from SNCSC.)

the mRNA, exposing the cleavage site and thereby decreasing mRNA stability (Figure 7-74B).

Regulation of mRNA Stability Involves P-bodies and Stress Granules

We saw in Chapter 6 that large aggregates of RNA and protein can form membraneless compartments in the nucleus, such as nucleoli and Cajal bodies. The cytosol also contains such biomolecular condensates, and here we discuss two of them, *Processing* or *P-bodies* and *stress granules*, each of which has a role in handling mRNAs (Figure 7–75). When an mRNA in the cytosol is no longer actively translated, it often moves to P-bodies where several fates are possible. P-bodies are rich in mRNA-degrading enzymes, and mRNAs that have already undergone significant poly-A shortening can continue to be degraded within P-bodies. Alternatively, some intact mRNAs can be stored in P-bodies in a translationally repressed form. According to the needs of the cell, these mRNAs can then be moved back to the cytosol and "reactivated" to begin translation again (Figure 7–76). mRNAs stored in this way often code for proteins that the cell needs quickly, and this strategy bypasses the time-consuming steps of *de novo* mRNA production.

Stress granules are dynamic membraneless organelles that form when the cell undergoes a sudden block to translation, whether by starvation, small-molecule inhibitors, or genetic manipulation. These treatments allow ongoing translation to be completed but block new translation initiation. The resulting ribosome-free mRNAs accumulate in stress granules that grow in size as more and more mRNAs enter them. As the stressful conditions are relieved, the stress granules shrink along with the release of the stored mRNAs to the cytosol where they resume being translated. Clearly, once a cell has made the large investment in producing a properly processed mRNA molecule, it carefully controls its subsequent fate.

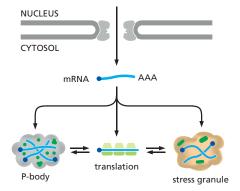

Figure 7–76 Possible fates of an intact mRNA molecule. An mRNA molecule released from the nucleus can be actively translated (center), stored in P-bodies (left), or, if the cell is stressed, moved into stress granules (right). As the needs of the cell change, stored mRNAs can be reactivated and returned to the cytosol to be translated into protein. Although not shown, all mRNA molecules are eventually degraded, and some of the final steps take place in P-bodies.

MBOC7_ptr_ch07_397-474.indd 461 02/12/21 12:45 PM

Summary

Many steps in the pathway from RNA to protein are regulated by cells in order to control gene expression. Most genes are regulated at multiple levels, in addition to being controlled at the initiation stage of transcription. The regulatory mechanisms include (1) attenuation of the RNA transcript by its premature termination, (2) alternative RNA splice-site selection, (3) control of 3'-end formation by cleavage and poly-A addition, (4) RNA covalent modifications including editing, (5) control of transport from the nucleus to the cytosol, (6) localization of mRNAs to particular parts of the cytoplasm, (7) control of translation initiation, and (8) regulated mRNA degradation. Most of these control processes require the recognition of specific sequences or structures in the RNA molecule being regulated, a task performed by either regulatory proteins or regulatory RNA molecules.

REGULATION OF GENE EXPRESSION BY NONCODING RNAs

In the previous chapter, we introduced the *central dogma*, according to which the flow of genetic information proceeds from DNA through RNA to protein (see Figure 6–1). But we have seen throughout this book that RNA molecules perform many critical tasks in the cell besides serving as intermediate carriers of genetic information. Among these noncoding RNAs are the rRNA and tRNA molecules, which are responsible for reading the genetic code and synthesizing proteins. The RNA molecule in telomerase serves as a template for the replication of chromosome ends, snoRNAs modify ribosomal RNA, and snRNAs direct RNA splicing. And earlier in this chapter we saw that Xist RNA has an important role in inactivating one copy of the X chromosome in female mammals. In this section, we introduce several additional classes of noncoding RNAs that have important roles in regulating gene expression and in protecting the genome from viruses and transposable elements. These RNAs also make possible powerful new experimental techniques in genome editing.

Small Noncoding RNA Transcripts Regulate Many Animal and Plant Genes Through RNA Interference

We begin our discussion with a group of short RNAs that carry out **RNA interference**, or **RNAi**. Here, short single-stranded RNAs (20–30 nucleotides) serve as guide RNAs that selectively bind—through complementary base-pairing—other RNAs in the cell. When the target is a mature mRNA, the small noncoding RNAs can inhibit its translation or catalyze its rapid destruction. If the target RNA molecule is in the process of being transcribed, the small noncoding RNA can bind to it and direct the formation of repressive chromatin on its attached DNA template to block further transcription (**Figure 7–77**).

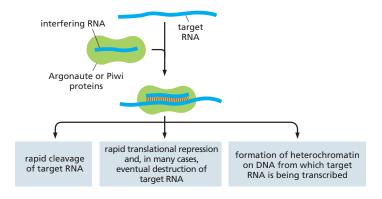

Figure 7–77 RNA interference in eukaryotes. Single-strand interfering RNAs locate target RNAs through complementary base-pairing, and, at this point, several fates are possible, as shown. As described in the text, there are several types of RNA interference; the way that interfering RNA is produced and the ultimate fate of the target RNA depend on the particular system.

MBOC7_ptr_ch07_397-474.indd 462 02/12/21 12:45 PM

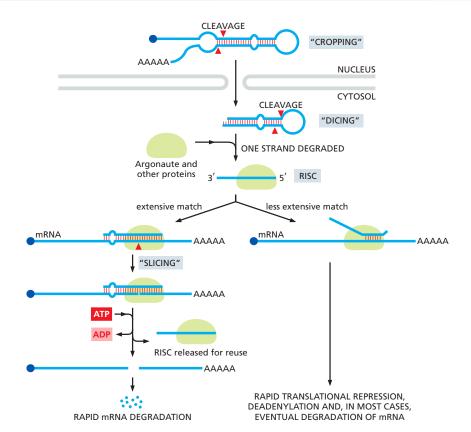

Figure 7-78 miRNA processing and mechanism of action. The precursor miRNA, through complementary basepairing between one part of its sequence and another, forms a double-strand structure. This RNA is "cropped" while still in the nucleus and then exported to the cytosol, where it is further cleaved ("diced") by the Dicer enzyme to form the miRNA proper, Argonaute, in conjunction with other components of RISC, initially associates with both strands of the miRNA and then cleaves and discards one of them. The other strand guides RISC to specific mRNAs through base-pairing. If the RNA-RNA match is extensive, as is commonly seen in plants, Argonaute cleaves the target mRNA ("slicing"), causing its rapid degradation. In mammals, the miRNA-mRNA match often does not extend beyond a short seven-nucleotide "seed" region near the 5' end of the miRNA. This less extensive base-pairing leads to a rapid inhibition of translation and, in most cases, eventual destruction of the

Three classes of small noncoding RNAs work in this way—*microRNAs* (*miRNAs*), *small interfering RNAs* (*siRNAs*), and *piwi-interacting RNAs* (*piRNAs*)— and we discuss them in turn in the next sections. Although they differ in both the way the short pieces of single-stranded RNA are generated and in their ultimate functions, all three types of RNAs locate their targets through RNA-RNA base-pairing, and they generally cause reductions in gene expression.

miRNAs Regulate mRNA Translation and Stability

More than 1000 different **microRNAs** (**miRNAs**) are produced from the human genome, and these appear to regulate at least one-half of all human protein-coding genes. Once made, miRNAs base-pair with specific mRNAs and fine-tune their translation and stability. The miRNA precursors are synthesized by RNA polymerase II and are capped and polyadenylated. They then undergo a special type of processing, after which the miRNA (typically 23 nucleotides in length) is assembled with a set of proteins to form an *RNA-induced silencing complex*, or *RISC*. Once formed, the RISC seeks out its target mRNAs by searching for complementary nucleotide sequences (**Figure 7–78**). This search is greatly facilitated by the Argonaute protein, a component of RISC, which holds the 5' region of the miRNA so that it is optimally positioned for base-pairing to another RNA molecule (**Figure 7–79**). In animals, the extent of base-pairing is typically at least seven nucleotide pairs, and this pairing most often occurs in the 3' UTR of the target mRNA.

Once an mRNA has been bound by an miRNA, several outcomes are possible. If the base-pairing is extensive (which is unusual in humans but common in many plants), the mRNA is cleaved (*sliced*) by the Argonaute protein, effectively removing the mRNA's poly-A tail and exposing it to exonucleases (see Figure 7–73). After cleavage of the mRNA, the RISC with its associated miRNA is released, and it can seek out additional mRNAs (see Figure 7–78). Thus, a single miRNA can act

MBOC7_ptr_ch07_397-474.indd 463 02/12/21 12:45 PM

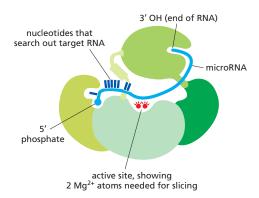

Figure 7–79 Human Argonaute protein carrying an miRNA. The protein is folded into four structural domains, each indicated by a different color. The miRNA is held in an extended form that is optimal for forming RNA–RNA base pairs. The active site of Argonaute that slices a target RNA, when it is extensively base-paired with the miRNA, is indicated in red. Many Argonaute proteins (three out of the four human proteins, for example) lack the catalytic site and therefore bind target RNAs without slicing them. (Adapted from C.D. Kuhn and L. Joshua-Tor, Trends Biochem. Sci. 38:263–271, 2013.)

catalytically to destroy many complementary mRNAs. These miRNAs can thus be thought of as guide sequences that repeatedly bring destructive nucleases into contact with specific mRNAs.

If the base-pairing between the miRNA and the mRNA is less extensive (as observed for most human miRNAs), Argonaute does not slice the mRNA; rather, translation of the mRNA is repressed by the recruitment of deadenylase enzymes—which shorten the poly-A tail—and other proteins that directly block access of the mRNA to the proteins needed to translate it. In many cases, the "blocked" mRNAs are shuttled to P-bodies (see Figure 7–76) where, sequestered from ribosomes, they are either degraded or, at a later time, released to the cytosol to be translated again.

Several features make miRNAs especially useful regulators of gene expression. First, a single miRNA can regulate a whole set of different mRNAs, so long as the mRNAs carry a short complementary sequence in their UTRs. This situation is common in humans, where a single miRNA can control hundreds of different mRNAs. Second, regulation by miRNAs can be combinatorial. As discussed earlier for transcription regulators, combinatorial control greatly expands the possibilities available to the cell by linking gene expression to a combination of different regulators rather than a single regulator. Like many transcription regulators, different miRNAs can bind cooperatively to their target mRNAs if their recognition sites are spaced appropriately. The basis for the cooperative binding is a scaffold protein that weakly holds two different RISCs together at a fixed spacing, thereby coupling their individual miRNA-mRNA binding energies. Third, an miRNA occupies relatively little space in the genome when compared with a protein. Indeed, their small size is one reason that miRNAs were discovered only recently. Although we are only beginning to appreciate the full impact of miRNAs, it is clear that they represent an important part of the cell's repertoire for regulating the expression of genes. We shall discuss specific examples of miRNAs with key roles in development in Chapter 21.

RNA Interference Also Serves as a Cell Defense Mechanism

Many of the proteins that participate in the miRNA regulatory mechanisms just described also serve a second function as a defense mechanism: they orchestrate the degradation of foreign RNA molecules, specifically those that occur in double-strand form. Many transposable elements and viruses produce double-stranded RNA at least transiently in their life cycles, and RNA interference helps to keep these potentially dangerous invaders in check. As we shall see, this form of RNAi also provides scientists with a powerful experimental technique to turn off the expression of individual genes.

The presence of double-stranded RNA in the cell triggers RNAi by attracting a protein complex containing *Dicer*, the same nuclease that processes miRNAs (see Figure 7–78). This protein cleaves the double-stranded RNA into small fragments (of approximately 23 nucleotide pairs) called **small interfering RNAs (siRNAs)**.

MBOC7_ptr_ch07_397-474.indd 464 02/12/21 12:45 PM

These double-stranded siRNAs are then bound by Argonaute and other components of RISC. As we saw earlier for miRNAs, one strand of the duplex RNA is then cleaved by Argonaute and discarded. The single-strand siRNA molecule that remains directs RISC back to complementary RNA molecules produced by the virus or transposable element. Because the match is usually exact, Argonaute also cleaves these molecules, leading to their rapid destruction.

Each time RISC cleaves a new RNA molecule, the RISC is released; thus, as we saw for miRNAs, a single RNA molecule can act catalytically to destroy many complementary RNAs. Some organisms employ an additional mechanism that amplifies the RNAi response even further. In these organisms, RNA-dependent RNA polymerases use siRNAs as primers to produce additional copies of double-stranded RNAs that are then cleaved into siRNAs. This amplification ensures that, once initiated, RNA interference can continue even after all the initiating double-stranded RNA has been degraded or diluted out. For example, it permits progeny cells to continue carrying out the specific RNA interference that was provoked in the parent cells.

In some organisms, the RNA interference activity can be spread by the transfer of RNA fragments from cell to cell. This is particularly important in plants (whose cells are linked by fine connecting channels, as discussed in Chapter 19), because it allows an entire plant to become resistant to an RNA virus after only a few of its cells have been infected. In a broad sense, the RNAi response resembles certain aspects of the animal immune system; in both, an invading organism elicits a customized response, and—through amplification of the "attack" molecules—the host becomes systemically protected.

We have seen that although miRNAs and siRNAs are generated in different ways, they rely on some of the same proteins and seek out their targets in a fundamentally similar manner. Because siRNAs are found in widespread species, they are believed to be the most ancient form of RNA interference, with miRNAs being a later evolutionary refinement. The siRNA-mediated defense mechanisms are especially crucial for plants, worms, and insects. In mammals, a protein-based immune system (described in Chapter 24) has largely taken over the task of fighting off viruses.

RNA Interference Can Direct Heterochromatin Formation

The siRNA interference pathway just described does not necessarily stop with the inactivation of target RNA molecules. In some cases, the RNA interference machinery can also selectively shut off the synthesis of the target RNAs. For this to occur, the short siRNAs produced by the Dicer protein are assembled with a group of proteins (including Argonaute) to form an RITS (RNA-induced transcriptional silencing) complex. Using single-stranded siRNA as a guide sequence, this complex binds complementary RNA transcripts as they emerge from a transcribing RNA polymerase II (Figure 7-80). Positioned on the genome in this way, the RITS complex then attracts enzymes that covalently modify nearby histones and DNA causing the formation of a "constitutive" form of heterochromatin. As described in Chapter 4, this form of heterochromatin is distinguished by the H3K9me3 mark, and, in many cases, it also includes DNA methylation (see Figure 7-48). Although low levels of transcription probably persist (and may be important to continually signal where the heterochromatin should be formed), this form of heterochromatin, as we have seen, is generally resistant to transcription and effectively shuts off the genes that lie within it. In some cases, an RNA-dependent RNA polymerase and a Dicer enzyme are also recruited by the RITS complex to continually generate additional siRNAs in situ. This positive feedback loop ensures continued repression of the target gene even after the original, initiating siRNA molecules have disappeared.

RNAi-directed heterochromatin formation is an especially important cell defense mechanism; it limits the spread of transposable elements in genomes by maintaining their DNA sequences in a transcriptionally silent form. However, this same mechanism is also used in some normal processes in the cell. For example,

MBOC7_ptr_ch07_397-474.indd 465 02/12/21 12:45 PM

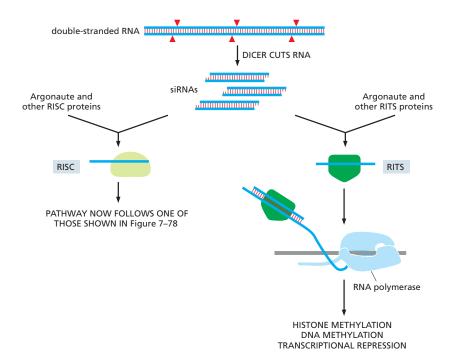

Figure 7–80 RNA interference directed by siRNAs. In many organisms, double-stranded RNA can trigger both the destruction of complementary mRNAs (left) and transcriptional silencing (right). The change in chromatin structure induced by the bound RITS (RNA-induced transcriptional silencing) complex resembles that of Figure 7–48.

in many organisms, the RNA interference machinery maintains the heterochromatin formed around centromeres. Centromeric DNA sequences are transcribed in both directions, producing complementary RNA transcripts that can base-pair to form double-stranded RNA. This double-stranded RNA triggers the RNA interference pathway and stimulates formation of the heterochromatin that surrounds centromeres, which is necessary for the centromeres to segregate chromosomes accurately during mitosis.

piRNAs Protect the Germ Line from Transposable Elements

A third system of RNA interference relies on piRNAs (piwi-interacting RNAs, named for Piwi, a class of proteins related to Argonaute). piRNAs are found in many organisms, and they carry out a diverse set of functions. Here, we describe one of their most important roles, which is to hold transposable elements (transposons) in check in the germ line of animals. The germ line is especially susceptible to transposon movement because many of the histone modifications and methylated DNA sites are "erased" during gametogenesis, temporarily releasing transposons from their normal constraints. piRNAs cover this vulnerability. Unlike miRNAs and siRNAs, they are synthesized from specialized piRNA "clusters" in the genome as long, single-strand RNA molecules that are then broken up and trimmed by specialized processing enzymes (different from the Dicer enzymes discussed earlier) into fragments that are slightly longer than miRNAs and siRNAs. These RNAs are covalently modified at their 3' ends by a 2'-O-methyl group (see Figure 6-43A) and assembled with Piwi proteins. Once complexed with their proteins, piRNAs seek out RNA targets by complementary base-pairing and, much like siRNAs, they both cleave the complementary RNAs and package the DNA on which they are being transcribed into repressive forms of chromatin. The piRNA clusters in the genome are rich with sequence fragments from transposons, and the piRNAs attack any transposon whose sequence is represented in the piRNA cluster. In this way, the genome contains a "hit list" of transposons that need to be inactivated during the vulnerable period of gametogenesis. It has been proposed that piRNA clusters are unusually attractive landing sites for transposons and, for this reason, they carry a record of all past bursts of transposon activity.

MBOC7_ptr_ch07_397-474.indd 466 02/12/21 12:45 PM

Although the genome carries a linear record of transposons to be inactivated, piRNAs have an additional way to attack those transposons that are most active during gametogenesis. In brief, once a piRNA and its associated proteins cleave a complementary, transposon-coded mRNA, additional piRNAs can be created from nearby sequences in the transposon mRNA. This mechanism not only amplifies the original response but extends its breadth by incorporating additional sequence information from active transposons, information that might not be carried in the piRNA clusters themselves.

Many mysteries surround piRNAs. More than a million piRNA species are coded in the genomes of many mammals and expressed in the testes, yet only a fraction seem to be directed against the transposons present in those genomes. Are the other piRNAs remnants of past invaders? Do they cover so much "sequence space" that they are broadly protective for any foreign DNA? Another curious feature of piRNAs is that many of them (particularly if base-pairing does not have to be perfect) should, in principle, attack the normal mRNAs made by the organism, yet they do not. It has been proposed that these large numbers of piRNAs may form a system to distinguish "self" RNAs from "foreign" RNAs and attack only the latter. If this is the case, there must be a special way for the cell to spare its own RNAs. One idea is that RNAs produced in the previous generation of an organism are somehow registered and set aside from piRNA attack in subsequent generations. Another idea holds that all legitimate mRNAs carry specialized sequences that spare them from attack. Whether or not this mechanism truly exists, and, if so, how it might work, are questions that demonstrate our incomplete understanding of the full range of RNA interference.

RNA Interference Has Become a Powerful Experimental Tool

Although it likely first arose in evolution as a defense mechanism against viruses and transposable elements, RNA interference, as we have seen, has become thoroughly integrated into many aspects of normal cell biology, ranging from the control of gene expression to a fine tuning of chromosome structure. RNA interference has also been developed by scientists into a powerful experimental tool that allows almost any gene to be inactivated by evoking an RNAi response to it. This technique, which can be readily carried out in cultured cells and, in many cases, whole animals and plants, has made possible new genetic approaches in cell and molecular biology. We shall discuss it in detail in the following chapter when we cover the modern genetic methods used to study cells (see pp. 533-534). RNAi also has potential in treating human disease. Because many human disorders result from the misexpression of genes, the ability to turn these genes off by experimentally introducing complementary siRNA molecules into cells holds great medical promise. Although delivery of RNA molecules to the appropriate tissue has been a persistent problem in using RNAi as a human therapy, the strategy is currently used to treat a rare disease called transthyretin amyloidosis. This inherited disease, which affects heart and nerve function, is caused by the accumulation of a mutated protein, and siRNAs directed by complementary base-pairing to the mutated mRNA relieve its symptoms. In this case, the siRNAs are delivered to the liver (the key site of synthesis of the mutated protein) by a special combination of lipids that forms tiny vesicles to encase the siRNA.

Cells Have Additional Mechanisms to Hold Transposons and Integrated Viral Genomes in Check

From the preceding sections, it should be clear that cells are locked in an eternal "arms race" with parasitic DNA elements, such as transposons and viruses. Indeed, it seems that our own genome came close to being overrun with such elements; even with our many defense mechanisms, they still make up nearly half our DNA (see Figure 4–63). Most of these elements have accumulated mutations

MBOC7_ptr_ch07_397-474.indd 467 02/12/21 12:45 PM

that prevent them from being active, but this process likely occurred after host-cell mechanisms came into play to hold them in check.

We have seen how siRNAs and piRNAs constitute surveillance systems to monitor transcription from transposable elements, to destroy their transcripts, and to package their DNA into repressive forms of chromatin. Although these overlapping defense mechanisms may seem highly effective, cells have at least one additional strategy for recognizing transposons and integrated viruses and silencing them. In contrast to the RNA-based strategies, which utilize complementary base-pairing to recognize these genome invaders, this additional system employs a special set of sequence-specific DNA-binding proteins to monitor the genome. When these proteins recognize a DNA sequence present in a transposon or integrated viral genome, they bind directly to that sequence and recruit both histone "writers" that place H3K9me3 marks on nearby histones and DNA methylases that heavily methylate the surrounding DNA. As discussed earlier in the chapter, this repressive form of chromatin can then spread and render the underlying DNA resistant to transcription and recombination (see Figure 7-48). Our genome codes for hundreds of different sequence-specific DNA proteins that carry out this surveillance (called KRAB-ZPF proteins), and they cover a wide variety of transposable element DNA and viral sequences. Most recognize a DNA sequence that is crucial for that element to transpose (or in the case of integrated viral genomes, for the virus to multiply), making it difficult for the element to escape through a mutation. However, such escape does apparently occur, because KRAB-ZPF proteins are evolving rapidly (compared with other human genes), and they appear to be "keeping up" with mutated versions of resident transposable elements. Their rapid evolution also suggests that the KRAB-ZPF proteins can easily adapt through mutation to attack new parasitic elements that might enter the genome.

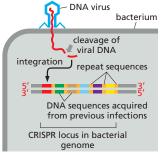

Transposable elements, if left unchecked, present many challenges to the cell: their sequences can serve as recombination sites leading to crossovers between nonhomologous chromosomes, double-strand DNA breaks are produced in the host genome when they move, and they can disrupt coding or regulatory sequences when they insert into a new position. On the other hand, their movement has provided a source of variation that is necessary for natural selection to occur. But the many different strategies host cells have evolved to neutralize these invaders suggest that the short-term dangers must far outweigh any long-term advantages.

Bacteria Use Small Noncoding RNAs to Protect Themselves from Viruses

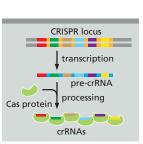

In the previous sections, we emphasized the defense systems of animals and plants, but it is important to keep in mind that bacteria and archaea make up the vast majority of Earth's diversity. Not surprisingly, the viruses that infect these single-cell organisms greatly outnumber plant and animal viruses. Many species of bacteria (and almost all species of archaea) use a repository of small noncoding RNA molecules to seek out and destroy invading viruses. Many features of this defense mechanism, known as CRISPR, resemble those of miRNAs, siRNAs, and piRNAs that we saw earlier. When bacteria and archaea are first infected by a virus, short fragments of that viral DNA become integrated into their genomes by a process that is only beginning to be understood. These serve as "vaccinations," in the sense that they become the templates for producing small noncoding RNAs known as crRNAs (CRISPR RNAs) that will thereafter destroy the virus should it reinfect the descendants of the original cell. This aspect of the CRISPR system resembles both human adaptive immunity and piRNA-based surveillance, insofar as the cell carries a record of past exposures that is used to protect against future exposures.

In most cases, crRNAs associate with special proteins that allow them to seek out and destroy invading viral genomes, which are typically composed of doublestranded DNA. Many distinct CRISPR systems exist across different species of

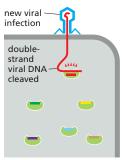

MBOC7_ptr_ch07_397-474.indd 468 02/12/21 12:45 PM

STEP 2: RNA is transcribed from CRISPR locus, processed, and bound to Cas protein

STEP 3: small crRNA in complex with Cas seeks out and destroys viral sequences

bacteria and archaea. Here we merely outline one of the most common and best understood, describing its three steps (Figure 7-81). In the first step, viral DNA sequences are integrated into special regions of the bacterial genome known as CRISPR (clustered regularly interspersed short palindromic repeat) loci, named for the peculiar DNA sequences that first drew the attention of scientists. In its simplest form, a CRISPR locus consists of several hundred repeats of a host DNA sequence interspersed with a large collection of DNA sequences (typically 25–70 nucleotide pairs each) derived from prior exposures to viruses and other foreign DNA. The newest viral sequence is always integrated at the 5' end of the CRISPR locus, the end that is transcribed first. Each locus, therefore, carries a temporal, ordered record of prior infections. Many bacterial and archaeal species carry several large CRISPR loci in their genomes and are thus immune to a wide range of viruses.

In the second step, the CRISPR locus is transcribed to produce a long RNA molecule, which is then processed into the much shorter (approximately 30 nucleotides) crRNAs. These crRNAs become complexed with *Cas* (*CRISPRassociated*) proteins, and, in the final step, they seek out complementary viral DNA sequences and direct their destruction by nucleases. Although structurally dissimilar, Cas proteins are analogous to the Argonaute and Piwi proteins discussed earlier: they hold small single-stranded RNAs in an extended configuration that is optimized, in this case, for seeking and forming complementary base pairs with double-stranded DNA.

We still have much to learn about CRISPR-based immunity in bacteria and archaea. For example, the mechanism through which viral sequences are first identified and integrated into the host genome is poorly understood. Moreover, in different species of bacteria and archaea, crRNAs are processed in different ways, and in some cases, the crRNAs can attack viral RNAs as well as DNAs. As might be predicted, many viruses have evolved anti-CRISPR systems to counteract the defense systems of their hosts. These anti-CRISPRs range from viral proteins that bind to and inactivate the Cas proteins to special coats that form around the viral DNA and protect it from CRISPR attack during replication, gene expression, and virus assembly.

In Chapter 8, we describe how bacterial CRISPR systems have been artificially "moved" into plants and animals, where they have revolutionized our ability to manipulate genomes.

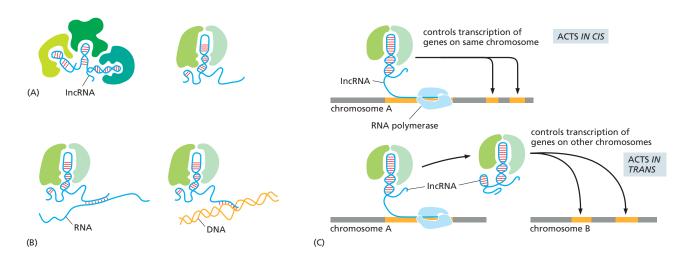

Long Noncoding RNAs Have Diverse Functions in the Cell

In this and the preceding chapters, we have seen that noncoding RNA molecules have many functions in the cell. Yet there remain many noncoding RNAs whose functions are still unknown. Many of these RNAs belong to a group known as **long noncoding RNA (lncRNA)**, arbitrarily defined as RNAs longer than 200 nucleotides that do not code for protein. The sheer number of lncRNAs (an estimated 5000 for the human genome, for example) came as a surprise to scientists. Most of these lncRNAs are transcribed by RNA polymerase II and have 5' caps and

Figure 7–81 CRISPR-mediated immunity in bacteria and archaea. After infection by a virus (*left panel*), a small bit of DNA from the viral genome is inserted into the CRISPR locus. For this to happen, a small fraction of infected cells must survive the initial viral infection. The surviving cells, or more generally their descendants, transcribe the CRISPR locus and process the transcript into crRNAs (*middle panel*). Upon reinfection with a virus that the population has already been "vaccinated" against, the incoming viral DNA is destroyed by a complementary crRNA (*right panel*).

For a CRISPR system to be effective, the crRNAs must not destroy the CRISPR locus itself, even though the crRNAs are complementary in sequence to it. How is this possible? In many species, there must be additional short nucleotide sequences carried by the target molecule in order for crRNAs to attack it. Because these sequences, known as PAMs (protospacer adjacent motifs), lie outside the crRNA sequences, the host CRISPR locus is spared (see Figure 8–57).

MBOC7_ptr_ch07_397-474.indd 469 02/12/21 12:45 PM

poly-A tails, and, in many cases, they are spliced. It has been difficult to accurately annotate lncRNAs, in part because low levels of RNA are now known to be made from about 75% of the human genome. Most of these RNAs are thought to result from a background "noise" of leaky transcription, and they are rapidly degraded. According to this idea, such nonfunctional RNAs provide no fitness advantage or disadvantage to the organism and are a tolerated by-product of the complex patterns of gene expression that need to be produced in multicellular organisms. For these reasons, it is difficult to estimate the number of lncRNAs that are likely to have a function in the cell and to distinguish them from the background of transcription noise.

In terms of biological function, lncRNA should be considered a catch-all phrase encompassing a great diversity of functions. We have already encountered a few notable lncRNAs, including the RNA in telomerase (see Figure 5-33), Xist RNA (see Figure 7-55), and an RNA involved in imprinting (see Figure 7-52). Other lncRNAs have been implicated in controlling the enzymatic activity of proteins, inactivating transcription regulators, affecting splicing patterns, and blocking translation of certain mRNAs through complementary base-pairing. However, there are three unifying features of lncRNAs that can account for their many roles in the cell. The first is that they can function as scaffold RNA molecules, holding together groups of proteins to coordinate their functions (Figure 7-82A; see also Figure 7-21). We have already seen examples in telomerase, the ribosome, and X-inactivation, where an RNA molecule holds together and organizes protein components. These RNA-based scaffolds are analogous to protein scaffolds we discussed in Chapter 3 (see Figure 3-76). RNA molecules are well suited to act as scaffolds: small bits of RNA sequence, often those portions that form stem-loop structures, can serve as binding sites for proteins, and these can be strung together with random sequences of RNA in between. This property may be one reason that many lncRNAs show relatively little primary-sequence conservation across species.

A second key feature of lncRNAs is their ability to serve as guide sequences, binding to specific RNA or DNA target molecules through base-pairing. By doing so, they bring proteins that are bound to them into close proximity with the DNA and RNA sequences (Figure 7–82B). This behavior is similar to that of snoRNAs (see Figure 6–43), miRNAs (see Figure 7–78), siRNAs (see Figure 7–80), and crRNAs (see Figure 7–81), all of which act in this way to guide protein enzymes to specific nucleic acid sequences. A third characteristic of RNA in general is its ability to organize biomolecular condensates, the non-membrane-bound assemblies of proteins and nucleic acids discussed in this and previous chapters. For example, rRNA is crucial for formation of the nucleolus, and untranslated mRNA provides the framework for P-bodies and stress granules. The propensity of RNA to form

Figure 7-82 Roles of long noncoding RNA (IncRNA). (A) As described in Chapter 6, RNAs can fold into short, specific three-dimensional structures whose specific features can be recognized by proteins. Thus, IncRNAs can serve as scaffolds, bringing together proteins that function together in the same process and thereby facilitating their interactions and speeding the reactions that they catalyze (B) IncRNAs can also, through formation of complementary base pairs, localize the proteins that they bind near specific nucleotide sequences on RNA or DNA molecules. (C) In some cases, IncRNAs act only in cis at their sites of synthesis—as, for example, when the RNA is held in place by the RNA polymerase that produced them (top). But as shown, other IncRNAs diffuse from their sites of synthesis and are said to act in trans.

MBOC7_ptr_ch07_397-474.indd 470 02/12/21 12:45 PM

condensates derives in part from its ability to bind multiple proteins, as discussed above, but also because many RNAs can form multiple weak intramolecular interactions that, on their own, can lead to condensation. Some lncRNAs are thought to function solely by organizing and driving formation of such condensates.

In some of the simplest cases, lncRNAs work simply by base-pairing, without bringing in enzymes or other proteins. For example, a number of lncRNA genes are embedded in protein-coding genes, but they are transcribed in the "wrong direction." These *antisense RNAs* can form complementary base pairs with the mRNA (transcribed in the "correct" direction) and block its translation into protein (see Figure 7–70D). Other antisense lncRNAs base-pair with pre-mRNAs as they are synthesized and change the pattern of RNA splicing by masking the preferred splice-site sequences. Still others act as "sponges," base-pairing with miRNAs and thereby reducing their effects.

Finally, we note that some lncRNAs act only *in cis*; that is, they affect only the chromosome from which they are transcribed. This readily occurs when the transcribed RNA has not yet been released from RNA polymerases (Figure 7–82C) or when the completed RNA molecule does not diffuse away from the chromosome as for the case of Xist (see Figure 7–55). Many lncRNAs, however, leave their site of synthesis and act *in trans*. Although the best-understood lncRNAs work in the nucleus, many are found in the cytosol. The functions—if any—of the great majority of these cytosolic lncRNAs remain undiscovered.

Summary

RNA molecules have many uses in the cell besides carrying the information needed to specify the order of amino acids during protein synthesis. Although we have encountered noncoding RNAs in other chapters (tRNAs, rRNAs, snoRNAs, for example), the sheer number of noncoding RNAs produced by cells has surprised scientists. One well-understood use of noncoding RNAs occurs in RNA interference, where guide RNAs (miRNAs, siRNAs, piRNAs) base-pair with mRNAs. RNA interference can cause mRNAs to be either destroyed or translationally repressed. It can also cause specific genes to become packaged into heterochromatin suppressing their transcription. In bacteria and archaea, RNA interference is used as an adaptive immune response to destroy viruses that infect them. A large family of large noncoding RNAs (lncRNAs) has recently been discovered through detailed genomic analyses. Although the function (if any) of most of these RNAs is unknown, some serve as RNA scaffolds to bring specific proteins and RNA molecules together to speed up needed reactions.

MBOC7_ptr_ch07_397-474.indd 471 02/12/21 12:45 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **7–1** When the nucleus of a fully differentiated carrot cell is injected into a frog egg whose nucleus has been removed, the injected donor nucleus is capable of programming the recipient egg to produce a normal carrot.
- **7–2** In terms of the way it interacts with DNA, the helix-loop-helix motif is more closely related to the leucine zipper motif than it is to the helix-turn-helix motif.
- **7–3** Many transcription regulators in eukaryotes can act even when they are bound to DNA thousands of nucleotide pairs away from the promoter they influence.
- **7–4** Once cells have differentiated to their final specialized forms, they never again alter expression of their genes.
- **7–5** CG islands are thought to have arisen during evolution because they were associated with portions of the genome that remained unmethylated in the germ line.
- **7–6** In one extreme case, a single gene in *Drosophila*—the *Dscam* gene—has the potential to produce more than 38,000 different proteins by alternative splicing; thus, the complexity of this one gene rivals the complexity of the whole human genome.
- **7–7** crRNAs in bacteria and piRNAs in animals serve analogous functions; they defend against foreign invaders.

Discuss the following problems.

- 7–8 Comparisons of the patterns of mRNA abundance across different human cell types show that the level of expression of almost every active gene is different. The patterns of mRNA abundance are so characteristic of cell type that they can be used to determine the tissue of origin of cancer cells, even though the cells may have metastasized to different parts of the body. By definition, however, cancer cells are different from their noncancerous precursor cells. How do you suppose then that patterns of mRNA expression might be used to determine the tissue source of a human cancer?
- **7–9** What are the two fundamental components of a genetic switch?
- **7–10** The nucleus of a eukaryotic cell is much larger than a bacterium, and it contains much more DNA. As a consequence, a transcription regulator in a eukaryotic cell must be able to select its specific binding site from among many more unrelated sequences than does a transcription regulator in a bacterium. Does this present any special problems for eukaryotic gene regulation?

Consider the following situation. Assume that the eukaryotic nucleus and the bacterial cell each have a single copy of the same DNA binding site. In addition,

- assume that the nucleus is 500 times the volume of the bacterium and has 500 times as much DNA. If the concentration of the transcription regulator that binds the site were the same in the nucleus and in the bacterium, would the regulator occupy its binding site equally as well in the eukaryotic nucleus as it does in the bacterium? Explain your answer.
- **7–11** The genes encoding the enzymes for arginine biosynthesis are located at several positions around the genome of *E. coli*. The ArgR transcription regulator coordinates their expression. The activity of ArgR is modulated by arginine. Upon binding arginine, ArgR dramatically changes its affinity for the *cis*-regulatory sequences in the promoters of the genes for the arginine biosynthetic enzymes. Given that ArgR is a transcription repressor, would you expect that ArgR would bind more tightly or less tightly to the regulatory sequences when arginine is abundant? If ArgR functioned instead as a transcription activator, would you expect the binding of arginine to increase or to decrease its affinity for its regulatory sequences? Explain your answers.
- **7–12** Some transcription regulators bind to DNA and cause the double helix to bend at a sharp angle. Such "bending proteins" can affect the initiation of transcription without directly contacting any other protein. Can you devise a plausible explanation for how such proteins might work to modulate transcription? Draw a diagram that illustrates your explanation.
- **7–13** How is it that protein–protein interactions that are too weak to cause proteins to assemble in solution can nevertheless allow the same proteins to assemble into complexes on DNA?
- **7–14** Imagine the two situations shown in **Figure Q7–1**. In cell 1, a transient signal induces the synthesis of protein A, which is a transcription activator that turns on many genes including its own. In cell 2,

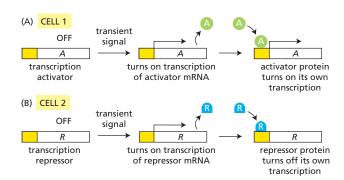

Figure Q7–1 Gene regulatory circuits and cell memory (Problem 7–14). (A) Induction of synthesis of transcription activator A by a transient signal. (B) Induction of synthesis of transcription repressor R by a transient signal.

MBOC7_ptr_ch07_397-474.indd 472 02/12/21 12:45 PM

PROBLEMS 473

a transient signal induces the synthesis of protein R, which is a transcription repressor that turns off many genes including its own. In which, if either, of these situations will the descendants of the original cell "remember" that the progenitor cell had experienced the transient signal? Explain your reasoning.

7–15 Examine the two pedigrees shown in Figure Q7–2. One results from deletion of a maternally imprinted autosomal gene. The other pedigree results from deletion of a paternally imprinted autosomal gene. In both pedigrees, affected individuals (*red symbols*) are heterozygous for the deletion. These individuals are affected because one copy of the chromosome carries an imprinted, inactive gene, while the other carries a deletion of the gene. *Dotted yellow symbols* indicate individuals that carry the deleted locus but do not display the mutant phenotype. Which pedigree is based on paternal imprinting and which on maternal imprinting? Explain your answer.

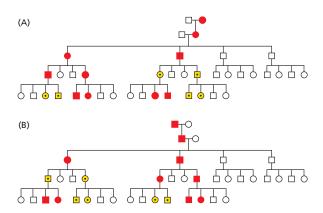

Figure Q7–2 Pedigrees reflecting maternal and paternal imprinting (Problem 7–15). In one pedigree, the gene is paternally imprinted; in the other, it is maternally imprinted. In generations 3 and 4, only one of the two parents in the indicated matings is shown; the other parent is a normal individual from outside this pedigree. Affected individuals are represented by red circles for females and red squares for males. Dotted yellow symbols indicate individuals that carry the deletion but do not display the phenotype.

7–16 To determine the role of the *Xist* gene in X-inactivation, scientists generated embryonic stem cells that carried one normal X chromosome and one mutant X chromosome with a nonfunctional *Xist* gene. Sequence differences allowed them to distinguish the two X chromosomes. What pattern of X-inactivation do you predict was observed in mice derived from these embryonic stem cells? Explain your reasoning.

- A. Only the normal X chromosomes were inactivated.
- B. Only the mutant X chromosomes were inactivated.
- C. None of the X chromosomes were inactivated.
- **D.** The X chromosomes were randomly inactivated.
- 7–17 The level of β -tubulin gene expression in cells is controlled by an unusual regulatory pathway, in which

the intracellular concentration of free tubulin dimers (composed of one α -tubulin and one β -tubulin subunit) regulates the rate of new β -tubulin synthesis at the level of β -tubulin mRNA stability. The first 12 nucleotides of the coding portion of the mRNA were found to contain the site responsible for this autoregulatory control. Because the critical segment of the mRNA involves a coding region, it was not clear whether the regulation of mRNA stability resulted from the interaction of tubulin dimers with the RNA or with the nascent protein. Either interaction might plausibly trigger a nuclease that would destroy the mRNA.

These two possibilities were tested by mutagenizing the regulatory region on a cloned version of the gene. The mutant genes were then expressed in cells, and the stability of their mRNAs was assayed in the presence of excess free tubulin dimers. The results from a dozen mutants that affect the regulatory region of the mRNA are shown in Figure Q7–3. Does the regulation of β -tubulin mRNA stability result from an interaction with the RNA or from an interaction with the encoded protein? Explain your reasoning. (The genetic code is inside the back cover of this book.)

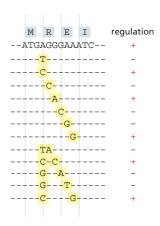

Figure Q7–3 Effects of mutations on the regulation of β-tubulin mRNA stability (Problem 7–17). The wild-type sequence for the first 12 nucleotides of the coding portion of the gene is shown at the top, and the first four amino acids beginning with methionine (M) are indicated above the codons. The nucleotide changes in the 12 mutants are shown below; only the altered nucleotides are indicated. Regulation of mRNA stability is shown on the right: + indicates wild-type response to changes in intracellular tubulin concentration, and – indicates no response to changes. Vertical lines mark the position of the first nucleotide in each codon.

7–18 If you insert a β -galactosidase gene lacking its own transcription control region into a cluster of piRNA genes in *Drosophila*, you find that β -galactosidase expression from a normal copy elsewhere in the genome is strongly inhibited in the fly's germ cells. If the inactive β -galactosidase gene is inserted outside the piRNA gene cluster, the normal gene is properly expressed. What do you suppose is the basis for this observation? How would you test your hypothesis?

WAYS OF WORKING WITH CELLS

Analyzing Cells, Molecules, and Systems

CHAPTER

8

Progress in science is often driven by advances in technology. The entire field of cell biology, for example, came into being when optical craftsmen learned to grind small lenses of sufficiently high quality to observe cells and their substructures. Innovations in lens grinding, rather than any conceptual or philosophical advance, allowed Hooke and van Leeuwenhoek to discover a previously unseen cellular world, where tiny creatures tumble and twirl in a droplet of water (Figure 8–1).

The twenty-first century is a particularly exciting time for biology. New methods for analyzing cells, proteins, DNA, and RNA are fueling an information explosion and allowing scientists to study cells and their macromolecules in previously unimagined ways. We now have access to the sequences of many billions of nucleotides, providing the complete molecular blueprints for hundreds of organisms—from microbes and mustard weeds to worms, flies, mice, dogs, chimpanzees, and humans. And powerful new techniques are helping us to decipher that information, allowing us not only to compile huge, detailed catalogs of genes and proteins but also to begin to unravel how these components work together to form functional cells and organisms. The long-range goal is nothing short of obtaining a complete understanding of what takes place inside a cell as it responds to its environment and interacts with its neighbors.

In this and the following chapter, we present some of the principal methods used to study cells and their molecular components. Chapter 9 describes the remarkable advances in microscopy that have helped fuel our understanding of the structure and function of cells. In this chapter, we first discuss the rapidly developing methods for analysis of the molecules and genes that drive cell behavior. We present the techniques used to determine protein structure, function, and interactions, and we discuss the breakthroughs in DNA technology that continue to revolutionize our understanding of cell function. We end the chapter with an overview of some of the mathematical approaches that are helping us understand the enormous complexity of cells. By considering cells as dynamic systems with many moving parts, mathematical approaches can reveal hidden insights into

how the many components of cells work together to produce the special qualities of life.

ISOLATING CELLS AND GROWING THEM IN CULTURE

As described in Chapter 1, numerous model organisms are used by researchers to unravel the molecular basis of cell biology. In the first section of this chapter, we concern ourselves with the organisms and cells best suited for biochemical studies of proteins in the cell. Typically, we gain access to these proteins by obtaining large numbers of cells and physically breaking them open. Unicellular organisms, such as bacteria and yeast, are easy to produce in large amounts in the laboratory and are rich sources of the proteins involved in fundamental cell processes. But a deep understanding of human proteins in specific cell types requires human cells, or at the very least cells from a mammal. Specific animal tissues can be a useful solution, but these tend to be composed of a heterogeneous mixture of cell types. To obtain as much information as possible about specific cell types in a tissue, biologists have developed ways of dissociating cells from tissues and separating them according to type. These manipulations result in a relatively homogeneous population of cells that can then be analyzed—either directly or after their number has been greatly increased by allowing the cells to proliferate in culture.

Cells Can Be Isolated from Tissues and Grown in Culture

Intact tissues provide the most realistic source of material, as they represent the actual cells found within the body. For some biochemical preparations, the protein of interest can be obtained in sufficient quantity without having to separate the tissue or organ into cell types. Examples include the preparation of histones from calf thymus, actin from rabbit muscle, or tubulin from cow brain. For the majority of proteins, however, tissues are not an ideal source and it is preferable to use specific cell types grown in culture. Cultured cells provide a more homogeneous population of cells from which to extract material, and they are also much more convenient to work with in the laboratory. Given appropriate surroundings, most animal cells can live, multiply, and even express differentiated properties in a culture dish. The cells can be watched continually under the microscope or analyzed biochemically, and the effects of adding or removing specific molecules, such as hormones or growth factors, can be systematically explored.

Experiments performed on cultured cells are sometimes said to be carried out *in vitro* (literally, "in glass") to contrast them with experiments using intact organisms, which are said to be carried out *in vivo* (literally, "in the living organism"). These terms can be confusing, however, because they are often used in a very different sense by biochemists. In the biochemistry lab, *in vitro* refers to reactions carried out in a test tube in the absence of living cells, whereas *in vivo* refers to any reaction taking place inside a living cell, even if that cell is growing in culture.

Tissue culture began in 1907 with an experiment designed to settle a controversy in neurobiology. The hypothesis under examination was known as the neuronal doctrine, which proposed that each nerve fiber is the outgrowth of a single nerve cell and not the product of the fusion of many cells. To test this contention, small pieces of spinal cord were placed in lymphatic fluid in a warm, moist chamber and observed at regular intervals under the microscope. After a day or so, individual nerve cells could be seen extending long, thin filaments (axons) into the clot. Thus, the neuronal doctrine received strong support, and the foundation was laid for the cell-culture revolution.

These original experiments on nerve fibers used cultures of small tissue fragments called explants. Today, cultures are more commonly made from suspensions of cells dissociated from tissues. The first step in isolating individual cells is to disrupt the extracellular matrix and cell-cell junctions that hold the cells together. For this purpose, a tissue sample is typically treated with proteolytic enzymes (such as trypsin and collagenase) to digest proteins in the extracellular

matrix and with agents (such as ethylenediaminetetraacetic acid, or EDTA) that bind, or chelate, the Ca^{2+} on which cell-cell adhesion depends. The tissue can then be teased apart into single cells by gentle agitation.

Unlike yeast, most tissue cells are not adapted to living suspended in fluid and require a solid surface on which to grow and divide. For cell cultures, this support is usually provided by the surface of a plastic culture dish. Cells vary in their requirements, however, and many do not proliferate or differentiate unless the culture dish is coated with materials that cells adhere to, such as polylysine or extracellular matrix components.

Cultures prepared directly from the tissues of an organism are called *primary cultures*. These can be made with or without an initial fractionation step to separate different cell types. In most cases, cells in primary cultures can be removed from the culture dish and recultured repeatedly in so-called secondary cultures; in this way, they can be repeatedly subcultured (*passaged*) for weeks or months. Such cells often display many of the differentiated properties appropriate to their origin (**Figure 8–2**): fibroblasts continue to secrete collagen; cells derived from embryonic skeletal muscle fuse to form muscle fibers that contract spontaneously in the culture dish; nerve cells extend axons that are electrically excitable and make synapses with other nerve cells; and epithelial cells form extensive sheets with many of the properties of an intact epithelium. Because these properties are maintained in culture, they are accessible to study in ways that are often not possible in intact tissues.

Embryonic stem cells are an important cell type isolated from the early mammalian embryo. As described in Chapter 22, these cells are *pluripotent*; that is, they have the potential to differentiate into any cell type in the body. When cultured in the presence of the appropriate extracellular signaling factors and nutrients, stem cells can be directed to differentiate into a wide range of specific cell types. Under some conditions, it is even possible to stimulate these cells to assemble into three-dimensional multicellular structures that are miniature versions of certain organs, such as the gut. These *organoids* provide a powerful tool for the analysis of tissue function (see Chapter 22).

Cell culture is not limited to animal cells. When a piece of plant tissue is cultured in a sterile medium containing nutrients and appropriate growth regulators, many of the cells are stimulated to proliferate indefinitely in a disorganized manner, producing a mass of relatively undifferentiated cells called a *callus*. If the nutrients and growth regulators are carefully manipulated, one can induce the formation of a shoot and then root apical meristems within the callus, and,

MBOC7_ptr_ch08_475-562.indd 477 02/12/21 12:42 PM

in many species, regenerate a whole new plant. Similar to animal cells, callus cultures can be dissociated into single cells, which will grow and divide as a suspension culture (see Figure 8-2D).

Eukaryotic Cell Lines Are a Widely Used Source of Homogeneous Cells

The cell cultures obtained by disrupting tissues tend to suffer from a problem—eventually the cells die. Most vertebrate cells stop dividing after a finite number of cell divisions in culture, a process called *replicative cell senescence* (discussed in Chapter 17). Normal human fibroblasts, for example, typically divide only 25–40 times in culture before they stop. In these cells, the limited proliferation capacity reflects a progressive shortening and uncapping of the cell's telomeres, the repetitive DNA sequences and associated proteins that cap the ends of each chromosome (discussed in Chapter 5). Human somatic cells in the body have turned off production of the enzyme, called *telomerase*, that normally maintains the telomeres, which is why their telomeres shorten with each cell division. Human fibroblasts can often be coaxed to proliferate indefinitely by providing them with the gene that encodes the catalytic subunit of telomerase; in this case, they can be propagated as an *immortalized* cell line.

Some human cells, however, cannot be immortalized by this trick. Although their telomeres remain long, they still stop dividing after a limited number of divisions because culture conditions cause excessive stimulation of cell proliferation, which activates a poorly understood protective mechanism that stops cell division—a process sometimes called *culture shock*. To immortalize these cells, one has to do more than introduce telomerase. One must also inactivate the protective mechanisms, which can be done by introducing certain cancer-promoting oncogenes (discussed in Chapter 20).

Unlike human cells, most rodent cells do not turn off production of telomerase, and therefore their telomeres do not shorten with each cell division. Therefore, if culture shock can be avoided, some rodent cell types will divide indefinitely in culture. In addition, rodent cells often undergo spontaneous genetic changes in culture that inactivate their protective mechanisms, thereby producing immortalized cell lines.

Cell lines can often be most easily generated from cancer cells, but these cultures—referred to as *transformed cell lines*—differ from those prepared from normal cells in several ways. Transformed cell lines often grow without attaching to a surface, for example, and they can proliferate to a much higher density in a culture dish. Similar properties can be induced experimentally in normal cells by transforming them with a tumor-inducing virus or chemical. The resulting transformed cell lines can usually cause tumors if injected into a susceptible animal.

Transformed and nontransformed cell lines are extremely useful in cell research as sources of very large numbers of cells of a uniform type, especially because they can be stored in liquid nitrogen at -196°C for an indefinite period and retain their viability when thawed. It is important to keep in mind, however, that cell lines nearly always differ in important ways from their normal progenitors in the tissues from which they were derived.

Some widely used cell lines are listed in **Table 8-1**. Different lines have different advantages; for example, the PtK epithelial cell lines derived from the rat kangaroo remain flat during mitosis (unlike many other cell types), allowing the mitotic apparatus to be readily observed in action.

Hybridoma Cell Lines Are Factories That Produce Monoclonal Antibodies

As we see in this chapter and throughout this book, antibodies are particularly useful tools for cell biology. Their great specificity allows precise detection of selected proteins among the many thousands that each cell typically produces.

TABLE 8–1 Some Commonly Used Cell Lines	
Cell line*	Cell type and origin
NIH-3T3	Fibroblast (mouse)
MDCK	Kidney epithelial cell (dog)
HeLa	Cervical epithelial cell (human)
PtK	Kidney epithelial cell (rat kangaroo)
L6	Myoblast (rat)
PC12	Chromaffin cell (rat)
COS	Kidney fibroblast (monkey)
HEK293	Kidney epithelial cell (human)
CHO	Ovary epithelial cell (Chinese hamster)
RPE	Retinal pigment epithelial cell (human)
Vero	Kidney epithelial cell (African green monkey)
Jurkat	White blood cell (human)
*Many of these cell lines were derived	

*Many of these cell lines were derived from tumors. All of them are capable of indefinite replication in culture and express at least some of the special characteristics of their cells of origin.

MBOC7_ptr_ch08_475-562.indd 478 02/12/21 12:42 PM

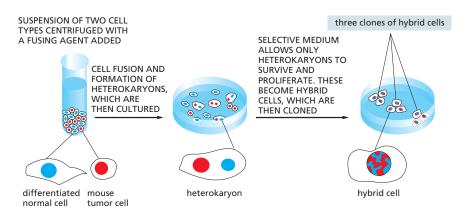

Figure 8–3 The production of hybrid cells. It is possible to fuse one cell with another to form a heterokaryon, a combined cell with two separate nuclei. Typically, a suspension of cells is treated with certain inactivated viruses or with polyethylene glycol, each of which alters the plasma membranes of cells in a way that induces them to fuse. Eventually, a heterokarvon proceeds to mitosis and produces a hybrid cell in which the two separate nuclear envelopes have been disassembled, allowing all the chromosomes to be brought together in a single large nucleus. Such hybrid cells can give rise to immortal hybrid cell lines. If one of the parent cells was from a tumor cell line, the hybrid cell is called a hybridoma.

Antibodies are often produced by inoculating animals with the protein of interest and subsequently isolating the antibodies specific to that protein from the serum of the animal. However, only limited quantities of antibodies can be obtained from a single inoculated animal, and the *polyclonal* antibodies produced will be a heterogeneous mixture of antibodies that recognize a variety of different antigenic sites on the protein. Moreover, antibodies specific for the antigen will constitute only a fraction of the antibodies found in the serum. An alternative technology, which allows the production of an unlimited quantity of identical antibodies and greatly increases the specificity and convenience of antibody-based methods, is the production of monoclonal antibodies by hybridoma cell lines.

This procedure involves propagating a clone of cells from a single antibody-secreting B lymphocyte to obtain a homogeneous preparation of antibodies in large quantities. B lymphocytes normally have a limited life span in culture, but individual antibody-producing B lymphocytes from an immunized mouse, when fused with cells derived from a transformed B lymphocyte cell line, can give rise to hybrids that have both the ability to make a particular antibody and the ability to multiply indefinitely in culture (Figure 8-3). These hybridomas are propagated as individual clones, each of which provides a permanent and stable source of a single type of monoclonal antibody. Each type of monoclonal antibody recognizes a single type of antigenic site; for example, a particular cluster of five or six amino acid side chains on the surface of a protein. Their uniform specificity makes monoclonal antibodies much more useful than conventional antisera for many purposes.

An important advantage of the hybridoma technique is that monoclonal antibodies can be made against molecules that constitute only a minor component of a complex mixture. In an ordinary antiserum made against such a mixture, the proportion of antibody molecules that recognize the minor component would be too small to be useful. But if the B lymphocytes that produce the various components of this antiserum are made into hybridomas, it becomes possible to screen individual hybridoma clones from the large mixture to select one that produces the desired type of monoclonal antibody and to propagate the selected hybridoma indefinitely so as to produce that antibody in unlimited quantities. In principle, therefore, a monoclonal antibody can be made against any protein in a biological sample. Once an antibody has been made, it can be used to localize the protein in cells and tissues, to follow its movement, and to purify the protein to study its structure and function.

Monoclonal antibodies are not just useful research tools but are valuable as treatments for a number of human diseases. Certain cancers, for example, can be treated by intravenous infusion of monoclonal antibodies that bind and inhibit signaling receptors on the cancer cell surface, thereby reducing proliferation of the tumor cells. In other cases, monoclonal antibodies that bind specific cell-surface immune regulators can promote immunological attack of cancer cells. Monoclonal antibodies that bind and inhibit specific immunestimulatory molecules provide useful therapies in autoimmune diseases such

MBOC7_ptr_ch08_475-562.indd 479 02/12/21 12:42 PM

as rheumatoid arthritis. Monoclonal antibodies against specific viral proteins can reduce infection. Given their exquisite specificity, it is likely that monoclonal antibodies will continue to be developed as effective therapies for these and other diseases.

Summary

Tissues can be dissociated into their component cells, from which individual cell types can be purified and used for biochemical analysis or for the establishment of cell cultures. Many animal and plant cells survive and proliferate in a culture dish if they are provided with a suitable culture medium containing nutrients and appropriate signal molecules. Although many animal cells stop dividing after a finite number of cell divisions, cells that have been immortalized through spontaneous mutations or genetic manipulation can be maintained indefinitely as cell lines. Hybridoma cells are widely employed to produce unlimited quantities of uniform monoclonal antibodies, which are used to detect and purify cell proteins, as well as to diagnose and treat diseases.

PURIFYING PROTEINS

The challenge of isolating a single type of protein from the thousands of other proteins in a cell is formidable but must be overcome to study protein function *in vitro*. As we shall see later in this chapter, *recombinant DNA technology* can enormously simplify this task by engineering cells to produce large quantities of a given protein, thereby making its purification much easier. Whether the source of the protein is an engineered cell or a natural tissue, a purification procedure usually starts with subcellular fractionation to reduce the complexity of the material and is then followed by purification steps of increasing specificity.

Cells Can Be Separated into Their Component Fractions

To purify a protein, it must first be extracted from inside the cell. Cells can be broken up in various ways: they can be subjected to osmotic shock or ultrasonic vibration, forced through a small orifice, or ground up in a blender. These procedures break many of the membranes of the cell (including the plasma membrane and endoplasmic reticulum) into fragments that immediately reseal to form small closed vesicles. If carefully carried out, however, the disruption procedures leave organelles such as nuclei, mitochondria, the Golgi apparatus, lysosomes, and peroxisomes largely intact. The suspension of cells is thereby reduced to a thick slurry (called a *homogenate* or *extract*) that contains a variety of membrane-enclosed organelles, each with a distinctive size and density. Provided that the homogenization medium has been carefully chosen (by trial and error for each organelle), the various components—including the vesicles derived from the endoplasmic reticulum, called microsomes—retain most of their original biochemical properties.

The different components of the homogenate must then be separated. Such cell fractionations became possible only after the commercial development in the early 1940s of an instrument known as the *preparative ultracentrifuge*, which rotates extracts of broken cells at high speeds (Figure 8–4). This treatment separates cell components by size and density: in general, the largest objects experience the largest centrifugal force and move the most rapidly. At relatively low speed, large components such as nuclei sediment to form a pellet at the bottom of the centrifuge tube; at slightly higher speed, a pellet of mitochondria is deposited; and at even higher speeds and with longer periods of centrifugation, first vesicles and then ribosomes can be collected (Figure 8–5). All of these fractions are impure, but many of the contaminants can be removed by resuspending the pellet and repeating the centrifugation procedure several times.

Centrifugation is the first step in most fractionations, but it separates only components that differ greatly in size. A finer degree of separation can be achieved by

MBOC7_ptr_ch08_475-562.indd 480 02/12/21 12:42 PM

PURIFYING PROTEINS 481

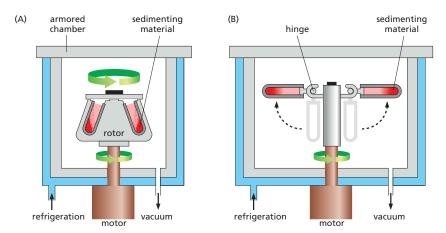

Figure 8–4 The preparative ultracentrifuge. (A) The sample is contained in tubes that are inserted into a ring of angled cylindrical holes in a metal *rotor*. Rapid rotation of the rotor generates enormous centrifugal forces, which cause particles in the sample to sediment against the bottom sides of the sample tubes, as shown here. The vacuum reduces friction, preventing heating of the rotor and allowing the refrigeration system to maintain the sample at 4°C. (B) Some fractionation methods require a different type of rotor called a *swinging-bucket rotor*. In this case, the sample tubes are placed in metal tubes on hinges that allow the tubes to swing outward when the rotor spins. Sample tubes are therefore horizontal during spinning, and samples are sedimented toward the bottom, not the sides, of the tube, providing better separation of differently sized components (see Figures 8–5 and 8–6).

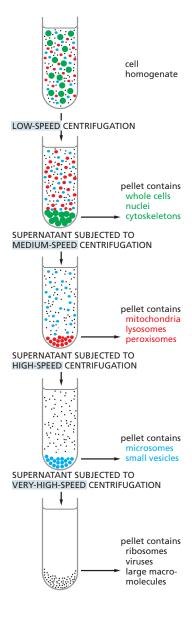

layering the homogenate in a thin band on top of a salt solution that fills a centrifuge tube. When centrifuged, the various components in the mixture move as a series of distinct bands through the solution, each at a different rate, in a process called *velocity sedimentation* (Figure 8-6A). For the procedure to work effectively, the bands must be protected from convective mixing, which would normally occur whenever a denser solution (for example, one containing organelles) finds itself on top of a lighter one (the salt solution). This is achieved by augmenting the solution in the tube with a shallow gradient of sucrose prepared by a special mixing device. The resulting density gradient—with the dense end at the bottom of the tube—keeps each region of the solution denser than any solution above it, and it thereby prevents convective mixing from distorting the separation.

When sedimented through sucrose gradients, different cell components separate into distinct bands that can be collected individually. The relative rate at which each component sediments depends primarily on its size and shape—normally being described in terms of its sedimentation coefficient, or S value. Present-day ultracentrifuges rotate at speeds of up to 80,000 rpm and produce forces as high as 500,000 times gravity. These enormous forces drive even small macromolecules, such as tRNA molecules and simple enzymes, to sediment at an appreciable rate and allow them to be separated from one another by size.

The ultracentrifuge is also used to separate cell components on the basis of their buoyant density, independently of their size and shape. In this case, the sample is sedimented through a steep density gradient that contains a very high concentration of sucrose or cesium chloride. Each cell component begins to move down the gradient as in Figure 8–6A, but it eventually reaches a position where the density of the solution is equal to its own density. At this point, the component

Figure 8–5 Cell fractionation by centrifugation. Repeated centrifugation at progressively higher speeds will fractionate homogenates of cells into their components. In general, the smaller the subcellular component, the greater the centrifugal force required to sediment it. Typical values for the various centrifugation steps referred to in the figure are:

low speed: 1000 times gravity for 10 minutes medium speed: 20,000 times gravity for 20 minutes high speed: 80,000 times gravity for 1 hour very high speed: 150,000 times gravity for 3 hours

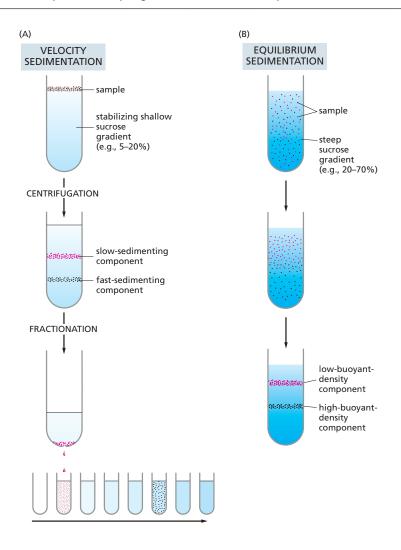

Figure 8-6 Comparison of velocity sedimentation and equilibrium sedimentation. (A) In velocity sedimentation, subcellular components sediment at different speeds according to their size and shape when layered over a solution containing sucrose. To stabilize the sedimenting bands against convective mixing caused by small differences in temperature or solute concentration, the tube contains a continuous shallow gradient of sucrose, which increases in concentration toward the bottom of the tube (typically from 5 to 20% sucrose). After centrifugation, the different components can be collected individually. most simply by puncturing the plastic centrifuge tube with a needle and collecting drops from the bottom, as illustrated here. (B) In equilibrium sedimentation, subcellular components move up or down when centrifuged in a gradient until they reach a position where their density matches that of their surroundings. Although a sucrose gradient is shown here, denser gradients, which are especially useful for protein and nucleic acid separation, can be formed from cesium chloride. The final bands, at equilibrium, can be collected as in A.

floats and can move no farther. A series of distinct bands is thereby produced in the centrifuge tube, with the bands closest to the bottom of the tube containing the components of highest buoyant density (**Figure 8–6B**). This method, called *equilibrium sedimentation*, is so sensitive that it can separate macromolecules that have incorporated heavy isotopes, such as ¹³C or ¹⁵N, from the same macromolecules that contain the lighter, common isotopes (¹²C or ¹⁴N). In fact, the cesium-chloride method was developed in 1957 to separate the labeled from the unlabeled DNA produced after exposure of a growing population of bacteria to nucleotide precursors containing ¹⁵N; this classic experiment provided direct evidence for the semiconservative replication of DNA (see Figure 5–5).

Cell Extracts Provide Accessible Systems to Study Cell Functions

Studies of organelles and other large subcellular components isolated in the ultracentrifuge have contributed enormously to our understanding of the functions of different cell components. Experiments on mitochondria and chloroplasts purified by centrifugation, for example, demonstrated the central function of these organelles in converting energy into forms that the cell can use. Similarly, resealed vesicles formed from fragments of rough and smooth endoplasmic reticulum (microsomes) have been separated from each other and analyzed as functional models of these compartments of the intact cell.

Similarly, highly concentrated cell extracts, especially undiluted cytoplasm from *Xenopus laevis* (African clawed frog) oocytes and fertilized eggs, have played

MBOC7_ptr_ch08_475-562.indd 482 02/12/21 12:42 PM

PURIFYING PROTEINS 483

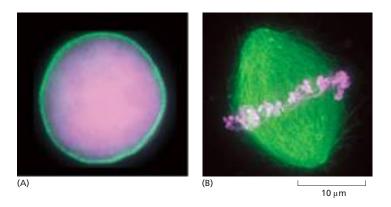

Figure 8-7 The formation of subcellular structures in a cytoplasmic extract. Concentrated cytoplasm was prepared from unfertilized eggs of the frog Xenopus laevis. After addition of Xenopus sperm chromosomes, these extracts were stimulated to progress through the cell cycle. (A) In an interphase extract, a nuclear envelope (green) forms around the sperm chromosomes (pink). (B) In a metaphase extract, the nuclear envelope breaks down and the microtubules (green) form a mitotic spindle that is attached to the condensed chromosomes (pink). [B, T. Maresca et al., J Cell Biol. 169(6):859-69, 2005, doi 10.1083/jcb.200503031. With permission from Rockefeller University Press.]

a critical role in the study of such complex and highly organized processes as the cell-division cycle, the assembly and function of the mitotic spindle (Figure 8–7), and the vesicular-transport steps involved in the movement of proteins through the secretory pathway.

Cell extracts also provide, in principle, the starting material for the complete separation of all of the individual macromolecular components of the cell. We now consider how this separation is achieved, focusing on proteins.

Proteins Can Be Separated by Chromatography

Proteins are most often fractionated by **column chromatography**, in which a mixture of proteins in solution is passed through a column containing a porous gel matrix. Different proteins are retarded to different extents by their interaction with the matrix, and they can be collected separately as they flow out of the bottom of the column (**Figure 8–8**). Depending on the choice of matrix, proteins can be separated according to their charge (*ion-exchange chromatography*), their hydrophobicity (*hydrophobic chromatography*), their size (*gel-filtration*)

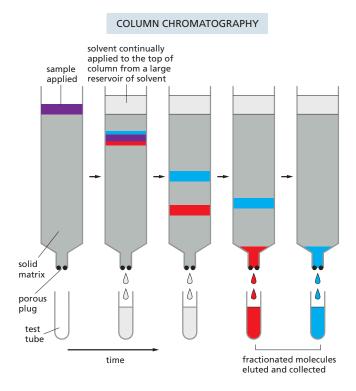

Figure 8–8 The separation of molecules by column chromatography. The sample, a solution containing a mixture of different molecules, is applied to the top of a cylindrical glass or plastic column filled with a permeable gel matrix, such as cellulose. A large amount of solvent is then passed slowly through the column and collected in separate tubes as it emerges from the bottom. Because various components of the sample travel at different rates through the column, they are fractionated into different tubes.

MBOC7_ptr_ch08_475-562.indd 483 02/12/21 12:42 PM

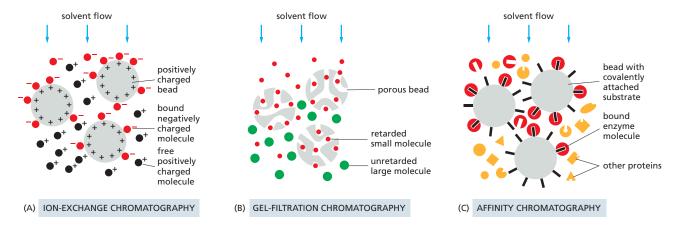

Figure 8-9 Three types of matrices used for chromatography. (A) In ion-exchange chromatography, the insoluble matrix carries ionic charges that retard the movement of molecules of opposite charge. Matrices used for separating proteins include diethylaminoethylcellulose (DEAE-cellulose), which is positively charged, and carboxymethylcellulose (CM-cellulose) and phosphocellulose, which are negatively charged. Analogous matrices based on agarose or other polymers are also frequently used. The strength of the association between the dissolved molecules and the ion-exchange matrix depends on both the ionic strength and the pH of the solution that is passing down the column, which may therefore be varied systematically (as in Figure 8-10) to achieve an effective separation. (B) In gel-filtration chromatography, the small beads that form the matrix are inert but porous. Molecules that are small enough to penetrate into the matrix beads are thereby delayed and travel more slowly through the column than do larger molecules that cannot penetrate. Beads of cross-linked polysaccharide (dextran, agarose, or acrylamide) are available commercially in a wide range of pore sizes, making them suitable for the fractionation of molecules of various masses, from less than 500 daltons to more than 5 × 106 daltons. (C) Affinity chromatography uses an insoluble matrix that is covalently linked to a specific ligand, such as an antibody molecule or an enzyme substrate, that will bind a specific protein. Enzyme molecules that bind to immobilized substrates on such columns can be eluted with a concentrated solution of the free form of the substrate molecule, while molecules that bind to immobilized antibodies can be eluted by dissociating the antibody-antigen complex with concentrated salt solutions or solutions of high or low pH. High degrees of purification can be achieved in a single pass through an affinity column.

chromatography), or their ability to bind to particular small molecules or to other macromolecules (*affinity chromatography*).

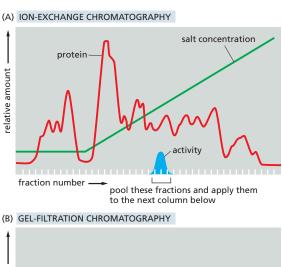

Many types of matrices are available. Ion-exchange columns (Figure 8–9A) are packed with small beads that carry either a positive or a negative charge, so that proteins are fractionated according to the arrangement of charges on their surface. Hydrophobic columns are packed with beads from which hydrophobic side chains protrude, selectively retarding proteins with exposed hydrophobic regions. Gel-filtration columns (Figure 8–9B), which separate proteins according to their size, are packed with tiny porous beads: molecules that are small enough to enter the pores linger inside successive beads as they pass down the column, while larger molecules remain in the solution flowing between the beads and therefore move more rapidly, emerging from the column first. Besides providing a means of separating molecules, gel-filtration chromatography is a convenient way to estimate their size.

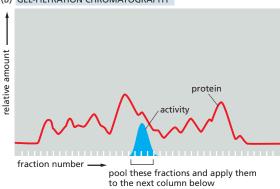

Affinity chromatography (Figure 8–9C) takes advantage of the biologically important binding interactions that occur on protein surfaces. If a substrate molecule is covalently coupled to an inert matrix such as a polysaccharide bead, the enzyme that operates on that substrate will often be specifically retained by the matrix and can then be eluted (washed out) in nearly pure form. Likewise, short DNA oligonucleotides of a specifically designed sequence can be immobilized in this way and used to purify DNA-binding proteins that normally recognize this sequence of nucleotides in chromosomes. Alternatively, specific antibodies can be coupled to a matrix to purify protein molecules recognized by the antibodies (called *immunoaffinity chromatography*). Because of the great specificity of all such affinity columns, 1000- to 10,000-fold purifications can sometimes be achieved in a single pass.

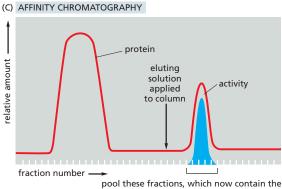

If one starts with a complex mixture of proteins, a single passage through an ion-exchange or a gel-filtration column does not produce very highly purified

MBOC7_ptr_ch08_475-562.indd 484 02/12/21 12:42 PM

PURIFYING PROTEINS 485

pool these fractions, which now contain the highly purified protein

fractions, because these methods individually increase the proportion of a given protein in the mixture no more than twentyfold. Because most individual proteins represent less than 1/1000 of the total cell protein, it is usually necessary to use several different types of columns in succession to attain sufficient purity, with affinity chromatography being the most efficient (Figure 8–10).

Imperfections in the matrices (such as cellulose), which cause an uneven flow of solvent through the column, limit the resolution of conventional column chromatography. Special chromatography resins (usually silica-based) composed of tiny spheres (3–10 μm in diameter) can be packed with a special apparatus to form a uniform column bed. Such **high-performance liquid chromatography (HPLC)** columns attain a high degree of resolution. In HPLC, the solutes are passed through the column at high pressure and equilibrate very rapidly with the interior of the tiny spheres, and so solutes with different affinities for the matrix are efficiently separated from one another even at very fast flow rates. HPLC is therefore the method of choice for separating many proteins and small molecules.

Figure 8-10 Protein purification by chromatography. Typical results obtained when three different chromatographic steps are used in succession to purify a protein. In this example, a homogenate of cells was first fractionated by allowing it to percolate through an ion-exchange resin packed into a column (A). The column was washed to remove all unbound contaminants, and the bound proteins were then eluted by pouring a solution containing a gradually increasing concentration of salt onto the top of the column. Proteins with the lowest affinity for the ion-exchange resin passed directly through the column and were collected in the earliest fractions eluted from the bottom of the column. The remaining proteins were eluted in sequence according to their affinity for the resin-those proteins binding most tightly to the resin requiring the highest concentration of salt to remove them. The protein of interest was eluted in several fractions and was detected by its enzymatic activity. The fractions with activity were pooled and then applied to a gel-filtration column (B). The elution position of the still-impure protein was again determined by its enzymatic activity, and the active fractions were pooled and purified to homogeneity on an affinity column (C) that contained an immobilized substrate of the enzyme.

MBOC7_ptr_ch08_475-562.indd 485 02/12/21 12:42 PM

Immunoprecipitation Is a Rapid Affinity Purification Method

Immunoprecipitation is a useful variation on the theme of affinity chromatography. Specific antibodies that recognize the protein to be purified are attached to small agarose beads. Rather than being packed into a column, as in affinity chromatography, a small quantity of the antibody-coated beads is simply added to a protein extract in a test tube and mixed in suspension for a short period of time—thereby allowing the antibodies to bind the desired protein. The beads are then collected by low-speed centrifugation, and the unbound proteins in the supernatant are discarded. This method is commonly used to purify small amounts of enzymes from cell extracts for analysis of enzymatic activity or for identification of associated proteins. As we describe later in this chapter, immunoprecipitation also provides a method to identify DNA or RNA sequences recognized by specific proteins.

Genetically Engineered Tags Provide an Easy Way to Purify Proteins

Using the recombinant DNA methods discussed later in this chapter, any gene can be modified to produce its protein with an extra amino acid sequence that provides a specific recognition tag, so as to make subsequent purification of the protein simple and rapid. Often the recognition tag is an antigenic determinant, or *epitope*, which can be recognized by a highly specific monoclonal antibody. The antibody can then be used to purify the protein by affinity chromatography or immunoprecipitation (Figure 8–11). Other types of tags are specifically designed for protein purification. For example, a repeated sequence of the amino acid histidine binds to certain metal ions, including nickel and copper. If genetic-engineering techniques are used to attach a short string of histidines to one end of a protein, the slightly modified protein can be retained selectively on an affinity column containing immobilized nickel ions. Metal affinity chromatography can thereby be used to purify the modified protein from a complex molecular mixture.

In other cases, an entire protein is used as the recognition tag. When cells are engineered to synthesize the small enzyme glutathione *S*-transferase (GST) attached to a protein of interest, the resulting **fusion protein** can be purified from the other contents of the cell with an affinity column containing glutathione, a substrate molecule that binds specifically and tightly to GST.

As a further refinement of purification methods using recognition tags, an amino acid sequence that forms a cleavage site for a highly specific proteolytic enzyme can be engineered between the protein of choice and the recognition tag. Because the amino acid sequences at the cleavage site are very rarely found by chance in proteins, the tag can later be cleaved off without destroying the purified protein.

This type of specific cleavage is used in an especially powerful purification methodology known as *tandem affinity purification tagging* (*TAP-tagging*). Here, one end of a protein is engineered to contain two recognition tags that are separated by a protease cleavage site. The tag on the very end of the construct is chosen to bind irreversibly to an affinity column, allowing the column to be washed extensively to remove all contaminating proteins. Protease cleavage then releases the protein, which is then further purified using the second tag. Because this two-step strategy provides an especially high degree of protein purification with relatively little effort, it is used extensively in cell biology.

Purified Cell-free Systems Are Required for the Precise Dissection of Molecular Functions

Purified cell-free systems provide a means of studying biological processes free from all of the complex side reactions that occur in a living cell. To make this possible, cell homogenates are fractionated with the aim of purifying each of the

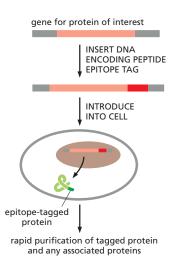

Figure 8–11 Epitope tagging for the purification of proteins. Using standard genetic-engineering techniques, a short amino acid sequence can be added to a protein of interest. If the tag is an antigenic determinant, or epitope, it can be targeted by an appropriate antibody, which can be used to purify the protein by immunoprecipitation or affinity chromatography.

MBOC7_ptr_ch08_475-562.indd 486 02/12/21 12:42 PM

ANALYZING PROTEINS 487

individual macromolecules that are needed to catalyze a biological process of interest. For example, the experiments to decipher the mechanisms of protein synthesis began with a cell homogenate that could translate RNA molecules to produce proteins. Fractionation of this homogenate, step by step, produced in turn the ribosomes, tRNAs, and various enzymes that together constitute the protein-synthetic machinery. Once individual pure components were available, each could be added or withheld separately to define its exact role in the overall process.

A major goal for cell biologists is the reconstitution of every biological process in a purified cell-free system. Only in this way can we define all of the components needed for the process and control their concentrations, which is required to work out their precise mechanism of action. Although much remains to be done, a great deal of what we know today about the molecular biology of the cell has been discovered by studies in such cell-free systems. They have been used, for example, to decipher the molecular details of DNA replication and DNA transcription, RNA splicing, protein translation, muscle contraction, particle transport along microtubules, and many other processes that occur in cells.

Summary

Populations of cells can be analyzed biochemically by disrupting them and fractionating their contents, allowing functional cell-free systems to be developed. Highly purified cell-free systems are needed for determining the molecular details of complex cell processes, and the development of such systems requires extensive purification of all the proteins and other components involved. The proteins in soluble cell extracts can be purified by column chromatography; depending on the type of column matrix, biologically active proteins can be separated on the basis of their molecular weight, hydrophobicity, charge characteristics, or affinity for other molecules. In a typical purification, the sample is passed through several different columns in turn, with the enriched fractions obtained from one column being applied to the next. Recombinant DNA techniques (described later) allow special recognition tags to be attached to proteins, thereby greatly simplifying their purification.

ANALYZING PROTEINS

Proteins perform most cellular processes: they catalyze metabolic reactions, use nucleotide hydrolysis to do mechanical work, and serve as the major structural elements of the cell. The great variety of protein structures and functions has stimulated the development of a multitude of techniques to study them.

Proteins Can Be Separated by SDS Polyacrylamide-Gel Electrophoresis

Proteins usually possess a net positive or negative charge, depending on the mixture of charged amino acids they contain. An electric field applied to a solution containing a protein molecule causes the protein to migrate at a rate that depends on its net charge and on its size and shape. The most useful application of this property is **sodium dodecyl sulfate polyacrylamide-gel electrophore-sis (SDS-PAGE)**. It uses a highly cross-linked gel of polyacrylamide as the inert matrix through which the proteins migrate. The gel is prepared by polymerization of monomers; the pore size of the gel can be adjusted so that it is small enough to retard the migration of the protein molecules of interest. The proteins are dissolved in a solution that includes a powerful negatively charged detergent, sodium dodecyl sulfate, or SDS (**Figure 8–12**). Because this detergent binds to hydrophobic regions of the protein molecules, causing them to unfold into extended polypeptide chains, the individual protein molecules are released from their associations with other proteins or lipid molecules and rendered freely soluble in the detergent solution. In addition, a reducing agent such as β -mercaptoethanol

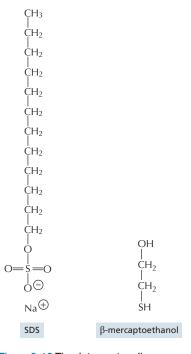

Figure 8–12 The detergent sodium dodecyl sulfate (SDS) and the reducing agent β -mercaptoethanol. These two chemicals are used to solubilize proteins for SDS polyacrylamide-gel electrophoresis. The SDS is shown here in its ionized form.

MBOC7_ptr_ch08_475-562.indd 487 02/12/21 12:42 PM

(see Figure 8-12) is usually added to break any disulfide linkages in the proteins, so that all of the constituent polypeptides in multisubunit proteins can be analyzed separately.

What happens when a mixture of SDS-solubilized proteins is run through a slab of polyacrylamide gel? Each protein molecule binds large numbers of the negatively charged detergent molecules, which mask the protein's intrinsic charge and cause it to migrate toward the positive electrode when a voltage is applied. Proteins of the same size tend to move through the gel with similar speeds because (1) their native structure is completely unfolded by the SDS, so that their shapes are the same, and (2) they bind the same amount of SDS and therefore have the same amount of negative charge. Larger proteins, with more charge, are subjected to larger electrical forces but also to a larger drag. In free solution, the two effects would cancel out, but, in the mesh of the polyacrylamide gel, which acts as a molecular sieve, large proteins are retarded much more than small ones. As a result, a complex mixture of proteins is fractionated into a series of discrete protein bands mostly according to their mass (Figure 8-13). The major proteins are readily detected by staining the proteins in the gel with a dye such as Coomassie blue. When small amounts of protein are present and more sensitive methods are required, gels can be treated with a silver stain, which will detect as little as 10 ng of protein in a band. For some purposes, specific proteins can also be labeled with a radioactive isotope tag; exposure of the gel to film or a radiation detector results in an autoradiograph on which the labeled proteins are visible (see Figure 8-16).

SDS-PAGE is widely used because it can separate all types of proteins, including those that are normally insoluble in water—such as the many proteins in

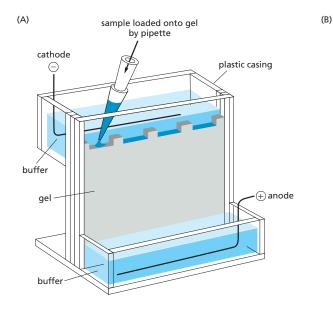

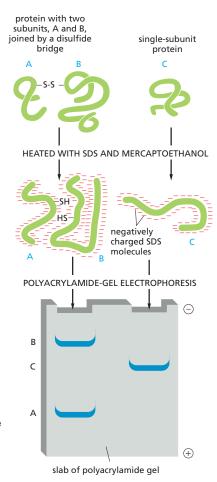

Figure 8–13 SDS polyacrylamide-gel electrophoresis (SDS-PAGE). (A) An electrophoresis apparatus, in which a polyacrylamide gel is sandwiched between two glass plates, with each end of the gel immersed in a buffer connected to an electrode. (B) Individual polypeptide chains form a complex with negatively charged molecules of sodium dodecyl sulfate (SDS) and therefore migrate as a negatively charged SDS-protein complex through a porous gel of polyacrylamide. Because smaller polypeptides move more quickly through the gel, this technique can be used to determine the approximate mass of a polypeptide chain as well as the subunit composition of a protein complex. If the protein contains a large amount of carbohydrate, however, it will move anomalously on the gel, and its apparent mass estimated by SDS-PAGE will be misleading. Other modifications, such as phosphorylation, can also cause small changes in a protein's migration in the gel.

MBOC7_ptr_ch08_475-562.indd 488 02/12/21 12:42 PM

ANALYZING PROTEINS 489

Figure 8–14 Analysis of protein samples by SDS polyacrylamide-gel electrophoresis. The photograph shows a Coomassie blue–stained gel that has been used to detect the proteins present at successive stages in the purification of an enzyme. The leftmost lane (lane 1) contains the complex mixture of proteins in the starting cell extract, and each succeeding lane analyzes the proteins obtained after a chromatographic fractionation of the protein sample analyzed in the previous lane (see Figure 8–10). The same total amount of protein (10 μg) was loaded onto the gel at the top of each lane. Individual proteins normally appear as sharp, dye-stained bands; a band broadens, however, when it contains a large amount of protein. (From T. Formosa and B.M. Alberts, *J. Biol. Chem.* 261:6107–6118, 1986.)

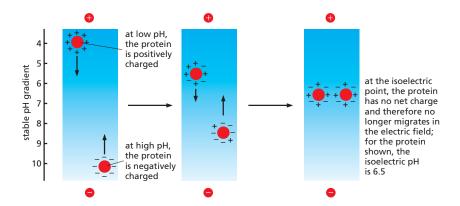

membranes. And because the method separates polypeptides by size, it provides information about the mass and subunit composition of proteins. Figure 8–14 presents a photograph of a gel that has been used to analyze each of the successive stages in the purification of a protein.

Two-dimensional Gel Electrophoresis Provides Greater Protein Separation

Because different proteins can have similar sizes, shapes, masses, and overall charges, most separation techniques such as SDS polyacrylamide-gel electrophoresis or ion-exchange chromatography cannot typically separate all the proteins in a cell or even in an organelle. In contrast, **two-dimensional gel electrophoresis**, which combines two different separation procedures, can resolve up to 2000 proteins in the form of a two-dimensional protein map.

In the first step, the proteins are separated by their intrinsic charges. The sample is dissolved in a small volume of a solution containing a nonionic (uncharged) detergent, together with β -mercaptoethanol and the denaturing reagent urea. This solution solubilizes, denatures, and dissociates all the polypeptide chains but leaves their intrinsic charge unchanged. The polypeptide chains are then separated in a pH gradient by a procedure called *isoelectric focusing*, which takes advantage of the variation in the net charge on a protein molecule with the pH of its surrounding solution. Every protein has a characteristic isoelectric point, the pH at which the protein has no net charge and therefore does not migrate in an electric field. In isoelectric focusing, proteins are separated electrophoretically in a narrow tube of polyacrylamide gel in which a gradient of pH is established by a mixture of special buffers. Each protein moves to a position in the gradient that corresponds to its isoelectric point and remains there (Figure 8–15). This is the first dimension of two-dimensional polyacrylamide-gel electrophoresis.

In the second step, the narrow tube of gel containing the separated proteins is soaked in SDS and placed along the top edge of an SDS polyacrylamide-gel slab. Electrophoresis is then carried out as in one-dimensional SDS-PAGE, and each polypeptide chain migrates into the gel to form a discrete spot. The only proteins left unresolved are those that have both identical sizes and identical isoelectric points, a relatively rare situation. Even trace amounts of each polypeptide chain

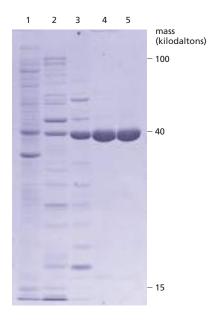

Figure 8-15 Separation of protein molecules by isoelectric focusing. At low pH (high H⁺ concentration), the carboxylic acid groups of proteins tend to be uncharged (-COOH) and their nitrogencontaining basic groups fully charged (for example, -NH₃+), giving most proteins a net positive charge. At high pH, the carboxylic acid groups are negatively charged (-COO-) and the basic groups tend to be uncharged (for example, -NH₂), giving most proteins a net negative charge. At its isoelectric point, a protein has no net charge because the positive and negative charges balance. Thus, when a tube containing a fixed pH gradient is subjected to a strong electric field in the appropriate direction, each protein species migrates until it forms a sharp band at its isoelectric point, as shown.

MBOC7_ptr_ch08_475-562.indd 489 02/12/21 12:42 PM

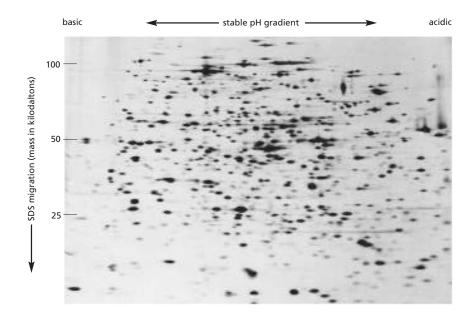

Figure 8-16 Two-dimensional polyacrylamide-gel electrophoresis. All the proteins in an Escherichia coli bacterial cell are separated in this gel, in which each spot corresponds to a different polypeptide chain. The proteins were first separated on the basis of their isoelectric points by isoelectric focusing in the horizontal dimension. They were then further fractionated according to their mass by electrophoresis from top to bottom in the presence of SDS. Note that different proteins are present in very different amounts. The bacteria were fed with a mixture of radioisotope-labeled amino acids so that all of their proteins were radioactive and could be detected by autoradiography. (Courtesy of Patrick O'Farrell.)

can be detected on the gel by various staining procedures—or by autoradiography if the protein sample was initially labeled with a radioisotope (Figure 8–16). The technique has such great resolving power that it can distinguish between two proteins that differ in only a single charged amino acid or a single negatively charged phosphorylation site.

Specific Proteins Can Be Detected by Blotting with Antibodies

A specific protein can be identified after its fractionation on a polyacrylamide gel by exposing all the proteins on the gel to a specific antibody that has been labeled with a radioactive isotope or a fluorescent dye. This procedure is normally carried out after transferring all of the separated proteins in the gel onto a sheet of nitrocellulose paper or nylon membrane. Placing the membrane against the gel and driving the proteins out of the gel with a strong electric current transfers the protein onto the membrane. The membrane is then soaked in a solution of labeled antibody to reveal the protein of interest. This method of detecting proteins is called **Western blotting**, or **immunoblotting** (**Figure 8–17**). Sensitive Western-blotting methods can detect very small amounts of a specific protein (1 nanogram or less) in a total cell extract or some other heterogeneous protein mixture. The method can be very useful when assessing the amounts of a specific protein in the cell or when measuring changes in those amounts under various conditions.

Hydrodynamic Measurements Reveal the Size and Shape of a Protein Complex

Most proteins in a cell are subunits of larger complexes, and knowledge of the size and shape of these complexes often leads to insights regarding their function. This information can be obtained in several ways. Sometimes, a complex can be directly visualized using electron microscopy, as described in Chapter 9. A complementary approach relies on the hydrodynamic properties of a complex; that is, its behavior as it moves through a liquid medium. Usually, two separate measurements are made. One measure is the velocity of a complex as it moves under the influence of a centrifugal field produced by an ultracentrifuge (see Figure 8–6A). The sedimentation coefficient (or S value) obtained depends on both the size and the shape of the complex and does not, by itself, convey especially useful information. However, once a second hydrodynamic measurement is performed—by charting the migration of a complex through a gel-filtration chromatography

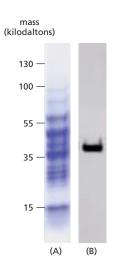

Figure 8-17 Western blotting. In this experiment, proteins of the budding yeast Saccharomyces cerevisiae were separated on a polyacrylamide gel. In (A), the gel was stained with Coomassie blue to reveal the most abundant proteins. In (B), the proteins in the gel were transferred to a membrane and exposed to antibodies directed against a specific protein. Unbound antibodies were washed away, and antibodies bound to the protein were detected with a fluorescent label. By this sensitive Western blotting method, small amounts of a single rare protein can be detected in a complex mixture of other proteins. (Courtesy of Jonathan Asfaha.)

ANALYZING PROTEINS 491

column (see Figure 8-9B)—both the approximate shape of a complex and its mass can be calculated.

The mass of a protein complex can also be determined more directly by using an analytical ultracentrifuge, a complex device that allows protein absorbance measurements to be made on a sample while it is subjected to centrifugal forces. In this approach, the sample is centrifuged until it reaches equilibrium, where the centrifugal force on a protein complex exactly balances its tendency to diffuse away. Because this balancing point is dependent on a complex's mass but not on its particular shape, the mass can be directly calculated.

Mass Spectrometry Provides a Highly Sensitive Method for Identifying Unknown Proteins

A frequent problem in cell biology and biochemistry is the identification of a protein or collection of proteins that has been obtained by one of the purification procedures discussed in the preceding pages. Because the genome sequences of most experimental organisms are known, catalogs of all the proteins produced in those organisms are available. The task of identifying an unknown protein (or collection of unknown proteins) thus reduces to matching some of the amino acid sequences present in the unknown sample with known cataloged genes. This task is now performed almost exclusively by mass spectrometry in conjunction with computer searches of databases.

Charged particles have very precise dynamics when subjected to electric and magnetic fields in a vacuum. *Mass spectrometry* exploits this principle to separate ions according to their mass-to-charge (m/z) ratio. It is an enormously sensitive technique. It requires very little material and is capable of determining the precise mass of intact proteins and of peptides derived from them by enzymatic or chemical cleavage. Masses can be obtained with great accuracy, often with an error of less than one part in a million.

Mass spectrometry is performed using complex instruments with three major components (Figure 8–18A). The first is the *ion source*, which transforms tiny amounts of a peptide sample into a gas containing individual charged peptide molecules. These ions are accelerated by an electric field into the second component, the *mass analyzer*, where electric or magnetic fields are used to separate the ions on the basis of their mass-to-charge ratios. Finally, the separated ions collide with a *detector*, which generates a mass spectrum containing a series of peaks representing the masses of the molecules in the sample.

There are many different types of mass spectrometer, varying mainly in the nature of their ion sources and mass analyzers. One of the most common ion sources depends on a technique called matrix-assisted laser desorption ionization (MALDI). In this approach, the proteins in the sample are first cleaved into short peptides by a protease such as trypsin. These peptides are mixed with an organic acid and then dried onto a metal or ceramic slide. A brief laser burst is directed toward the sample, producing a gaseous puff of ionized peptides, each carrying one or more positive charges. In many cases, the MALDI ion source is coupled to a mass analyzer called a time-of-flight (TOF) analyzer, which is a long chamber through which the ionized peptides are accelerated by an electric field toward a detector. Their mass and charge determine the time it takes them to reach the detector: large peptides move more slowly, and more highly charged molecules move more quickly. By analyzing those ionized peptides that bear a single charge, the precise masses of peptides present in the original sample can be determined. This information is then used to search genomic databases, in which the masses of all proteins and of all their predicted peptide fragments have been tabulated from the genomic sequences of the organism. An unambiguous match to a particular open reading frame can often be made by knowing the mass of only a few peptides derived from a given protein.

By employing two mass analyzers in tandem (an arrangement known as tandem mass spectrometry, or MS/MS; Figure 8-18B), it is possible to directly determine the amino acid sequences of individual peptides in a complex mixture.

MBOC7_ptr_ch08_475-562.indd 491 02/12/21 12:42 PM

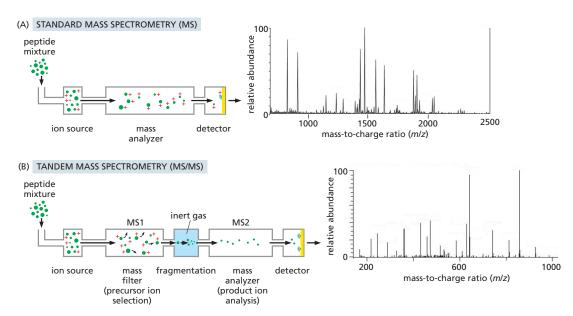

Figure 8-18 The mass spectrometer. (A) Mass spectrometers used in biology contain an ion source that generates gaseous peptides or other molecules under conditions that render most molecules positively charged. The two major types of ion source are MALDI and electrospray, as described in the text. Ions are accelerated into a mass analyzer, which separates the ions on the basis of their mass and charge by one of three major methods: (1) Time-of-flight (TOF) analyzers determine the mass-to-charge ratio of each ion in the mixture from the rate at which it travels from the ion source to the detector. (2) Quadrupole mass filters contain a long chamber lined by four electrodes that produce oscillating electric fields that govern the trajectory of ions; by varying the properties of the electric field over a wide range, a spectrum of ions with specific mass-to-charge ratios is allowed to pass through the chamber to the detector, while other ions are discarded. (3) Ion traps contain doughnut-shaped electrodes producing a three-dimensional electric field that traps all ions in a circular chamber; the properties of the electric field can be varied over a wide range to eject a spectrum of specific ions to a detector. (B) Tandem mass spectrometry typically involves two mass analyzers separated by a collision chamber containing an inert, high-energy gas. The electric field of the first mass analyzer is adjusted to select a specific peptide ion, called a precursor ion, which is then directed to the collision chamber. Collision of the peptide with gas molecules causes random peptide fragmentation, primarily at peptide bonds, resulting in a highly complex mixture of fragments containing one or more amino acids from throughout the original peptide. The second mass analyzer is then used to measure the masses of the fragments (called product or daughter ions). With computer assistance, the pattern of fragments can be used to deduce the amino acid sequence of the original peptide.

The MALDI-TOF instrument described above is not ideal for this method. Instead, MS/MS typically involves an *electrospray* ion source, which produces a continuous thin stream of peptides that are ionized and accelerated into the first mass analyzer. The mass analyzer is typically either a *quadrupole* or *ion trap*, which employs large electrodes to produce oscillating electric fields inside the chamber containing the ions. These instruments act as *mass filters*: the electric field is adjusted over a broad range to select a single peptide ion and discard all the others in the peptide mixture. In tandem mass spectrometry, this single ion is then exposed to an inert, high-energy gas, which collides with the peptide, resulting in fragmentation, primarily at peptide bonds. The second mass analyzer then determines the masses of the peptide fragments, which can be used by computational methods to determine the amino acid sequence of the original peptide and thereby identify the protein from which it came.

Tandem mass spectrometry is also useful for detecting and precisely mapping post-translational modifications of proteins, such as phosphorylation or acetylation. Because these modifications impart a characteristic mass increase to an amino acid, they are easily detected during the analysis of peptide fragments in the second mass analyzer, and the precise site of the modification can often be deduced from the spectrum of peptide fragments.

A powerful, "two-dimensional" mass spectrometry technique can be used to determine all of the proteins present in an organelle or another complex mixture of proteins. First, the mixture of proteins present is digested with trypsin to

MBOC7_ptr_ch08_475-562.indd 492 02/12/21 12:42 PM

ANALYZING PROTEINS 493

produce short peptides. Next, these peptides are separated by an automated high-performance form of liquid chromatography (LC). Every peptide fraction from the chromatographic column is injected directly into an electrospray ion source on a tandem mass spectrometer, providing the amino acid sequence and post-translational modifications for every peptide in the mixture. This method, often called LC-MS/MS, is used to identify hundreds or thousands of proteins in complex protein mixtures from specific organelles or from whole cells. It can also be used to map all of the phosphorylation sites in the cell, or all of the proteins targeted by other post-translational modifications such as acetylation or ubiquitylation.

Sets of Interacting Proteins Can Be Identified by Biochemical Methods

Because most proteins in the cell function as part of complexes with other proteins, an important way to begin to characterize the biological role of an unknown protein is to identify all of the other proteins to which it specifically binds.

A key method for identifying proteins that bind to one another tightly is *co-immunoprecipitation*. A target protein is immunoprecipitated from a cell lysate using specific antibodies coupled to beads, as described earlier. If the target protein is associated tightly enough with another protein when it is captured by the antibody, the partner precipitates as well and can be identified by mass spectrometry. This method is useful for identifying proteins that are part of a complex inside cells, including those that interact only transiently; for example, when extracellular signal molecules stimulate cells (discussed in Chapter 15).

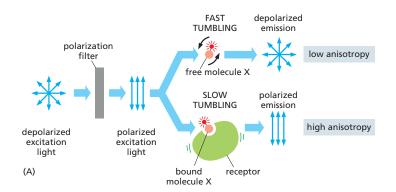

Optical Methods Can Monitor Protein Interactions

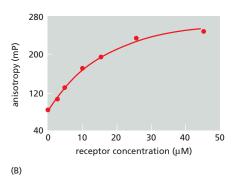

Once two proteins—or a protein and a small molecule—are known to associate, it becomes important to characterize their interaction in more detail. Proteins can associate with each other more or less permanently (like the subunits of RNA polymerase or the proteasome), or engage in transient encounters that may last only a few milliseconds (like a protein kinase and its substrate). To understand how a protein functions inside a cell, we need to determine how tightly it binds to other proteins and how covalent modifications, small molecules, or other proteins influence these interactions.

As we discussed in Chapter 3 (see Figure 3–42), the extent to which two proteins interact is determined by the rates at which they associate and dissociate. These rates depend, respectively, on the association rate constant ($k_{\rm on}$) and dissociation rate constant ($k_{\rm off}$). The kinetic rate constant $k_{\rm off}$ is a particularly useful number because it provides valuable information about how long two proteins remain bound to one another. The ratio of the two kinetic constants ($k_{\rm on}/k_{\rm off}$) yields another very useful number called the equilibrium constant (K, also known as $K_{\rm eq}$ or $K_{\rm a}$), the inverse of which is the more commonly used dissociation constant, $K_{\rm d}$. The equilibrium constant is useful as a general indicator of the affinity of the interaction, and it can be used to estimate the amount of bound complex at different concentrations of the two protein partners—thereby providing insights into the importance of the interaction at the protein concentrations found inside the cell.

A wide range of methods can be used to determine binding constants for a two-protein complex. In a simple *equilibrium binding experiment*, two proteins are mixed at a range of concentrations, allowed to reach equilibrium, and the amount of bound complex is measured; half of the protein complex will be bound at a concentration that is equal to K_d . Equilibrium experiments often involve the use of radioactive or fluorescent tags on one of the protein partners, coupled with biochemical or optical methods for measuring the amount of bound protein. In a more complex *kinetic binding experiment*, the kinetic rate constants are determined using rapid methods that allow real-time measurement of the formation of a bound complex over time (to determine $k_{\rm on}$) or the dissociation of a bound complex over time (to determine $k_{\rm off}$).

MBOC7_ptr_ch08_475-562.indd 493 02/12/21 12:42 PM

Optical techniques provide particularly rapid, convenient, and accurate binding measurements, and in some cases the proteins do not even need to be labeled. Certain amino acids (tryptophan, for example) exhibit weak fluorescence that can be detected with sensitive fluorimeters. In many cases, the fluorescence intensity, or the emission spectrum of fluorescent amino acids located in a protein-protein interface, will change when two proteins associate. When this change can be detected by fluorimetry, it provides a simple and sensitive measure of protein binding that is useful in both equilibrium and kinetic binding experiments. A related but more widely useful optical binding technique is based on *fluorescence anisotropy*, a change in the polarized light that is emitted by a fluorescently tagged protein in the bound and free states (Figure 8-19).

Another optical method for probing protein interactions uses *green fluorescent protein* (discussed in detail later) and its derivatives of different colors. In this application, two proteins of interest are each labeled with a different fluorescent protein, such that the emission spectrum of one fluorescent protein overlaps the absorption spectrum of the second. If the two proteins come very close to each other (within about 1–5 nm), the energy of the absorbed light is transferred from one fluorescent protein to the other. The energy transfer, called *fluorescence resonance energy transfer* (*FRET*), is determined by illuminating the first fluorescent protein and measuring emission from the second (see Figure 9–19). When combined with fluorescence microscopy, this method can be used to characterize protein–protein interactions at specific locations inside living cells (discussed in Chapter 9).

Protein Structure Can Be Determined Using X-ray Diffraction

A deep understanding of protein function in the cell requires knowledge of its three-dimensional structure at atomic resolution, revealing the precise position of every amino acid in the protein. Structural analysis provides powerful insights into the mechanisms underlying a protein's enzymatic activity and its interactions with other proteins or small molecules. Numerous methods are used to unravel protein structure. In this chapter, we discuss well-established methods that depend on x-ray crystallography and nuclear magnetic resonance spectroscopy. Chapter 9 describes recently developed methods by which electron microscopy is being used to determine the high-resolution structures of larger proteins and protein complexes.

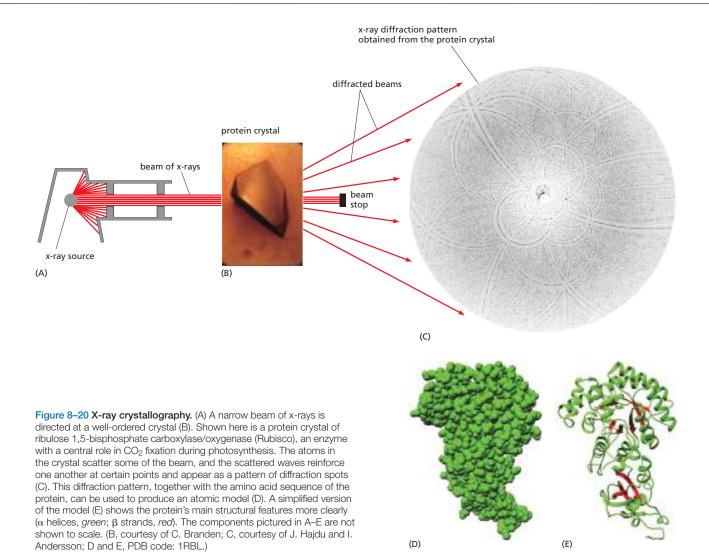

For many decades, the primary technique for protein structural analysis has been x-ray crystallography. X-rays, like light, are a form of electromagnetic radiation, but they have a much shorter wavelength, typically around 0.1 nm (the diameter of a hydrogen atom). If a narrow beam of parallel x-rays is directed at a sample of a pure protein, most of the x-rays pass straight through it. A small fraction, however, is scattered by the atoms in the sample. If the sample is a well-ordered crystal, the scattered waves reinforce one another at certain points and appear as diffraction spots when recorded by a suitable detector (Figure 8–20).

The slowest step in this technique is likely to be the generation of suitable protein crystals. This step requires large amounts of very pure protein and often involves

Figure 8-19 Measurement of binding with fluorescence anisotropy. This method depends on a fluorescently tagged protein that is illuminated with polarized light at the appropriate wavelength for excitation; a fluorimeter is used to measure the intensity and polarization of the emitted light. If the fluorescent protein is fixed in position and therefore does not rotate during the brief period between excitation and emission, then the emitted light will be polarized at the same angle as the excitation light. This directional effect is called fluorescence anisotropy. Protein molecules in solution rotate or tumble rapidly, however, so that there is a decrease in the amount of anisotropic fluorescence. Larger molecules tumble at a slower rate and therefore have higher fluorescence anisotropy. (A) To measure the binding between a small molecule and a large receptor protein, the smaller molecule is labeled with a fluorophore. In the absence of its binding partner, the molecule tumbles rapidly, resulting in low fluorescence anisotropy (top). When the small molecule binds to its larger partner, however, it tumbles less rapidly, resulting in an increase in fluorescence anisotropy (bottom). (B) In the equilibrium binding experiment shown here, a small, fluorescent peptide ligand was present at a low concentration, and the amount of fluorescence anisotropy (in millipolarization units: mP) was measured after incubation with various concentrations of a larger protein receptor for the ligand. From the hyperbolic curve that fits the data, it can be seen that 50% binding occurred at about 10 µM, which is equal to the dissociation constant K_d for the binding interaction.

MBOC7_ptr_ch08_475-562.indd 494 02/12/21 12:42 PM

ANALYZING PROTEINS 495

years of trial and error to discover the proper crystallization conditions; the pace has greatly accelerated with the use of recombinant DNA techniques to produce pure proteins and robotic techniques to test large numbers of crystallization conditions.

The position and intensity of each spot in the x-ray diffraction pattern contain information about the locations of the atoms in the crystal that gave rise to it. Computer-assisted computational methods process the diffraction pattern to generate a three-dimensional electron-density map. Interpreting this map—translating its contours into a three-dimensional structure—can be a laborious procedure. Largely by trial and error, the sequence and the electron-density map are correlated by computer to give the best possible fit. The reliability of the final atomic model depends on the resolution of the original crystallographic data: 0.5-nm resolution might produce a low-resolution map of the polypeptide backbone, whereas a resolution of 0.15 nm allows all of the non-hydrogen atoms in the molecule to be reliably positioned.

A complete atomic model is often too complex to appreciate directly, but simplified versions that show a protein's essential structural features can be readily derived from it. The three-dimensional structures of tens of thousands of different proteins have been determined—enough to allow the grouping of common structures into families (Movie 8.1). These structures or protein folds often seem to be more conserved in evolution than are the amino acid sequences that form them (see Figure 3–13).

MBOC7_ptr_ch08_475-562.indd 495 02/12/21 12:42 PM

NMR Can Be Used to Determine Protein Structure in Solution

Nuclear magnetic resonance (NMR) spectroscopy has been widely used for many years to analyze the structure of small molecules, small proteins, or protein domains. Unlike x-ray crystallography, NMR does not depend on having a crystalline sample. It simply requires a small volume of concentrated protein solution that is placed in a strong magnetic field; indeed, it is the main technique that yields detailed evidence about the three-dimensional structure of molecules in solution.

Certain atomic nuclei, particularly hydrogen nuclei, have a magnetic moment or spin; that is, they have an intrinsic magnetization, like a bar magnet. When exposed to a strong magnetic field in an NMR experiment, the spin of these nuclei aligns with the magnetic field, but it can be forced into a misaligned, excited state by radiofrequency (RF) pulses of electromagnetic radiation. As the excited hydrogen nuclei return to their aligned state, they emit RF radiation, which can be measured and displayed as a spectrum. The signal of the emitted radiation, called the chemical shift, depends on the environment of each hydrogen nucleus, such that every nucleus in a protein displays a slightly different chemical shift. Furthermore, if one nucleus is excited, it influences the absorption and emission of radiation by other nuclei that lie close to it. It is consequently possible, by an ingenious elaboration of the basic NMR technique known as two-dimensional (2D) NMR, to distinguish the signals from hydrogen nuclei in different amino acid residues and to identify and measure the small changes in these signals that occur when these hydrogen nuclei lie close enough together to interact. Because the size of such a change reveals the distance between the interacting pair of hydrogen atoms, NMR can provide information about the distances between the parts of the protein molecule. Additional information can be gained by heteronuclear 2D NMR, which analyzes hydrogen nuclei in parallel with the nuclei of a nitrogen isotope. By combining this information with a knowledge of the amino acid sequence, it is possible in principle to compute the threedimensional structure of the protein (Figure 8-21). For technical reasons, NMR spectroscopy is used primarily to determine the structure of small proteins of about 30,000 daltons or less.

Because NMR studies are performed in solution, this method also offers a convenient means of monitoring changes in protein structure; for example, during protein folding or when the protein binds to another molecule. NMR is also used widely to investigate molecules other than proteins and is valuable, for example, as a method to determine the three-dimensional structures of RNA molecules and the complex carbohydrate side chains of glycoproteins.

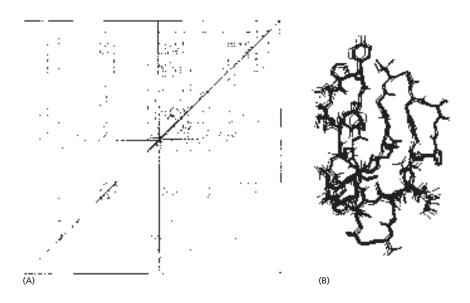

Figure 8-21 NMR spectroscopy. (A) An example of the data from an NMR machine. This NMR spectrum, displaying chemical shifts of hydrogen nuclei in two dimensions, is derived from the C-terminal domain of the enzyme cellulase. The spots away from the diagonal represent interactions between hydrogen atoms that are near neighbors in the protein; their positions reflect the distance that separates them. Complex computing methods, in conjunction with the known amino acid sequence, enable possible compatible structures to be derived. (B) Ten structures of the enzyme, all of which satisfy the distance constraints equally well, are shown superimposed on one another, giving a good indication of the probable three-dimensional structure. (Courtesy of P. Kraulis.)

MBOC7_ptr_ch08_475-562.indd 496 02/12/21 12:42 PM

ANALYZING PROTEINS 497

A major problem in structural biology is the analysis of large protein complexes, which are difficult to crystallize and too large for NMR analysis. Single-particle analysis by cryo-electron microscopy provides a relatively straightforward approach to the analysis of large macromolecular assemblies, as we describe in Chapter 9.

Protein Sequence and Structure Provide Clues About Protein Function

Having discussed methods for purifying and analyzing proteins, we now turn to a common situation in cell and molecular biology: an investigator has identified a gene important for a biological process but has no direct knowledge of the biochemical properties of its protein product.

Thanks to the proliferation of protein and nucleic acid sequences that are cataloged in genome databases, the function of a gene—and its encoded protein—can often be predicted by simply comparing its sequence with those of previously characterized genes. Because amino acid sequence determines protein structure, and structure dictates biochemical function, proteins that share a similar amino acid sequence usually have the same structure and usually perform similar biochemical functions, even when they are found in distantly related organisms. Thus, the study of a newly discovered protein usually begins with a search for previously characterized proteins that are similar in their amino acid sequences.

Searching a collection of known sequences for similar genes or proteins simply involves selecting a database and entering the desired sequence. A sequence-alignment program—the most popular is *BLAST* (*Basic Local Alignment Search Tool*)—scans the database for similar sequences by sliding the submitted sequence along the archived sequences until a cluster of residues falls into full or partial alignment (Figure 8–22).

As was explained in Chapter 3, many proteins that adopt the same conformation and have related functions are too distantly related to be identified from a comparison of their amino acid sequences alone (see Figure 3–13). Thus, an ability to reliably predict the three-dimensional structure of a protein from its amino acid sequence would improve our ability to infer protein function from the sequence information in genomic databases. In recent years, major progress has been made in predicting the precise structure of a protein. These predictions are based, in part, on our knowledge of the thousands of protein structures that have already been determined by x-ray crystallography and NMR spectroscopy and, in part, on computations using our knowledge of the physical forces acting on the atoms. However, it remains a substantial and important challenge to predict

Figure 8-22 Results of a BLAST search.

Sequence databases can be searched to find similar amino acid or nucleic acid sequences. Here, a search for proteins similar to the human cell-cycle regulatory protein Cdk1 (Query) locates maize Cdk1 (Sbict), which is 68% identical to human Cdk1 in its amino acid sequence. The alignment begins at residue 57 of the Query protein, suggesting that the human protein has an N-terminal region that is absent from the maize protein. The green blocks indicate differences in sequence, and the vellow bars summarize the similarities: when the two amino acid sequences are identical, the residue is shown; similar amino acid substitutions are indicated by a plus sign (+). Only one small gap has been introduced—indicated by the red arrowhead at position 194 in the Query sequence—to align the two sequences maximally. The alignment score (Score), which is expressed in two different types of units, takes into account penalties for substitutions and gaps: the higher the alignment score, the better the match. The significance of the alignment is reflected in the Expectation (E) value, which specifies how often a match this good would be expected to occur by chance. The lower the E value, the more significant the match; the extremely low value here (e⁻¹¹¹) indicates certain significance. E values much higher than 0.1 are unlikely to reflect true relatedness. For example, an E value of 0.1 means there is a 1 in 10 likelihood that such a match would arise solely by chance.

MBOC7_ptr_ch08_475-562.indd 497 02/12/21 12:42 PM

the structures of proteins that are large or have multiple domains or to predict structures at the very high levels of resolution needed to assist in computer-based drug discovery.

While finding related sequences and structures for a new protein will provide many clues about its function, it is usually necessary to test these insights through direct experimentation. However, the clues generated from sequence comparisons typically point the investigator in the correct experimental direction, and their use has therefore become one of the most important strategies in modern cell biology.

Summary

Many methods exist for identifying proteins and analyzing their biochemical properties, structures, and interactions with other proteins. The most powerful and commonly used methods include protein separation by polyacrylamide gel electrophoresis, protein analysis by mass spectrometry, and high-resolution structural determination. Because proteins with similar structures often have similar functions, the biochemical activity of a protein can often be predicted by searching databases for previously characterized proteins that are similar in their amino acid sequences.

ANALYZING AND MANIPULATING DNA

Until the early 1970s, DNA was the most difficult biological molecule for the biochemist to analyze. Enormously long and chemically monotonous, the string of nucleotides that forms the genetic material of an organism could be determined only indirectly, from protein sequence or by genetic analysis. Today, the situation has changed entirely. From being the most difficult macromolecule of the cell to analyze, DNA has become the easiest. It is now possible to determine the entire nucleotide sequence of a bacterial or fungal genome in a matter of hours and the sequence of an individual human genome in less than a day. Once the nucleotide sequence of a genome is known, any individual gene can be easily isolated, and large quantities of the gene product (be it RNA or protein) can be made either by introducing the gene into bacteria or animal cells and coaxing these cells to overexpress the foreign gene or by synthesizing the gene product in vitro. In this way, proteins and RNA molecules that might be present in only tiny amounts in living cells can be produced in large quantities for biochemical and structural analyses. And this approach can also be used to produce large quantities of human proteins (such as insulin, or interferon, or blood-clotting proteins) for use as human pharmaceuticals. As we will see later in this chapter, it is also possible for scientists to alter an isolated gene and transfer it back into the germ line of an animal or plant, so as to become a functional and heritable part of the organism's genome. In this way, the biological roles of any gene can be assessed by observing—in the whole organism—the results of modifying it.

The ability to manipulate DNA with precision in a test tube or an organism, known as **recombinant DNA technology**, has had a dramatic impact on all aspects of cell and molecular biology. We now describe the key features of these techniques.

Restriction Nucleases Cut Large DNA Molecules into Specific Fragments

Unlike a protein, a gene does not exist as a discrete entity in cells, but rather as a small region of a much longer DNA molecule. Although the DNA molecules in a cell can be randomly broken into small pieces by mechanical force, a fragment containing a single gene in a mammalian genome would still be only one among a hundred thousand or more DNA fragments, indistinguishable in their average size. How could such a gene be separated from all the others? Because all DNA molecules consist of an approximately equal mixture of the same four

MBOC7_ptr_ch08_475-562.indd 498 02/12/21 12:42 PM

nucleotides, they cannot be readily separated, as proteins can, on the basis of their different charges and biochemical properties. The solution to this problem began to emerge with the discovery of **restriction nucleases**. These enzymes, which are purified from bacteria, cut the DNA double helix at specific sites defined by the local nucleotide sequence, thereby cleaving a long, double-strand DNA molecule into fragments of strictly defined sizes.

Like many of the tools of recombinant DNA technology, restriction nucleases were discovered by researchers trying to understand an intriguing biological phenomenon. It had been observed that certain bacteria always degraded "foreign" DNA that was introduced into them experimentally. A search for the mechanism responsible revealed a then unanticipated class of bacterial nucleases that cleave DNA at specific nucleotide sequences. The bacterium's own DNA is protected from cleavage by methylation of these same sequences, thereby protecting the bacterium from being overrun by foreign DNA. Because these enzymes restrict the transfer of DNA into bacteria, they were called restriction nucleases. The pursuit of this seemingly arcane biological puzzle set off the development of technologies that have forever changed the way cell and molecular biologists study living things.
