Different bacterial species produce different restriction nucleases, each cutting at a different, specific nucleotide sequence (Figure 8–23). Because these target sequences are short—generally four to eight nucleotide pairs—many sites of cleavage will occur, purely by chance, in any long DNA molecule. The reason restriction nucleases are so useful in the laboratory is that each enzyme will always cut a particular DNA molecule at the same sites. Thus for a given sample of DNA (which contains many identical molecules), a particular restriction nuclease will reliably generate the same set of DNA fragments.

The size of the resulting fragments depends on the length of the target sequences of the restriction nucleases. As shown in Figure 8–23, the enzyme HaeIII cuts at a sequence of four nucleotide pairs; a sequence this long would be expected to occur purely by chance approximately once every 256 nucleotide pairs (1 in 4^4). In comparison, a restriction nuclease with a target sequence that is eight nucleotides long would be expected to cleave DNA on average once every 65,536 nucleotide pairs (1 in 4^8). This difference in sequence selectivity makes it possible to cleave a long DNA molecule into the fragment sizes that are most suitable for a given application.

Gel Electrophoresis Separates DNA Molecules of Different Sizes

The same types of gel-electrophoresis methods that have proved so useful in the analysis of proteins (see Figure 8–13) can be applied to DNA molecules. The procedure is actually simpler than for proteins: because each nucleotide in a nucleic acid molecule carries a single negative charge (on the phosphate group), there is no need to add the negatively charged detergent SDS that is required to make protein molecules move uniformly toward the positive electrode. Larger DNA

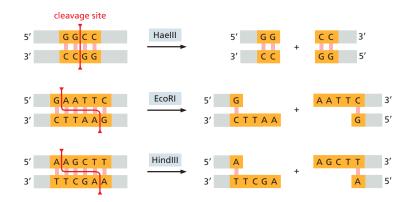

Figure 8–23 Restriction nucleases cleave DNA at specific nucleotide sequences.

Like the sequence-specific DNA-binding proteins we encountered in Chapter 7 (see Figure 7-9), restriction enzymes often work as dimers, and the DNA sequence that each restriction enzyme recognizes and cleaves is often symmetrical around a central point. Here, both strands of the DNA double helix are cut at specific points within the target sequence (orange). Some enzymes, such as Haelll, cut straight across the double helix and leave two blunt-ended DNA molecules; with others, such as EcoRI and HindIII. the cuts on each strand are staggered. These staggered cuts generate "sticky ends"-short, single-strand overhangs that help the cut DNA molecules join back together through complementary basepairing. This rejoining of DNA molecules becomes important for DNA cloning, as we discuss later. Restriction nucleases are usually obtained from bacteria, and their names reflect their origins; for example, the enzyme EcoRI comes from Escherichia coli. Hundreds of different restriction enzymes are commercially available.

MBOC7_ptr_ch08_475-562.indd 499 02/12/21 12:42 PM

fragments will migrate more slowly because their progress is impeded to a greater extent by the gel matrix. In less than an hour, the DNA fragments become spread out across the gel according to size, forming a ladder of discrete bands, each composed of a collection of DNA molecules of identical length (Figure 8–24A and B). To separate DNA molecules longer than 500 nucleotide pairs, the gel is made of a diluted solution of agarose (a polysaccharide isolated from seaweed). For DNA fragments less than 500 nucleotides long, specially designed polyacrylamide gels allow the separation of molecules that differ in length by as little as a single nucleotide (Figure 8–24C).

A variation of agarose-gel electrophoresis, called *pulsed-field gel electrophoresis*, makes it possible to separate extremely long DNA molecules, even those found in whole chromosomes. Ordinary gel electrophoresis fails to separate very large DNA molecules because the steady electric field stretches them out so that they travel end-first through the gel in snake-like configurations at a rate that is independent of their length. In pulsed-field gel electrophoresis, by contrast, the direction of the electric field changes periodically, which forces the molecules to reorient before continuing to move snake-like through the gel. This reorientation takes much more time for larger molecules, so that longer molecules move more slowly than shorter ones. As a consequence, entire bacterial or yeast chromosomes separate into discrete bands in pulsed-field gels and so can be sorted and identified on the basis of their size (Figure 8-24D). Although a typical mammalian chromosome of 10⁸ nucleotide pairs is still too long to be sorted even in this way, large segments of these chromosomes are readily separated and identified if the chromosomal

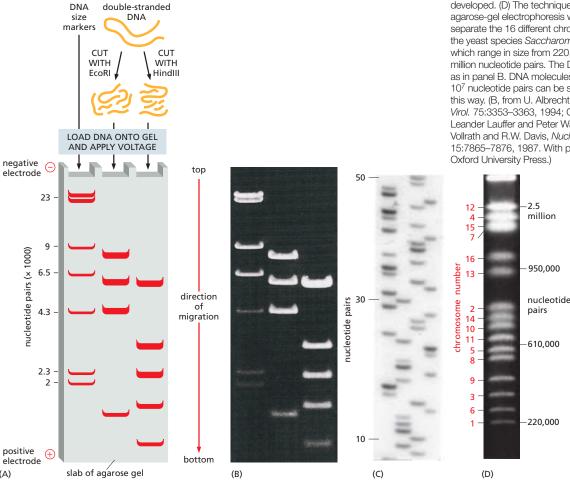

Figure 8-24 DNA molecules can be separated by size using gel electrophoresis. (A) Schematic illustration comparing the results of cutting the same DNA molecule (in this case, the genome of a virus that infects wasps) with two different restriction nucleases, EcoRI (middle) and HindIII (right). The fragments are then separated by gel electrophoresis using a gel matrix of agarose. Because larger fragments migrate more slowly than smaller ones the lowermost bands on the gel contain the smallest DNA fragments. The sizes of the fragments can be estimated by comparing them to a set of DNA fragments of known sizes (left). (B) Photograph of an actual agarose gel showing DNA bands that have been stained with ethidium bromide. (C) A polyacrylamide gel with small pores was used to separate short DNA molecules that differ by only a single nucleotide. Shown here are the results of a dideoxy sequencing reaction, explained later in this chapter. From left to right, the bands in the four lanes were produced by adding G, A, T, and C chainterminating nucleotides (see Figure 8-42). The DNA molecules were labeled with ³²P, and the image shown was produced by laying a piece of photographic film over the gel and allowing the ³²P to expose the film, producing the dark bands observed when the film was developed. (D) The technique of pulsed-field agarose-gel electrophoresis was used to separate the 16 different chromosomes of the yeast species Saccharomyces cerevisiae, which range in size from 220,000 to 2.5 million nucleotide pairs. The DNA was stained as in panel B. DNA molecules as large as 10⁷ nucleotide pairs can be separated in this way. (B, from U. Albrecht et al., J. Gen. Virol. 75:3353-3363, 1994; C, courtesy of Leander Lauffer and Peter Walter; D, from D. Vollrath and R.W. Davis, Nucleic Acids Res. 15:7865-7876, 1987. With permission from

MBOC7_ptr_ch08_475-562.indd 500 02/12/21 12:42 PM

DNA is first cut with a restriction nuclease selected to recognize sequences that occur only rarely.

The DNA bands on agarose or polyacrylamide gels are invisible unless the DNA is labeled or stained in some way. A particularly sensitive method of staining DNA is to soak the gel in the dye *ethidium bromide*, which fluoresces under ultraviolet light when it is bound to DNA (see Figure 8–24B and D). Even more sensitive detection methods incorporate a radioisotope or chemical marker into the DNA molecules before electrophoresis, as we next describe.

Purified DNA Molecules Can Be Specifically Labeled with Radioisotopes or Chemical Markers in Vitro

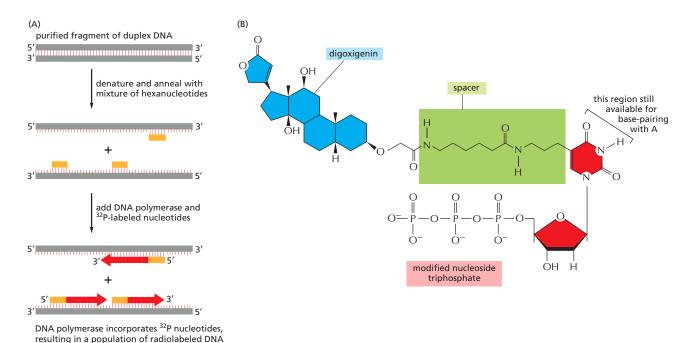

The DNA polymerases that synthesize and repair DNA (discussed in Chapter 5) have become important tools in experimentally manipulating DNA. They are often used in the test tube to create exact copies of existing DNA molecules. In some experiments, the copies can include specially modified nucleotides (Figure 8–25). To synthesize DNA in this way, the DNA polymerase is presented with a template and a pool of nucleotide precursors that contain the modification. As long as the polymerase can use these precursors, it automatically makes new, modified molecules that match the sequence of the template. Modified DNA molecules have many uses. DNA labeled with the radioisotope ³²P can be detected after gel electrophoresis by exposing the gel to photographic film or a radiation detector (see Figure 8–24C). Other types of modified DNA, such as that labeled by digoxigenin (see Figure 8–25B), are useful for visualizing DNA molecules in whole cells, a topic we discuss later in this chapter.

Genes Can Be Cloned Using Bacteria

molecules that contain sequences from both strands

Any DNA fragment can be cloned. In molecular biology, the term **DNA cloning** refers to the act of making many identical copies (typically billions) of a DNA molecule; that is, the amplification of a specific DNA sequence (often a particular gene) from the rest of the cell's genome. We note that elsewhere in the book, cloning can also refer to the generation of many genetically identical cells starting from a single cell or even to the generation of genetically identical organisms (see,

Figure 8-25 Methods for labeling DNA molecules in vitro. (A) A purified DNA polymerase enzyme can incorporate radiolabeled nucleotides as it synthesizes new DNA molecules. In this way, radiolabeled versions of any DNA sequence can be prepared in the laboratory. (B) The method in panel A is also used to produce nonradioactive DNA molecules that carry a specific chemical marker that can be detected with an appropriate antibody. The base on the nucleoside triphosphate shown is an analog of thymine, in which the methyl group on T has been replaced by a spacer arm linked to the plant steroid digoxigenin. An anti-digoxigenin antibody coupled to a visible marker such as a fluorescent dve is then used to visualize the DNA. Other chemical labels, such as biotin. can be attached to nucleotides and used in the same way. The only requirements are that the modified nucleotides properly base-pair and appear "normal" to the DNA polymerase.

MBOC7_ptr_ch08_475-562.indd 501 02/12/21 12:42 PM

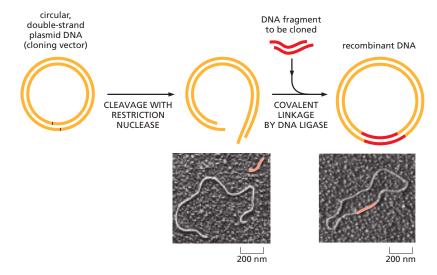

Figure 8–26 The insertion of a DNA fragment into a bacterial plasmid with the enzyme DNA ligase. The plasmid is cut open with a restriction nuclease (in this case, one that produces staggered ends) and is mixed with the DNA fragment to be cloned (which has been prepared with the same restriction nuclease). DNA ligase and ATP are added. The staggered ends basepair, and DNA ligase seals the nicks in the DNA backbone, producing a complete recombinant DNA molecule. In the accompanying micrographs, the inserted DNA is colored red. (Micrographs courtesy of Huntington Potter and David Dressler.)

for example, Figure 7-2). In all cases, cloning refers to the act of making many identical copies, and here we use the term to refer to methods designed to generate many identical copies of a defined segment of nucleic acid.

DNA cloning can be accomplished in several ways. One of the simplest involves inserting a particular fragment of DNA into the purified DNA of a self-replicating genetic element—usually a plasmid. The plasmid vectors most widely used for gene cloning are small, circular molecules of double-stranded DNA derived from plasmids that occur naturally in bacterial cells. They generally account for only a minor fraction of the total host bacterial cell DNA, but owing to their small size, they can easily be separated from the much larger chromosomal DNA molecules. For use as cloning vectors, the purified plasmid DNA circles are first cut with a restriction nuclease to create linear DNA molecules. The DNA to be cloned is added to the cut plasmid and then covalently joined using the enzyme DNA ligase (Figure 8-26 and Figure 8-27). As discussed in Chapter 5, this enzyme is used by the cell to stitch together the Okazaki fragments produced during DNA replication. The recombinant DNA circle is introduced back into bacterial cells that have been made transiently permeable to DNA. As the cells grow and divide, doubling in number every 30 minutes, the recombinant plasmids also replicate to produce an enormous

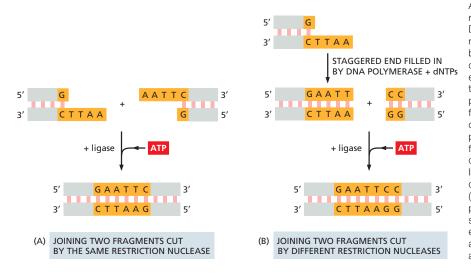

Figure 8-27 DNA ligase can join together any two DNA fragments in vitro to produce recombinant DNA molecules. ATP provides the energy necessary to reseal the sugar-phosphate backbone of DNA (see Figure 5-12). (A) DNA ligase can readily join two DNA fragments produced by the same restriction nuclease, in this case EcoRI. Note that the staggered ends produced by this enzyme enable the ends of the two fragments to basepair correctly with each other, greatly facilitating their rejoining. (B) DNA ligase can also be used to join DNA fragments produced by different restriction nucleases; for example, EcoRI and HaelII. In this case, before the fragments undergo ligation, DNA polymerase plus a mixture of deoxyribonucleoside triphosphates (dNTPs) are used to fill in the staggered cut produced by EcoRI. Each DNA fragment shown in the figure is oriented so that its 5' ends are at the left end of the upper strand and the right end of the lower strand, as indicated.

MBOC7_ptr_ch08_475-562.indd 502 02/12/21 12:42 PM

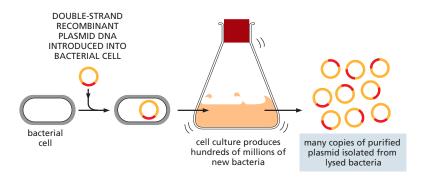

Figure 8–28 A DNA fragment can be replicated inside a bacterial cell. To clone a particular fragment of DNA, it is first inserted into a plasmid vector, as shown in Figure 8–26. The resulting recombinant plasmid DNA is then introduced into a bacterium, where it is replicated many millions of times as the bacterium multiplies. For simplicity, the genome of the bacterial cell is not shown.

number of copies of DNA circles containing the foreign DNA (Figure 8-28). Once the cells are lysed and the plasmid DNA isolated, the cloned DNA fragment can be readily recovered by cutting it out of the plasmid DNA with the same restriction nuclease that was used to insert it, and then separating it from the plasmid DNA by gel electrophoresis. Together, these steps allow the amplification and purification of any segment of DNA from the genome of any organism.

A particularly useful plasmid vector is based on the naturally occurring F plasmid of *E. coli*. Unlike smaller bacterial plasmids, the F plasmid—and its engineered derivative, the **bacterial artificial chromosome (BAC)**—is present in only one or two copies per *E. coli* cell. The fact that BACs are kept in such low numbers means that they can stably maintain very long DNA sequences, up to 1 million nucleotide pairs in length. With only a few BACs present per bacterium, it is less likely that the cloned DNA fragments will become scrambled by recombination with sequences carried on other copies of the plasmid. Because of their stability, ability to accept large DNA inserts, and ease of handling, BACs are the preferred vector for handling large fragments of foreign DNA.

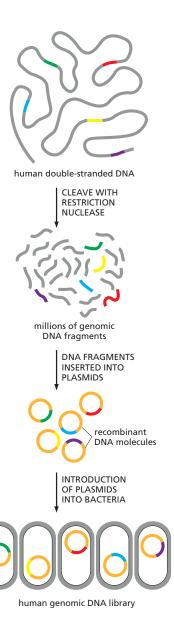

An Entire Genome Can Be Represented in a DNA Library

Often it is useful to break up a genome into much smaller fragments and clone every fragment, separately, using a plasmid vector. This approach is useful because it allows scientists to work with easily managed, discrete pieces of a genome instead of whole, unwieldy chromosomes.

This strategy involves cleaving genomic DNA into small pieces using a restriction nuclease (or, in some cases, by mechanically shearing the DNA) and ligating the entire collection of DNA fragments into plasmid vectors, using conditions that favor the insertion of a single DNA fragment into each plasmid molecule. These recombinant plasmids are then introduced into *E. coli* at a concentration that ensures that no more than one plasmid molecule is taken up by each bacterium. The collection of cloned plasmid molecules is known as a DNA library. Because the DNA fragments were derived directly from the chromosomal DNA of the organism of interest, the resulting collection—called a **genomic library**—will represent the entire genome of that organism (**Figure 8–29**), spread out over tens of thousands of individual bacterial colonies.

An alternative strategy, one that enriches for protein-coding genes, is to begin the cloning process by selecting only those DNA sequences that are transcribed into mRNA and thus correspond to protein-encoding genes. This is done by extracting the mRNA from cells and then making a DNA copy of each mRNA

Figure 8–29 Human genomic libraries containing DNA fragments that represent the whole human genome can be constructed using restriction nucleases and DNA ligase. Such a genomic library consists of a set of bacteria, each carrying a different fragment of human DNA. For simplicity, only the *colored* DNA fragments are shown in the library; in reality, all of the different *gray* fragments will also be represented.

MBOC7_ptr_ch08_475-562.indd 503 02/12/21 12:42 PM

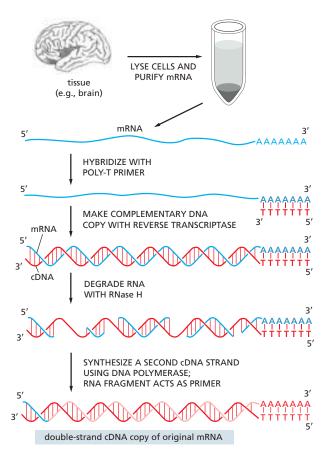

Figure 8–30 The synthesis of cDNA. Total mRNA is extracted from a particular tissue, and the enzyme reverse transcriptase (see Figure 5–61) is used to produce DNA copies (cDNA) of the mRNA molecules. For simplicity, the copying of just one of these mRNAs into cDNA is illustrated. A short oligonucleotide complementary to the poly-A tail at the 3′ end of the mRNA is first hybridized to the RNA to act as a primer for the reverse transcriptase, which then copies the RNA into a complementary DNA chain, thereby forming a DNA–RNA hybrid helix. Treating the DNA–RNA hybrid with a specialized ribonuclease (RNase H) that attacks only the RNA produces nicks and gaps in the RNA strand. DNA polymerase then copies the remaining single-stranded cDNA into double-stranded cDNA. Because DNA polymerase can synthesize through the bound RNA molecules, the RNA fragment that is base-paired to the 3′ end of the first DNA strand usually acts as the primer for the second strand synthesis, as shown. Any remaining RNA is eventually degraded during subsequent cloning steps. As a result, the nucleotide sequences at the extreme 5′ ends of the original mRNA molecules are often absent from cDNA libraries.

molecule present—a so-called *complementary DNA*, or *cDNA*. The copying reaction is catalyzed by the reverse transcriptase enzyme of retroviruses, which synthesizes a complementary DNA chain on an RNA template. The single-strand cDNA molecules synthesized by the reverse transcriptase are converted by DNA polymerase into double-strand cDNA molecules, and these molecules are inserted into a plasmid or virus vector and cloned (**Figure 8–30**). Each clone obtained in this way is called a **cDNA clone**, and the entire collection of clones derived from one mRNA preparation constitutes a **cDNA library**.

The most important advantage of cDNA clones, over genomic clones, is that they contain the uninterrupted coding sequence of a gene. When the aim of the cloning is to produce the protein in large quantities by expressing the cloned gene in a bacterial or other cell type, it is best to start with cDNA.

Cloning DNA in bacteria revolutionized the study of genomes and is still in wide use today. However, there is an even simpler way to clone DNA and produce

MBOC7_ptr_ch08_475-562.indd 504 02/12/21 12:42 PM

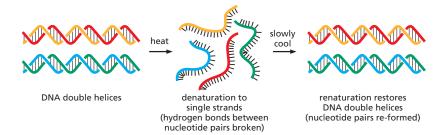

Figure 8–31 A molecule of DNA can undergo denaturation and renaturation (hybridization). For two single-strand molecules to hybridize, they must have complementary nucleotide sequences that allow base-pairing. In this example, the *red* and *orange* strands are complementary to each other, and the *blue* and *green* strands are complementary to each other. Although denaturation by heating is shown, DNA can also be renatured after being denatured by alkali treatment

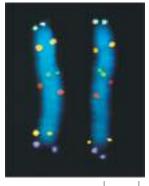

genomic libraries, entirely *in vitro*. We discuss this approach, called the *polymerase chain reaction*, shortly. However, first we need to review a fundamental, far-reaching property of DNA and RNA called *hybridization*.

Hybridization Provides a Powerful but Simple Way to Detect Specific Nucleotide Sequences

Under normal conditions, the two strands of a DNA double helix are held together by hydrogen bonds between the complementary base pairs (see Figure 4–3). These relatively weak, noncovalent bonds are easy to break. Such *DNA denaturation* releases the two strands from each other but does not break the covalent bonds that link together the nucleotides within each strand. The simplest way to achieve this separation is to heat the DNA to around 90°C. When the conditions are reversed—by slowly lowering the temperature—the complementary strands will readily come back together to re-form a double helix. This **hybridization**, or *DNA renaturation*, is driven by the re-formation of the hydrogen bonds between complementary base pairs (**Figure 8-31**).

This fundamental capacity of a single-strand nucleic acid molecule, either DNA or RNA, to form a double helix with a single-strand molecule of a complementary sequence provides a powerful and sensitive technique for detecting specific nucleotide sequences. Today, one simply designs a short, single-strand DNA molecule (often called a DNA probe) that is complementary to the nucleotide sequence of interest. Because the nucleotide sequences of so many genomes are known—and are stored in publicly accessible databases—designing a probe to hybridize anywhere in a genome is straightforward. Probes are single-stranded, typically 30 nucleotides in length, and are usually synthesized chemically by a commercial service for pennies per nucleotide. A DNA sequence of 30 nucleotides will occur by chance only once every 1×10^{18} nucleotides (4³⁰); so, even in the human genome of 3×10^9 nucleotide pairs, a DNA probe designed to match a unique 30-nucleotide sequence will be highly unlikely to hybridize—by chance anywhere else on the genome. The hybridization conditions can be set so that even a single mismatch will prevent hybridization to "near-miss" sequences. The exquisite specificity of nucleic acid hybridization can be easily appreciated by the in situ (Latin for "in place") hybridization experiment shown in Figure 8-32. As we will see throughout this chapter, nucleic acid hybridization has many uses in

Figure 8–32 In situ hybridization can be used to locate genes on isolated chromosomes. Here, six different DNA probes have been used to mark the locations of their complementary nucleotide sequences on human chromosome 5, isolated from a mitotic cell in metaphase. The DNA probes have been labeled with different chemical groups (see Figure 8–25B) and are detected using fluorescent antibodies specific for those groups. The chromosomal DNA has been partially denatured to allow the probes to base-pair with their complementary sequences. Both the maternal and paternal copies of chromosome 5 are shown, aligned side by side. Each probe produces two dots on each chromosome because chromosomes undergoing mitosis have already replicated their DNA; therefore, each chromosome contains two identical DNA helices. The technique employed here is nicknamed FISH, for fluorescence in situ hybridization. (Courtesy of David C. Ward.)

modern cell and molecular biology; one of the most powerful is in the cloning of DNA by the polymerase chain reaction, as we next discuss.

Genes Can Be Cloned in Vitro Using PCR

Genomic and cDNA libraries were once the only route to cloning genes. However, a powerful and versatile method for amplifying DNA, known as the **polymerase chain reaction (PCR)**, provides a more rapid and straightforward approach to DNA cloning, particularly in organisms whose complete genome sequence is known. Today, because genome sequences are abundant, cloning is often carried out by PCR.

Invented in the 1980s, PCR revolutionized the way that DNA and RNA are analyzed. The technique can amplify any nucleotide sequence selectively and is performed entirely in a test tube. Eliminating the need for bacteria makes PCR convenient and rapid—billions of copies of a nucleic acid sequence can be generated in a matter of hours. Starting with an entire genome, PCR allows DNA from a specified region—selected by the experimenter—to be greatly amplified, effectively purifying this DNA away from the remainder of the genome, which remains unamplified. Because of its power to greatly amplify nucleic acids, PCR is remarkably sensitive: the method can be used to detect the trace amounts of DNA in a drop of blood left at a crime scene or in a few copies of a viral genome in a sample of someone's saliva.

The success of PCR depends both on the selectivity of DNA hybridization and on the ability of DNA polymerase to copy a DNA template faithfully through repeated rounds of replication *in vitro*. As discussed in Chapter 5, this enzyme adds nucleotides to the 3' end of a growing strand of DNA (see Figure 5–4). To copy DNA, the polymerase requires a *DNA primer*—a short nucleotide sequence that provides a 3' end from which synthesis can begin. For PCR, the primers are designed by the experimenter, synthesized chemically, and, by hybridizing to genomic DNA, guide the polymerase to the part of the genome to copy. DNA primers can be designed to uniquely locate any position on a genome.

PCR is an iterative process in which the cycle of amplification is repeated many times. At the start of each cycle, the two strands of the double-strand DNA template are separated, and a different primer is annealed to each. These primers mark the right and left boundaries of the DNA to be amplified. DNA polymerase is then allowed to replicate each strand independently (Figure 8–33). In subsequent cycles, all the newly synthesized DNA molecules produced by the

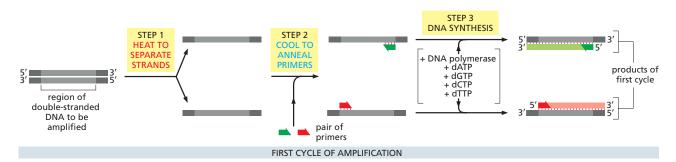

Figure 8–33 A pair of primers directs the synthesis of a desired segment of DNA in a test tube. Each cycle of PCR includes three steps: (1) The double-stranded DNA is heated briefly to separate the two strands. (2) The DNA is exposed to a large excess of a pair of specific primers—designed to bracket the region of DNA to be amplified—and the sample is cooled to allow the primers to hybridize to complementary sequences in the two DNA strands. (3) This mixture is incubated with DNA polymerase and the four deoxyribonucleoside triphosphates so that DNA can be synthesized, starting from the two primers. To amplify the DNA, the cycle is repeated many times by reheating the sample to separate the newly synthesized DNA strands (see Figure 8–34).

The technique depends on the use of a special DNA polymerase isolated from a thermophilic bacterium; this polymerase is stable at much higher temperatures than eukaryotic DNA polymerases, so it is not denatured by the heat treatment shown in step 1. The enzyme therefore does not have to be added again after each cycle.

MBOC7_ptr_ch08_475-562.indd 506 02/12/21 12:42 PM

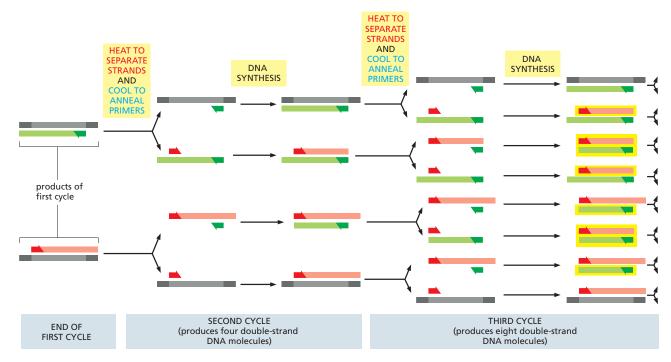

Figure 8–34 PCR uses repeated rounds of strand separation, hybridization, and synthesis to amplify DNA. As the procedure outlined in Figure 8–33 is repeated, all the newly synthesized fragments serve as templates in their turn. Because the polymerase and the primers remain in the sample after the first cycle, PCR involves simply heating and then cooling the same sample, in the same test tube, again and again. Each cycle doubles the amount of DNA synthesized in the previous cycle, so that within a few cycles, the predominant DNA is identical to the sequence bracketed by and including the two primers in the original template. In the example illustrated here, three cycles of reaction produce 16 DNA chains, 8 of which (boxed in yellow) correspond exactly to one or the other strand of the original bracketed sequence. After four more cycles, 240 of the 256 DNA chains will correspond exactly to the original sequence, and after several more cycles, essentially all of the DNA strands will be this length. Typically, 20–30 cycles are carried out to effectively clone a region of DNA starting from genomic DNA; the rest of the genome remains unamplified, and its concentration is therefore negligible compared with that of the amplified region (Movie 8.2).

polymerase serve as templates for the next round of replication (**Figure 8–34**). Through this iterative amplification process, many copies of the original sequence can be made—billions after about 20–30 cycles.

PCR is now the method of choice for cloning relatively short DNA fragments (say, under 10,000 nucleotide pairs). Each cycle takes only about 5 minutes, and automation of the whole procedure enables cell-free cloning of a DNA fragment in a few hours. The original template for PCR can be either DNA or RNA, so this method can be used to obtain either a genomic clone (complete with introns and exons) or a cDNA copy of an mRNA (Figure 8–35).

PCR Is Also Used for Diagnostic and Forensic Applications

The PCR method is extraordinarily sensitive; it can detect a single DNA molecule in a sample if at least part of the sequence of that molecule is known. Trace amounts of RNA can be analyzed in the same way by first transcribing them into DNA with reverse transcriptase. For these reasons, PCR is frequently employed for uses that go beyond simple cloning. For example, it can be used to detect invading pathogens at very early stages of infection. In this case, short sequences complementary to a segment of the infectious agent's genome are used as primers, and, after many cycles of amplification, even a few copies of an invading bacterial or viral genome in a human sample can be detected (Figure 8–36). For many infections, PCR has replaced the use of antibodies against microbial molecules to detect the presence of the invader. It is also used to verify the

MBOC7_ptr_ch08_475-562.indd 507 02/12/21 12:42 PM

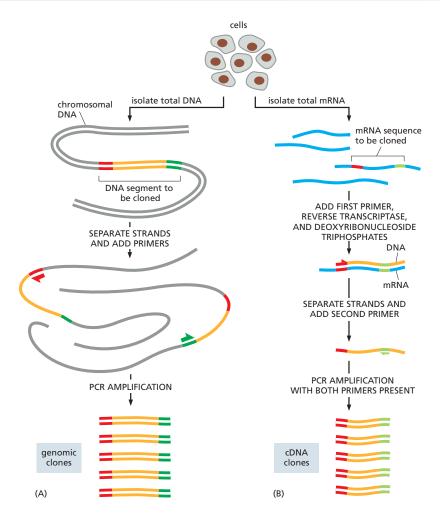

Figure 8-35 PCR can be used to obtain either genomic or cDNA clones. (A) To use PCR to clone a segment of chromosomal DNA, total genomic DNA is first purified from cells. PCR primers that flank the stretch of DNA to be cloned are added, and many cycles of PCR are completed (see Figure 8-34). Because only the DNA between (and including) the primers is amplified, PCR provides a way to obtain selectively any short stretch of chromosomal DNA in an effectively pure form. (B) To use PCR to obtain a cDNA clone of a gene, total mRNA is first purified from cells. The first primer is added to the population of mRNAs, and reverse transcriptase is used to make a DNA strand complementary to the specific RNA sequence of interest. The second primer is then added, and the DNA molecule is amplified through many cycles of PCR.

authenticity of a food source; for example, whether a sample of beef actually came from a cow.

Finally, PCR is now widely used in forensics. The method's extreme sensitivity allows forensic investigators to isolate DNA from minute traces of human blood or other tissue to obtain a *DNA fingerprint* of the person who left the sample behind. With the possible exception of identical twins, the genome of each human differs in DNA sequence from that of every other person on Earth. Using primer pairs targeted at genome sequences that are known to be highly variable in the human population, PCR makes it possible to generate a distinctive DNA fingerprint for any individual (Figure 8–37). Such forensic analyses can be used not only to help

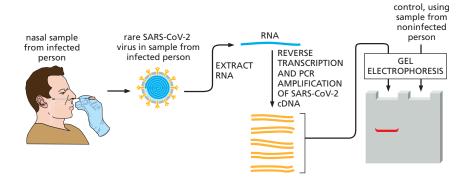

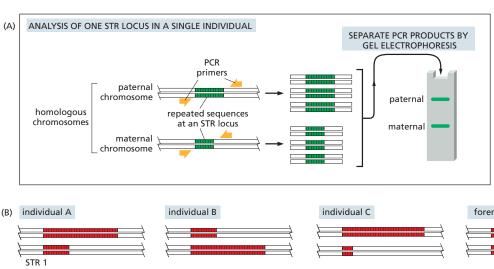

Figure 8-36 PCR can be used to detect the presence of a viral genome in a nasal sample. Because of its ability to amplify enormously the signal from a single molecule of nucleic acid, PCR is an extraordinarily sensitive method for detecting trace amounts of virus in a sample of saliva, blood, or other tissue, without the need to purify the virus. For the coronavirus SARS-CoV-2, the virus that causes COVID-19, the genome is a singlestrand molecule of RNA, as illustrated here. Typically, only a short segment of the viral genome (100-200 nucleotides) is amplified. Although it is possible to visualize the amplified DNA by gel electrophoresis as shown here, it is usually detected by rapid optical methods described later in the chapter (see Figure 8-64). Many other viruses that infect humans-such as HIVare detected using this strategy.

MBOC7_ptr_ch08_475-562.indd 508 02/12/21 12:42 PM

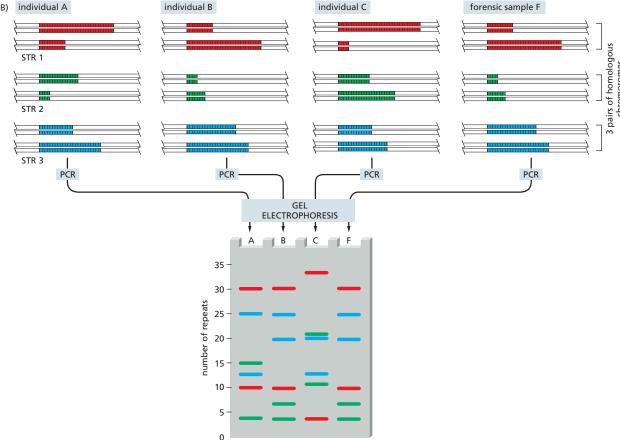

Figure 8–37 PCR is used in forensic science to distinguish one individual from another. The DNA sequences analyzed are short tandem repeats (STRs) composed of sequences such as CACACA... or GTGTGT.... STRs are found in various positions (loci) in the human genome. The number of repeats in each STR locus is highly variable in the population, ranging from 4 to 40 in different individuals. Because of the variability in these sequences, an individual will usually inherit a different number of repeats at each STR locus from his mother and from his father; two unrelated individuals, therefore, rarely contain the same pair of sequences at a given STR locus. (A) PCR using primers that recognize unique sequences on either side of one particular STR locus produces a pair of bands of amplified DNA from each individual, one band representing the maternal STR variant and the other representing the paternal STR variant. The length of the amplified DNA, and thus its position after gel electrophoresis, will depend on the exact number of repeats at the locus. (B) In the schematic example shown here, the same three STR loci are analyzed in samples from three suspects (individuals A, B, and C), producing six bands for each individual. Although different people can have several bands in common, the overall pattern is quite distinctive for each person. The band pattern can therefore serve as a DNA fingerprint to identify an individual nearly uniquely. The fourth lane (F) contains the products of the same PCR amplifications carried out on a hypothetical forensic DNA sample, which could have been obtained from a single hair or a tiny spot of blood left at a crime scene.

The more loci that are examined, the more confident one can be about the results. When examining the variability at 5–10 different STR loci, the odds that two random individuals would share the same fingerprint by chance are approximately 1 in 10 billion. In the case shown here, individuals A and C can be eliminated from inquiries, while B is a clear suspect. A similar approach is used routinely in paternity testing.

MBOC7_ptr_ch08_475-562.indd 509 02/12/21 12:42 PM

identify those who have done wrong, but also—equally important—to exonerate those who have been wrongfully accused.

PCR and Synthetic DNA Are Ideal Sources of Specific Gene Sequences for Cloning

PCR is a powerful technique for producing large amounts of specific DNA sequences *in vitro*. For many purposes—like those just described—there is no need to insert the PCR product in a bacterial plasmid for further analysis. Certain experiments, however, do require cloning of a specific DNA sequence in a plasmid for production in bacteria or other cells. Plasmids, for example, are important for the production and biochemical analysis of specific proteins, as we discuss later. In these cases, the desired DNA sequence can be readily produced by PCR amplification. Restriction nuclease cleavage sites in the PCR product are then cut to allow insertion into the appropriate plasmid as described earlier.

In recent years, a method called Gibson assembly (named for its inventor) has reduced the need for restriction nucleases in plasmid construction. A circular plasmid is cut open with a restriction nuclease that leaves blunt ends. In parallel, the desired DNA fragment is generated by PCR-mediated amplification from a genomic or cDNA source (see Figure 8-35). Importantly, the PCR primers are designed so that the ends of the PCR product contain 15-40 base pairs of the same sequence that surrounds the cut site in the plasmid. The PCR product and plasmid are then treated with a 5' exonuclease that degrades just one DNA strand at the ends of all DNA molecules, leaving single-strand sticky ends on the PCR product that will hybridize to complementary DNA on the plasmid (Figure 8-38). DNA polymerase then fills in the gaps, and DNA ligase joins the DNA strands. The resulting product is introduced into bacteria or other cell types as desired. This method can also be used to join a series of DNA fragments in a single plasmid. Each end of a DNA fragment must share sequence with the end of the fragment to which it will be joined. After treatment with 5' exonuclease, all the complementary sticky ends find each other and are thereby assembled in the correct order in the plasmid. Large genes can be assembled in this way from multiple subfragments.

Another key advance in recent years resulted from the rapid decline in the cost of methods for the chemical synthesis of DNA. Short single-strand DNA

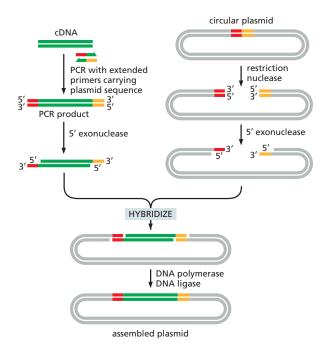

Figure 8-38 DNA cloning by Gibson assembly. It is often useful to insert a DNA fragment in a circular bacterial plasmid, as described earlier (see Figure 8-26). In Gibson assembly, as shown here, a plasmid is cleaved at a specific site with a restriction nuclease. In parallel, the DNA sequence to be cloned is amplified by PCR of a cDNA or other source. In addition to sequences complementary to the ends of the DNA to be amplified, the PCR primers include 15-40 nucleotides of sequence that matches the sequence on either side of the cut site in the linearized plasmid. The PCR product and plasmid are treated with a 5' exonuclease, which partially digests the DNA from the 5' end, resulting in single-strand 3' overhangs. These single-strand overhangs hybridize with their complementary sequence, neatly inserting the PCR product in the plasmid as shown. DNA polymerase is then added to fill in any gaps in the sequence, and DNA ligase seals the nicks to provide the fully assembled plasmid.

MBOC7_ptr_ch08_475-562.indd 510 02/12/21 12:42 PM

molecules, called *oligonucleotides*, are cheap to make and have been used for decades as probes and primers for PCR and other methods. Recently, it has become possible to cheaply synthesize much larger double-strand DNA molecules up to a few thousand base pairs in length. Thus, for many purposes, it is easier to order the desired DNA fragment from a DNA synthesis company than it is to produce it by PCR. If the ends of the synthetic DNA fragment are identical to those of a cut plasmid, then it is straightforward to insert the synthetic DNA in a plasmid by Gibson assembly (see Figure 8–38). Using multiple synthetic DNA fragments with interlocking ends, it is possible to assemble very large stretches of DNA (approaching the size of small genomes) from purely synthetic DNA.

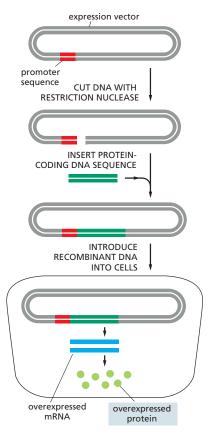

We will see later in this chapter that the study of gene and protein function often requires methods to produce a mutant gene or protein that carries specific point mutations that alter its function. In molecular biology, the production of a mutant DNA sequence, called *site-directed mutagenesis*, is readily achieved through the clever application of PCR and synthetic DNA. If the goal is a single point mutation, then one of the two PCR primers can be designed to include the mutation while still having sufficient flanking sequence to hybridize to the nonmutant source DNA. PCR then generates a DNA product with the mutation near one end. This mutant DNA fragment can be assembled in a plasmid with other portions of the gene. If multiple mutations in a DNA sequence are needed, then the simplest approach is to purchase a synthetic DNA containing the mutations and insert that into the desired plasmid.

DNA Cloning Allows Any Protein to Be Produced in Large Amounts

Using the genetic code (and assuming all intron and exon boundaries are known), the amino acid sequence of any protein coded in a genome can be deduced. As was discussed earlier, this sequence can often provide an important clue to the protein's function if found to be similar to the amino acid sequence of a protein that has already been studied (see Figure 8–22). Although this strategy is often successful, it typically provides only the likely biochemical function of the protein; for example, whether the protein resembles a kinase or a protease. It usually remains for the experimenter to verify (or refute) this assignment and, most important, to discover the protein's biological function in the whole organism.

An important approach in determining gene function is to alter the gene (or in some cases, its expression pattern), place the altered copy back into the organism, and deduce the function of the normal gene by the changes caused by its alteration. Various techniques to implement this strategy are discussed in the next section of this chapter. But it is equally important to study the biochemical and structural properties of a gene product, as outlined earlier in this chapter. One of the most important contributions of DNA cloning to cell and molecular biology is the ability to produce any protein, even the rare ones, in nearly unlimited amounts. Such high-level production is usually carried out in living cells using expression vectors (Figure 8–39). These are generally plasmids that have been designed to produce a large amount of stable mRNA that can be efficiently translated into protein when the plasmid is introduced into bacterial, yeast, insect, or

Figure 8–39 Production of large amounts of a protein from a protein-coding DNA sequence cloned into an expression vector and introduced into cells. A plasmid vector has been engineered to contain a highly active promoter, which causes unusually large amounts of mRNA to be produced from an adjacent protein-coding gene inserted into the plasmid vector. Depending on the characteristics of the cloning vector, the plasmid is introduced into bacterial, yeast, insect, or mammalian cells, where the inserted gene is efficiently transcribed and translated into protein. If the gene to be overexpressed has no introns (typical for genes from bacteria, archaea, and simple eukaryotes), it can simply be cloned from genomic DNA by PCR. For cloned animal and plant genes, it is often more convenient to obtain the gene as cDNA, either from a cDNA library (see Figure 8–30) or cloned directly by PCR from RNA isolated from the organism (see Figure 8–35). Alternatively, the DNA coding for the protein can be made by chemical synthesis.

MBOC7_ptr_ch08_475-562.indd 511 02/12/21 12:42 PM

Figure 8–40 Production of large amounts of a protein by using a plasmid expression vector. In this example, an expression vector that overproduces a DNA helicase has been introduced into bacteria. In this expression vector, transcription from this coding sequence is under the control of a viral promoter that becomes active only at a temperature of 37°C or higher. The total cell protein, either from bacteria grown at 25°C (no helicase protein made) or after a shift of the same bacteria to 42°C for up to 2 hours (helicase protein has become the most abundant protein species in the lysate), has been analyzed by SDS polyacrylamide-gel electrophoresis. (Courtesy of Kevin Hacker.)

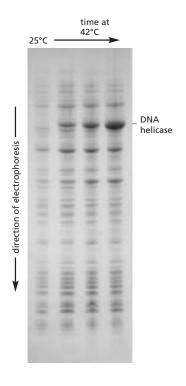

mammalian cells. To prevent the high level of the foreign protein from interfering with the cell's growth, the expression vector is often designed to delay the synthesis of the foreign mRNA and protein until shortly before the cells are harvested and lysed (Figure 8-40).

Because the desired protein made from an expression vector is produced inside a cell, it must be purified away from the host-cell proteins by chromatography after cell lysis. However, because the protein is such a plentiful species in the cell (often 1–10% of the total cell protein), the purification is usually easy to accomplish in only a few steps. As we saw earlier, it is also possible to fuse a molecular tag—a cluster of histidine residues or a small marker protein—to the expressed protein to facilitate easy purification by affinity chromatography (see Figure 8–11). A variety of expression vectors is available, each engineered to function in the type of cell in which the protein is to be made.

This technology is also used to make large amounts of many medically useful proteins, including hormones (such as insulin and growth factors) used as pharmaceuticals, and viral proteins for use in vaccines. Expression vectors also allow scientists to produce many proteins of biological interest in large enough amounts for detailed structural studies. Nearly all three-dimensional protein structures depicted in this book are of proteins produced in this way. Recombinant DNA techniques thus allow scientists to move with ease from protein to gene, and vice versa, so that the functions of both can be explored on multiple fronts (Figure 8–41).

DNA Can Be Sequenced Rapidly by Dideoxy Sequencing

Most current methods of manipulating DNA, RNA, and proteins rely on prior knowledge of the nucleotide sequence of the genome of interest. But how are these sequences determined in the first place? In the late 1970s, researchers developed several strategies for determining the nucleotide sequence of any purified DNA fragment. The method that became the most widely used is called dideoxy sequencing or Sanger sequencing (named after the scientist who

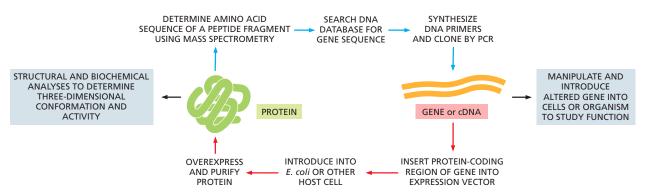

Figure 8–41 Recombinant DNA techniques make it possible to move experimentally from gene to protein and from protein to gene. If a gene has been identified (right), its protein-coding sequence can be inserted into an expression vector to produce large quantities of the protein (see Figure 8–39), which can then be studied biochemically or structurally. If a protein has been purified on the basis of its biochemical properties, mass spectrometry (see Figure 8–18) can be used to obtain a partial amino acid sequence, which is used to search a genome sequence for the corresponding nucleotide sequence. The complete gene can then be cloned by PCR from a sequenced genome (see Figure 8–35). The gene can also be manipulated and introduced into cells or organisms to study its function, a topic covered in the next section of this chapter.

MBOC7_ptr_ch08_475-562.indd 512 02/12/21 12:42 PM

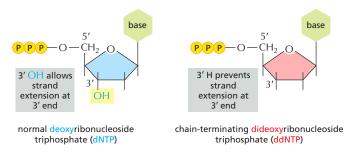

Figure 8–42 The dideoxy method of sequencing DNA relies on chain-terminating dideoxyribonucleoside triphosphates (ddNTPs). These ddNTPs are derivatives of the normal deoxyribonucleoside triphosphates (dNTPs) that lack the 3′-hydroxyl group. When incorporated into a growing DNA strand, they block further elongation of that strand.

invented it). This method uses DNA polymerase, along with special chain-terminating nucleotides called dideoxyribonucleoside triphosphates (Figure 8–42). Dideoxy sequencing reactions produce a collection of different DNA copies that terminate at every position in the original DNA sequence. In the original form of the method, four separate sequencing reactions were performed, each with a different dideoxyribonucleotide; the DNA copies were labeled with radioactivity and separated on polyacrylamide gels, which were then exposed to film to produce four ladders of bands that were read manually to reveal the sequence (see Figure 8–24C). This laborious method was replaced, beginning in the late 1980s, with technologies that are simpler, safer, and fully automated: robotic devices mix the reagents—including the four different chain-terminating dideoxyribonucleotides, each tagged with a different-colored fluorescent dye—and load the reaction samples onto long, thin capillary gels, which separate the reaction products into a series of distinct bands. A detector then records the color of each band, and a computer translates the information into a nucleotide sequence (Figure 8–43).

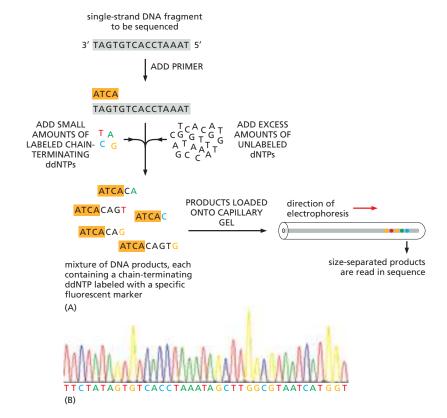

Figure 8-43 Automated dideoxy sequencing relies on a set of four ddNTPs, each bearing a uniquely colored fluorescent tag. (A) To determine the complete sequence of a single-strand fragment of DNA (gray), the DNA is first hybridized with a short DNA primer (orange). The DNA is then mixed with DNA polymerase (not shown), an excess amount of normal dNTPs, and a mixture containing small amounts of all four chain-terminating ddNTPs, each of which is labeled with a fluorescent tag of a different color. Because the chain-terminating ddNTPs will be incorporated only occasionally, each reaction produces a diverse set of DNA copies that terminate at different points in the sequence. The reaction products are loaded onto a long, thin capillary gel and separated by electrophoresis. A camera reads the color of each band on the gel and feeds the data to a computer that assembles the sequence (not shown). The sequence read from the gel will be complementary to the sequence of the original DNA molecule. (B) A tiny part of the data from such an automated sequencing run. Each colored peak represents a nucleotide in the DNA sequence.

MBOC7_ptr_ch08_475-562.indd 513 02/12/21 12:42 PM

Next-Generation Sequencing Methods Have Revolutionized DNA and RNA Analysis

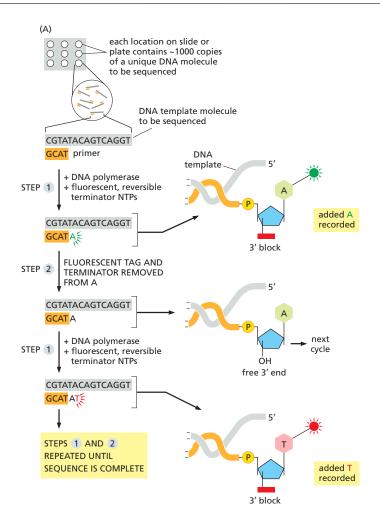

Automated dideoxy sequencing was used in the late 1990s and early 2000s to determine the nucleotide sequences of many genomes, including those of E. coli, yeast, fruit flies, nematode worms, and humans. It continues to be used today as a low-cost approach to small-scale sequencing. But newer methods, developed since 2005, are now used for most large-scale genomic analysis. With these so-called second-generation sequencing technologies, the cost of sequencing DNA has decreased dramatically, and the number of sequenced genomes has increased enormously. These rapid methods allow multiple genomes to be sequenced in a matter of weeks, enabling investigators to examine thousands of individual human genomes, catalog the variation in nucleotide sequences from people around the world, and uncover the mutations that increase the risk of various diseases, from cancer to autism. These methods have also made it possible to determine the genome sequence of extinct species, including Neanderthal man and the woolly mammoth (Movie 8.3). By sequencing genomes from many closely related species, they have also helped us understand the molecular basis of key evolutionary events in the tree of life. The ability to rapidly sequence DNA has had major effects on all branches of biology, agriculture, and medicine; it is almost impossible to imagine where we would be without it.

Several second-generation sequencing methods are now in wide use. The most common is *Illumina sequencing*, named for the company that manufactures the equipment and reagents. This approach begins with the construction of libraries of small DNA fragments that represent the DNA of the entire genome. Instead of using bacterial cells to generate these libraries, they are made using PCR amplification of billions of DNA fragments, each attached to the glass surface of a flow cell. The amplification is carried out so that the PCR-generated copies of an original DNA fragment, instead of floating away in solution, remain bound in proximity to that original DNA fragment—resulting in a cluster of about 1000 identical copies of that small bit of the genome. These clusters—a billion of which can fit in a single flow cell—are then sequenced at the same time; that is, in parallel.

Sequencing is achieved using chain-terminating nucleotides with uniquely colored fluorescent tags. Unlike conventional dideoxy sequencing, however, the fluorescent tag and the chemical group that blocks elongation are both removable. Once DNA polymerase has added the fluorescent, chain-terminating nucleotide, a photo of the reaction records the color to reveal the identity of the nucleotide that was added. The colored label and the chain-terminating group are then removed, allowing DNA polymerase to add the next nucleotide (Figure 8-44). This cycle is repeated hundreds of times to provide the sequence of the DNA in each cluster. Billions of these clusters are sequenced in parallel. The full genome sequence is then reconstructed in the computer by stitching together the sequences of all fragments, using the overlaps between fragments as a guide.

Illumina sequencing provides short DNA sequences of a few hundred nucleotides, which can sometimes be difficult to assemble into a complete genome sequence because of the many repeated sequences that are often found in genomes. Recently developed *third-generation sequencing methods* are capable of sequencing much longer DNA molecules. Two methods are particularly promising. The first is *single-molecule real-time* (*SMRT*) sequencing, which is carried out in an array of tiny wells, each containing a single DNA polymerase anchored to its bottom surface. The key to SMRT sequencing is that it uses deoxyribonucleoside triphosphates in which the fluorescent dye is attached to the terminal phosphate. As the DNA polymerase copies the template DNA, the binding of a fluorescent nucleotide generates a color signal that reveals its identity. The signal disappears when the fluorescent terminal phosphate is released during incorporation of the nucleotide into the growing DNA chain (see Figure 5–4). The sequence of the DNA is thus revealed by the colors of the brief fluorescent pulses that appear as

MBOC7_ptr_ch08_475-562.indd 514 02/12/21 12:42 PM

each nucleotide binds (Figure 8-45). Because very long DNA fragments (tens of kilobases) can be read by this method, and tens of thousands of reactions can be analyzed in parallel, complete genome sequences are well within reach in a short period of time. It is also possible to use circular DNA templates that are sequenced repeatedly on both strands, greatly improving the accuracy of the resulting sequence (see Figure 8-45C).

Another third-generation sequencing method, called nanopore sequencing, does not require DNA synthesis at all, but instead involves the transport of a single-strand DNA molecule through a tiny protein pore in a membrane. Voltage is applied across the membrane, resulting in current through the pore. The passage of nucleotides through the pore generates tiny shifts in electric current across the membrane, and the unique shape of each nucleotide base results in a slightly different disruption of the current. Measurement of these tiny current changes reveals the identity of each nucleotide as it passes through the pore. As in SMRT sequencing, extremely long DNAs can be sequenced in this manner. Another advantage is that modified nucleotides (such as 5-methylcytosine, depicted in Figure 7-46) can be identified because their effect on the current differs slightly from that of the unmodified nucleotide. Efforts are under way to allow direct sequencing of RNA by this approach as well. A major advantage of this method is that it can be performed with portable, handheld instruments that can be taken into the field, opening up exciting possibilities for DNA and RNA sequence analysis in global health and biology.

The development of cheaper and faster DNA sequencing methods has led to vast improvements in our ability to obtain and analyze genomic information. The

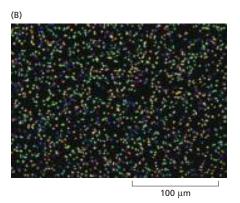

Figure 8-44 Principles of Illumina sequencing. (A) A genome or other large DNA sample is broken into millions of short fragments. These fragments are attached to the surface of a flow cell and amplified by PCR to generate DNA clusters, each containing about a thousand copies of a single DNA fragment. The large number of clusters provides complete coverage of the genome. In the first step, the anchored DNA clusters are incubated with DNA polymerase and a special set of all four nucleoside triphosphates (NTPs), each with two reversible chemical modifications: a uniquely colored fluorescent marker and a 3' chemical group that terminates DNA synthesis. Normal dNTPs are not present. After a nucleotide is added by DNA polymerase, a high-resolution digital camera records the color of the fluorescence at each DNA cluster. In the second step, the DNA is chemically treated to remove the fluorescent markers and chemical blockers. A new batch of fluorescent, reversible terminator NTPs is then added to initiate another round of DNA synthesis. These steps are repeated until the sequence is complete. The snapshots of each round of synthesis are compiled by computer to yield the sequence of each DNA fragment. The sequence of the millions of overlapping DNA fragments can then be used to reconstruct the complete genome sequence. (B) An image of the surface of the Illumina flow cell, showing individual DNA clusters after a round of DNA synthesis with colored NTPs. (B, courtesy of Illumina, Inc.)

MBOC7_ptr_ch08_475-562.indd 515 02/12/21 12:42 PM

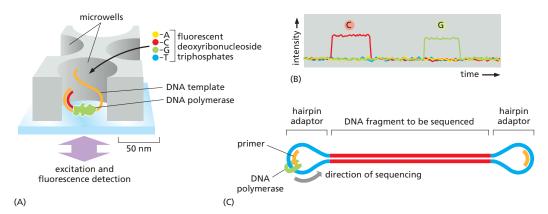

Figure 8–45 Single-molecule real-time (SMRT) sequencing. (A) SMRT sequencing uses a flow cell with thousands of tiny wells, each containing a single DNA polymerase, a single DNA template, and four fluorescently tagged deoxyribonucleoside triphosphates. Initial binding of a nucleotide to the template generates a local fluorescent signal that disappears when the terminal phosphates are removed during incorporation of the nucleotide into the DNA. To reduce background fluorescence from unbound nucleotides, only the bottom 30 nm of the well is illuminated, so that fluorescence is detected in a tiny volume (20 zeptoliters, or 20×10^{-21} liters). (B) Detection of fluorescent signals in the well reveals transient pulses of a single color, indicating the nucleotide that has been incorporated. (C) SMRT sequencing is often performed with a circular DNA template that is constructed by attaching hairpin adaptor DNAs to each end of the DNA to be sequenced. Using a primer that matches the adaptor, DNA polymerase can then replicate the template as shown in panel A. The enzyme used in this method is a *strand-displacing* polymerase that separates double-stranded DNA as it moves along the template, allowing it to continue around the entire circular molecule many times. Thus, both strands of the DNA are repeatedly sequenced, allowing the experimenter to eliminate sequence errors that arise from random mistakes made by the polymerase.

original "reference" sequence of the human genome, completed in 2003, cost more than \$1 billion and required many scientists from around the world working together for 13 years. The enormous progress made in the past 15 years has made it possible for a single person to complete the sequence of an individual human genome in less than a day, at a cost of less than \$1000.

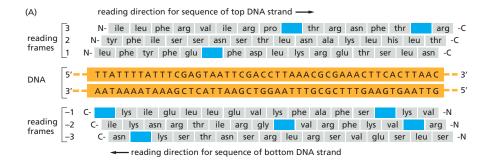

As mentioned above, next-generation sequencing methods are being developed for the direct sequencing of RNA. Currently, however, RNA sequencing is typically carried out by converting the RNA to cDNA (using reverse transcriptase) and using one of the methods described above for DNA sequencing. It is important to keep in mind that although genomes remain the same from cell to cell and from tissue to tissue, the RNA produced from the genome can vary enormously. We will see later in this chapter that sequencing the entire repertoire of RNA from a cell or tissue (known as **deep RNA sequencing**, or **RNA-seq**) is a powerful way to understand how the information present in the genome is used by different cells under different circumstances. RNA-seq is also a valuable tool for annotating genomes, as we discuss next.

To Be Useful, Genome Sequences Must Be Annotated

Long strings of nucleotides, at first glance, reveal nothing about how this genetic information directs the development of a living organism—or even what types of DNA, protein, and RNA molecules are produced by a genome. The process of **genome annotation** attempts to mark out all the genes (both protein-coding and noncoding) in a genome and ascribe a role to each. It also seeks to understand more subtle types of genome information, such as the *cis*-regulatory sequences that specify the time and place that a given gene is expressed and whether its mRNA undergoes alternative splicing to produce different protein isotypes. Clearly, this is a daunting task, and we are far short of completing it for any form of life, even the simplest bacterium. For many organisms, we know the approximate number of genes, and, for very simple organisms, we understand the functions of about half their genes.

How does one begin to make sense of a genome sequence? The first step is usually to translate *in silico* the entire genome into protein. There are six different

MBOC7_ptr_ch08_475-562.indd 516 02/12/21 12:42 PM

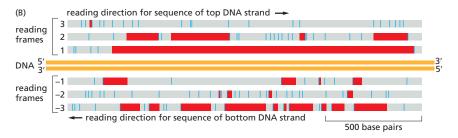

Figure 8–46 Finding the regions in a DNA sequence that encode a protein. (A) Any region of the DNA sequence can, in principle, code for six different amino acid sequences, because any one of three different reading frames can be used to interpret the nucleotide sequence on each strand. Note that a nucleotide sequence is always read in the 5′-to-3′ direction and encodes a polypeptide from the N-terminus to the C-terminus. For a random nucleotide sequence read in a particular frame, a stop signal for protein synthesis is encountered, on average, about once every 20 amino acids. In this sample sequence of 48 base pairs, each such signal (stop codon) is colored blue, and only reading frame 2 lacks a stop signal. (B) Search of a 1700-base-pair DNA sequence for a possible protein-encoding sequence. The information is displayed as in panel A, with each stop signal for protein synthesis denoted by a blue line. In addition, all of the regions between possible start and stop signals for protein synthesis are displayed as red bars. Only reading frame 1 actually encodes a protein, which is 475 amino acid residues long.

reading frames for any piece of double-stranded DNA (three on each strand). We saw in Chapter 6 that a random sequence of nucleotides, read in frame, will contain a stop codon about every 20 amino acids. In contrast, protein-coding regions will usually contain much longer stretches without stop codons (Figure 8–46). Known as open reading frames (ORFs), these usually signify bona fide protein-coding genes. This assignment is often "double-checked" by comparing the ORF amino acid sequence to the many databases of documented proteins from other species. If a match is found, even an imperfect one, it is very likely that the ORF will code for a functional protein (see Figure 8–22).

This strategy works very well for compact genomes, where intron sequences are rare and ORFs often extend for many hundreds of amino acids. However, in many animals and plants, the average exon size is 150–200 nucleotide pairs, and additional information is usually required to unambiguously locate all the exons of a gene. Although it is possible to search genomes for splicing signals and other features that help to identify exons (codon bias, for example), one of the most powerful methods is simply to sequence the total RNA produced from the genome in living cells. As can be seen in Figure 7–3, this RNA-seq information, when mapped onto the genome sequence, can be used to accurately locate all the introns and exons of even complex genes. By sequencing total RNA from different cell types, it is also possible to identify cases of alternative splicing.

RNA-seq also identifies noncoding RNAs produced by a genome. Although the function of some of them can be readily recognized (tRNAs or snoRNAs, for example), many have unknown functions and still others probably have no function at all. The existence of the many noncoding RNAs and our relative ignorance

MBOC7_ptr_ch08_475-562.indd 517 02/12/21 12:42 PM

of their function is the main reason that we know only the approximate number of genes in the human genome.

But even for protein-coding genes that have been unambiguously identified, we still have much to learn. Thousands of genomes have been sequenced, and we know from comparative genomics that many organisms share the same basic set of proteins. However, the functions of a very large number of identified proteins remain unknown. Depending on the organism, approximately one-third of the proteins encoded by a sequenced genome do not clearly resemble any protein that has been studied biochemically. This observation underscores a limitation of the emerging field of genomics: although comparative analysis of genomes reveals a great deal of information about the relationships between genes and organisms, it often does not provide immediate information about how these genes function or what roles they have in the physiology of an organism. Comparison of the full gene complement of several thermophilic bacteria, for example, does not reveal why these bacteria thrive at temperatures exceeding 70°C. And examination of the genome of the incredibly radiation-resistant bacterium Deinococcus radiodurans does not explain how this organism can survive a blast of radiation that can shatter glass. Further biochemical and genetic studies, like those described in the other sections of this chapter, are required to determine how genes, and the proteins they produce, function in the context of living organisms.

Summary

DNA cloning allows a copy of any specific part of a DNA or RNA sequence to be selected from the millions of other sequences in a cell and produced in unlimited amounts in pure form. DNA sequences can be amplified by inserting the desired DNA fragment into a self-replicating genetic element such as a bacterial plasmid. Bypassing cloning vectors and bacterial cells altogether, the polymerase chain reaction (PCR) allows DNA cloning to be performed directly with a DNA polymerase and DNA primers—provided that the DNA sequence of interest is already known.

The procedures used to obtain DNA clones that correspond in sequence to mRNA molecules are the same, except that a DNA copy of the mRNA sequence, called cDNA, is first made. Unlike genomic DNA clones, cDNA clones lack intron sequences, making them the clones of choice for analyzing the protein product of a gene.

Nucleic acid hybridization reactions provide a sensitive means of detecting any nucleotide sequence of interest. The enormous specificity of this hybridization reaction allows any single-strand sequence of nucleotides to be labeled with a radioisotope or chemical and used as a probe to find a complementary partner strand, even in a cell or cell extract that contains millions of different DNA and RNA sequences. DNA hybridization also makes it possible to use PCR to amplify any section of any genome once its sequence is known.

The nucleotide sequence of any genome can be determined rapidly and simply by using highly automated techniques that are based on several different strategies. Comparison of the genome sequences of different organisms allows us to trace the evolutionary relationships among genes and organisms, and it has proved valuable for discovering new genes and predicting their functions.

STUDYING GENE FUNCTION AND EXPRESSION

Ultimately, our goal is to understand how genes—and the proteins they encode—function in the intact organism. Although it may seem counterintuitive, one of the most direct ways to find out what a gene does is to see what happens to the organism when that gene is missing. Studying mutant organisms that have acquired changes or deletions in their nucleotide sequences is a time-honored practice in biology and forms the basis of the important field of **genetics**. Because mutations can disrupt cell processes, mutants often hold the key to understanding gene function. In the classical genetic approach, one begins by isolating mutants

MBOC7_ptr_ch08_475-562.indd 518 02/12/21 12:42 PM

that have an interesting or unusual appearance: fruit flies with white eyes or curly wings, for example. Working backward from the **phenotype**—the appearance or behavior of the individual—one then determines the organism's **genotype**, the form of the gene responsible for that characteristic (**Panel 8-1**).

Today, with numerous genome sequences available, the exploration of gene function often begins with a DNA sequence. Here, the challenge is to translate sequence into function. One approach, discussed earlier in the chapter, is to search databases for well-characterized proteins that have similar amino acid sequences to the protein encoded by a new gene. From there, the protein can be overexpressed and purified, and the methods described earlier in this chapter can be employed to study its biochemical properties and three-dimensional structure. But to determine directly a gene's function in a cell or organism, the most effective approach involves studying mutants that either lack the gene or express an altered version of it. Determining which cell processes have been disrupted or compromised in such mutants will usually shed light on a gene's biological role.

In this section, we describe several approaches to determining a gene's function, starting either from an individual with an interesting phenotype or from a DNA sequence. We begin with the classical genetic approach, which starts with a *genetic screen* for isolating mutants of interest and then proceeds toward identification of the gene or genes responsible for the observed phenotype. We then describe the set of techniques that are sometimes called reverse genetics, in which one begins with a gene or gene sequence and attempts to determine its function. This approach often involves some intelligent guesswork—searching for similar sequences in other organisms or determining when and where a gene is expressed—as well as generating mutant organisms and characterizing their phenotype.

Classical Genetic Screens Identify Random Mutants with Specific Abnormalities

Before the advent of gene cloning technology, most genes were identified by the abnormalities produced when the gene was mutated. Indeed, the very concept of the gene was deduced from the heritability of such abnormalities. This classical genetic approach—identifying the genes responsible for mutant phenotypes—is most easily performed in organisms that reproduce rapidly and are amenable to genetic manipulation, such as bacteria, yeasts, nematode worms, and fruit flies. Although spontaneous mutants can sometimes be found by examining extremely large populations—thousands or tens of thousands of individual organisms—isolating mutant individuals is much more efficient if one generates mutations with chemicals or radiation that damage DNA. By treating organisms with such mutagens, very large numbers of mutant individuals can be created quickly and then screened for a particular defect of interest.

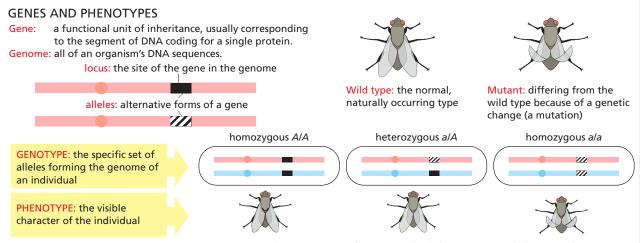

An alternative approach to chemical or radiation mutagenesis is called *insertional mutagenesis*. This method relies on the fact that exogenous DNA inserted randomly into the genome can produce mutations if the inserted fragment interrupts a gene or its regulatory sequences. The inserted DNA, whose sequence is known, then serves as a molecular tag that aids in the subsequent identification and cloning of the disrupted gene (**Figure 8–47**). In *Drosophila*, the use of the transposable P element to inactivate genes has revolutionized the study of gene function in the fly. Transposable elements (see Table 5–4, p. 308) have also been used to generate mutations in bacteria, yeast, mice, and the flowering plant *Arabidopsis*.

Once a collection of mutants in a model organism has been produced, one generally must examine thousands of individuals to find the altered phenotype of interest. Such a search is called a **genetic screen**, and the larger the genome, the less likely it is that any particular gene will be mutated. Therefore, the larger the genome of an organism, the bigger the screening task becomes. The phenotype being screened for can be simple or complex. Simple phenotypes are easiest to detect: one can screen many organisms rapidly, for example, for mutations

Figure 8–47 Insertional mutant of the snapdragon, Antirrhinum. A mutation in a single gene coding for a regulatory protein causes leafy shoots (left) to develop in place of flowers, which occur in the normal plant (right). The mutation causes cells to adopt a character that would be appropriate to a different part of the normal plant, so instead of a flower, the cells produce a leafy shoot. allele A is dominant (relative to a); allele a is recessive (relative to A) In the example above, the phenotype of the heterozygote is the same as that of one of the homozygotes; in cases where it is different from both, the two alleles are said to be codominant.

For simplicity, the cycle is shown for only one chromosome/chromosome pair.

The greater the distance between two loci on a single chromosome, the greater is the chance that they will be separated by crossing-over occurring at a site between them. If two genes are thus reassorted in x% of gametes, they are said to be separated on a chromosome by a genetic map distance of x map units (or x centimorgans).

MBOC7_ptr_ch08_475-562.indd 520 02/12/21 12:42 PM

TYPES OF MUTATIONS

POINT MUTATION: maps to a single site in the genome, corresponding to a single nucleotide pair or a very small part of a single gene

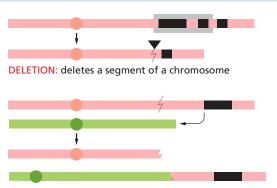

INVERSION: inverts a segment of a chromosome

lethal mutation: causes the developing organism to die prematurely.

conditional mutation: produces its phenotypic effect only under certain conditions, called the restrictive conditions. Under other conditions—the permissive conditions—the effect is not seen. For a temperature-sensitive mutation, the restrictive condition typically is high temperature, while the permissive condition is low temperature.

loss-of-function mutation: either reduces or abolishes the activity of the gene. These are the most common class of mutations. Loss-of-function mutations are usually recessive—the organism can usually function normally as long as it retains at least one normal copy of the affected gene. null mutation: a loss-of-function mutation that completely abolishes the activity of the gene.

TRANSLOCATION: breaks off a segment from one chromosome and attaches it to another

gain-of-function mutation: increases the activity of the gene or makes it active in inappropriate circumstances; these mutations are usually dominant.

dominant-negative mutation: dominant-acting mutation that blocks gene activity, causing a loss-of-function phenotype even in the presence of a normal copy of the gene. This phenomenon occurs when the mutant gene product interferes with the function of the normal gene product. suppressor mutation: suppresses the phenotypic effect of another mutation, so that the double mutant seems normal. An intragenic suppressor mutation lies within the gene affected by the first mutation; an extragenic suppressor mutation lies in a second gene—often one whose product interacts directly with the product of the first.

TWO GENES OR ONE?

Given two mutations that produce the same phenotype, how can we tell whether they are mutations in the same gene? If the mutations are recessive (as they most often are), the answer can be found by a complementation test.

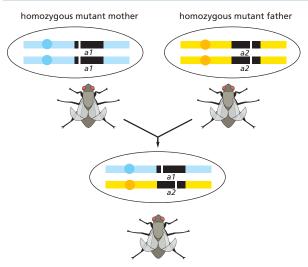

In the simplest type of complementation test, an individual who is homozygous for one mutation is mated with an individual who is homozygous for the other. The phenotype of the offspring gives the answer to the question.

COMPLEMENTATION: **MUTATIONS IN TWO DIFFERENT GENES**

homozygous mutant mother homozygous mutant father

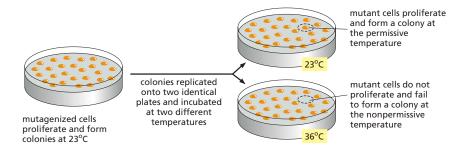

> hybrid offspring shows normal phenotype: one normal copy of each gene is present

NONCOMPLEMENTATION: TWO INDEPENDENT MUTATIONS IN THE SAME GENE

hybrid offspring shows mutant phenotype: no normal copies of the mutated gene are present

MBOC7_ptr_ch08_475-562.indd 521 02/12/21 12:42 PM

that make it impossible for the organism to survive in the absence of a particular amino acid or nutrient.

Because defects in genes that are required for fundamental cell processes—RNA synthesis and processing or cell-cycle control, for example—are usually lethal, the functions of these genes are often studied in individuals with **conditional mutations**. The mutant individuals function normally as long as *permissive* conditions prevail but demonstrate abnormal gene function when subjected to *restrictive* (*nonpermissive*) conditions. In organisms with *temperature-sensitive mutations*, for example, the abnormality can be switched on and off experimentally simply by changing the ambient temperature; thus, a cell containing a temperature-sensitive mutation in a gene essential for survival will die at a restrictive temperature but proliferate normally at a permissive temperature (**Figure 8–48**). The temperature-sensitive gene in such a mutant usually contains a point mutation that causes a subtle change in its protein product; for example, the mutant protein may function normally at low temperatures but unfold at higher temperatures.

Temperature-sensitive mutations were crucial to find the bacterial genes that encode the proteins required for DNA replication. The mutants were identified by screening populations of mutagen-treated bacteria for cells that stop making DNA when they are warmed from 30°C to 42°C. These mutants were later used to identify and characterize the corresponding DNA replication proteins (discussed in Chapter 5). Similarly, screens for temperature-sensitive mutations in yeast led to the identification of many proteins involved in regulating the cell cycle, as well as many proteins involved in moving proteins through the secretory pathway. Related screening approaches demonstrated the function of enzymes involved in the principal metabolic pathways of bacteria and yeast (discussed in Chapter 2) and identified many of the gene products responsible for the orderly development of the *Drosophila* embryo (discussed in Chapter 21).

Mutations Can Cause Loss or Gain of Protein Function

Gene mutations are generally classed as *loss of function* or *gain of function*. A loss-of-function mutation results in a gene product that either does not work or works too little; thus, it can reveal the normal function of the gene. A gain-of-function mutation results in a gene product that works too much, works at the wrong time or place, or works in a new way (Figure 8–49).

An important early step in the genetic analysis of any mutant cell or organism is to determine whether the mutation causes a loss or a gain of function. A standard test is to determine whether the mutation is *dominant* or *recessive*. A

Figure 8–48 Screening for temperature-sensitive bacterial or yeast mutants. Mutagenized cells are plated out at the permissive temperature. They divide and form colonies, which are transferred to two identical Petri dishes by replica plating. One of these plates is incubated at the permissive temperature, the other at the restrictive temperature. Cells containing a temperature-sensitive mutation in a gene essential for proliferation can divide at the normal (permissive) temperature but fail to divide at the elevated (restrictive) temperature.

Figure 8-49 Gene mutations that affect their protein product in different ways. In this example, the wild-type protein has a specific cell function denoted by the red rays. Mutations that eliminate this function or inactivate it at higher temperatures are shown. The conditional mutant protein carries an amino acid substitution (red) that prevents its proper folding at 37°C but allows the protein to fold and function normally at 25°C. Such temperature-sensitive conditional mutations are especially useful for studying essential genes (see Figure 8-48). In some cases, a mutation increases the activity of the mutant protein.

MBOC7_ptr_ch08_475-562.indd 522 02/12/21 12:42 PM

dominant mutation is one that still causes the mutant phenotype in the presence of a single copy of the wild-type gene. A recessive mutation is one that is no longer able to cause the mutant phenotype in the presence of a single wild-type copy of the gene. In the majority of cases, recessive mutations are loss of function and dominant mutations are gain of function—although cases have been described in which a loss-of-function mutation is dominant or a gain-of-function mutation is recessive. It is easy to determine if a mutation is dominant or recessive. One simply mates a mutant with a wild type to obtain diploid cells or organisms. The progeny from the mating will be heterozygous for the mutation. If the mutant phenotype is no longer observed, one can conclude that the mutation is recessive and is very likely to be a loss-of-function mutation (see Panel 8–1).

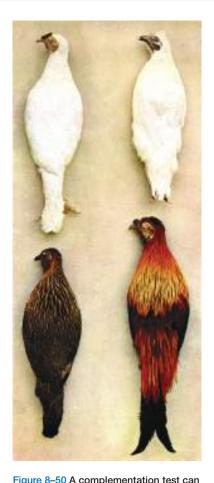

Complementation Tests Reveal Whether Two Mutations Are in the Same Gene or Different Genes

A large-scale genetic screen can turn up many different mutations that show the same phenotype. These defects might lie in different genes that function in the same process or they might represent different mutations in the same gene. Alternative forms of the same gene are known as alleles. The most common difference between alleles is a substitution of a single nucleotide pair, but different alleles can also bear deletions, substitutions, and duplications. How can we tell, then, whether two mutations that produce the same phenotype occur in the same gene or in different genes? If the mutations are recessive—if, for example, they represent a loss of function of a particular gene—a complementation test can be used to ascertain whether the mutations fall in the same gene or in different genes. To test complementation in a diploid organism, an individual that is homozygous for one mutation—that is, it possesses two identical alleles of the mutant gene in question—is mated with an individual that is homozygous for the other mutation. If the two mutations are in the same gene, the offspring show the mutant phenotype, because they still will have no normal copies of the gene in question. If, in contrast, the mutations fall in different genes, the resulting offspring show a normal phenotype, because they retain one normal copy (and one mutant copy) of each gene; the mutations thereby complement one another and restore a normal phenotype (Figure 8-50). Complementation testing of mutants identified during genetic screens has revealed, for example, that 5 different genes are required for yeast to digest the sugar galactose, 20 genes are needed for E. coli to build a functional flagellum, 48 genes are involved in assembling bacteriophage T4 viral particles, and hundreds of genes are involved in the development of an adult nematode worm from a fertilized egg.

Gene Products Can Be Ordered in Pathways by Epistasis Analysis

Once a set of genes involved in a particular biological process has been identified, it is helpful to determine the order in which the genes function. Gene order is perhaps easiest to explain for metabolic pathways, where, for example, enzyme A is necessary to produce the substrate for enzyme B. In this case, we would say that the gene encoding enzyme A acts before (upstream of) the gene encoding enzyme B in the pathway. Similarly, where one protein regulates the activity of another protein, we would say that the former gene acts before the latter. Gene order can, in many cases, be determined purely by genetic analysis without any knowledge of the mechanism of action of the gene products involved.

Suppose we have a biosynthetic process consisting of a sequence of steps, such that performance of step B requires completion of the preceding step A; and suppose gene A is required for step A, and gene B is required for step B. Then a null mutation (a mutation that abolishes function) in gene A will arrest the process at step A, regardless of whether gene B is functional or not, whereas a null mutation in gene B will cause arrest at step B only if gene A is still active. In such a case, gene A is said to be *epistatic* to gene B. By comparing the phenotypes of different combinations of mutations, we can therefore discover the order in which

reveal that mutations in two different genes are responsible for the same abnormal phenotype. When an albino (white) bird from one strain is bred with an albino from a different strain, the resulting offspring (bottom) have normal coloration. This restoration of the wild-type plumage indicates that the two white breeds lack color because of recessive mutations in different genes. (From W. Bateson, Mendel's Principles of Heredity, 1st ed. Cambridge, UK: Cambridge University Press. 1913.)

MBOC7_ptr_ch08_475-562.indd 523 02/12/21 12:42 PM

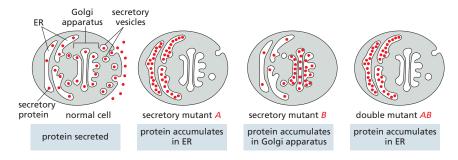

Figure 8–51 Using genetics to determine the order of function of genes. In normal cells, secretory proteins are loaded into vesicles, which fuse with the plasma membrane to secrete their contents into the extracellular medium. Two mutants, *A* and *B*, fail to secrete proteins. In mutant *A*, secretory proteins accumulate in the ER. In mutant *B*, secretory proteins accumulate in the Golgi. In the double mutant *AB*, proteins accumulate in the ER; this indicates that the gene defective in mutant *A* acts before the gene defective in mutant *B* in the secretory pathway.

the genes act. This type of analysis is called **epistasis analysis**. As an example, the pathway of protein secretion in yeast has been analyzed in this way. Different mutations in this pathway cause proteins to accumulate aberrantly in the endoplasmic reticulum (ER) or in the Golgi apparatus. When a yeast cell is engineered to carry both a mutation that blocks protein processing in the ER *and* a mutation that blocks processing in the Golgi apparatus, proteins accumulate in the ER. This indicates that proteins must pass through the ER before being sent to the Golgi before secretion (**Figure 8–51**). Strictly speaking, an epistasis analysis can only provide information about gene order in a pathway when both mutations are null alleles. When the mutations retain partial function, their epistasis interactions can be difficult to interpret.

Sometimes, a double mutant will show a new or more severe phenotype than either single mutant alone. This type of genetic interaction is called a *synthetic* phenotype, and if the phenotype is death of the organism, it is called *synthetic lethality*. In most cases, a synthetic phenotype indicates that the two genes act in two different parallel pathways, either of which is capable of mediating the same cell process. Thus, when both pathways are disrupted in the double mutant, the process fails altogether, and the synthetic phenotype is observed.

Mutations Responsible for a Phenotype Can Be Identified Through DNA Analysis

Once a collection of mutant organisms with interesting phenotypes has been obtained, the next task is to identify the gene or genes responsible for the altered phenotype. If the phenotype has been produced by insertional mutagenesis, locating the disrupted gene is fairly simple. DNA fragments containing the insertion (a transposon or a retrovirus, for example) are amplified by PCR, and the nucleotide sequence of the flanking DNA is determined. The gene affected by the insertion can then be identified by a computer-aided search of the complete genome sequence of the organism.

If a DNA-damaging chemical was used to generate the mutations, identifying the inactivated gene is often more laborious, but there are several powerful strategies available. With recent advances in DNA sequencing technology, it is possible to simply determine the genome sequence of the mutant organism and identify the affected gene by comparison with the wild-type sequence. Because of the continual accumulation of neutral mutations, there will probably be differences between the two genome sequences in addition to the mutation responsible for the phenotype. One way of proving that a mutation is causative is to introduce the putative mutation back into a normal organism and determine whether or not it causes the mutant phenotype. We will discuss how this is accomplished later in the chapter.

Rapid and Cheap DNA Sequencing Has Revolutionized Human Genetic Studies

Genetic screens in model experimental organisms have been spectacularly successful in identifying genes and relating them to various phenotypes, including many that are conserved between these organisms and humans. But how can we

MBOC7_ptr_ch08_475-562.indd 524 02/12/21 12:42 PM

study humans directly? They do not reproduce rapidly, cannot be treated with mutagens, and, if they have a defect in an essential process such as DNA replication, would die long before birth.

Despite their limitations compared to model organisms, humans are becoming increasingly attractive subjects for genetic studies. Because the human population is so large, spontaneous nonlethal mutations have arisen many times in all human genes. A substantial proportion of these mutations remains in the genomes of present-day humans. Deleterious mutations are discovered when the mutant individuals call attention to themselves by seeking medical help.

With the recent advances that have enabled the sequencing of entire human genomes cheaply and quickly, we can now identify such mutations and study their evolution and inheritance in ways that were impossible even a few years ago. By comparing the sequences of thousands of human genomes from all around the world, we can begin to identify directly the DNA differences that distinguish one individual from another. These differences hold clues to our evolutionary origins and can be used to explore the roots of disease.

Linked Blocks of Polymorphisms Have Been Passed Down from Our Ancestors

When we compare the sequences of multiple human genomes, we find that any two individuals will differ in roughly 1 nucleotide pair in 1000. As described in Chapter 4, most sequence variation results from substitution of a single nucleotide, called a *single-nucleotide variant* (*SNV*), while other variation is due to structural chromosome changes such as deletions and rearrangements. Human genetic studies have benefited greatly from a particularly common type of sequence variants, present in more than 1% of the population, that are called **polymorphisms**—most of which are **single-nucleotide polymorphisms**, or SNPs (Figure 8–52). Although these common variants can be found throughout the genome, they are not scattered randomly—or even independently. Instead, they tend to travel in groups called **haplotype blocks**—combinations of polymorphisms that are inherited as a unit.

To understand why such haplotype blocks exist, we need to consider our evolutionary history. It is thought that modern humans expanded from a relatively small population—perhaps around 10,000 individuals—that existed in Africa about 200,000 years ago. Among that small group of our ancestors, some individuals will have carried one set of genetic variants, others a different set. The chromosomes of a present-day human represent a shuffled combination of chromosome segments from different members of this small ancestral group of people. Because only about 2000 generations separate us from them, large segments of these ancestral chromosomes have passed from parent to child, unbroken by the crossover events that occur during meiosis. As described in Chapter 5, only a few crossovers occur between each set of homologous chromosomes during each meiosis (see Figure 5–52).

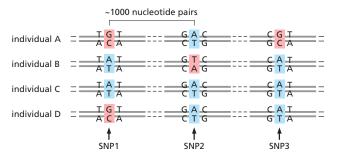

Figure 8–52 Single-nucleotide polymorphisms (SNPs) are sites in the genome where two or more alternative choices of a nucleotide are common in the population. Most such variations in the human genome occur at locations where they do not significantly affect a gene's function.

MBOC7_ptr_ch08_475-562.indd 525 02/12/21 12:42 PM

As a result, certain sets of DNA sequences—and their associated polymorphisms—have been inherited in linked groups, with little genetic rearrangement across the generations. These are the haplotype blocks. Like genes that exist in different allelic forms, haplotype blocks also come in a limited number of variants that are common in the human population, each representing a combination of DNA polymorphisms passed down from a particular ancestor long ago.

Sequence Variants Can Aid the Search for Mutations Associated with Disease

Mutations that give rise, in a reproducible way, to rare but clearly defined differences, such as albinism, hemophilia, or congenital deafness, can often be identified by studies of affected families. Such single-gene, or monogenic, disorders are referred to as *Mendelian* because their pattern of inheritance is easy to track. Moreover, individuals who inherit the causative mutation will exhibit the disorder irrespective of environmental factors such as diet or exercise. But for many common disorders, the genetic roots are more complex. Instead of a single allele of a single gene, such disorders stem from a combination of contributions from multiple genes. And often, environmental factors have strong influences on the severity of the disorder. For these *multigenic* conditions, such as diabetes or arthritis, population studies are often helpful in tracking down the genes that increase the risk of getting the disease.

In population studies, investigators collect DNA samples from a large number of people who have the disease and compare them to samples from a group of people who do not have the disease. They look for variants—SNPs, for example—that are more common among the people who have the disease. Because DNA sequences that are close together on a chromosome tend to be inherited together, the presence of such SNPs could indicate that an allele that increases the risk of the disease might lie nearby (Figure 8–53). Although, in principle, the disease could be caused by the SNP itself, the culprit is much more likely to be a change that is merely linked to the SNP as part of a haplotype block.

Such *genome-wide association studies* have been used to search for genes that predispose individuals to common diseases, including diabetes, coronary artery disease, rheumatoid arthritis, and even depression. For many of these conditions, the DNA polymorphisms identified increase the risk of disease only slightly. Moreover, environmental factors (diet and exercise, for example) play an important role in the onset and severity of the disease. Nonetheless, the identification of potential disease genes linked to polymorphisms is leading to a mechanistic understanding of some of our most common disorders.

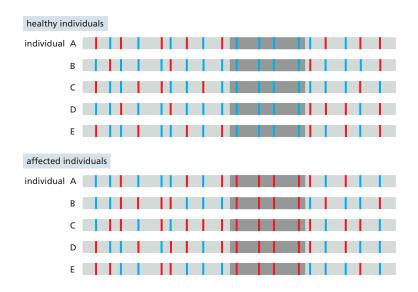

Figure 8-53 Genes that affect the risk of developing a common disease can often be tracked down through linkage to SNPs. Here, the patterns of SNPs are compared between two sets of individuals—a set of healthy controls and a set affected by a particular common disease. A segment of a typical chromosome is shown. For most polymorphic sites in this segment, it is a random matter whether an individual has one SNP variant (red vertical bars) or another (blue vertical bars); this same randomness is seen both for the control group and for the affected individuals. However, in the part of the chromosome that is shaded in dark gray, a bias is seen: most healthy individuals have the blue SNP variants, whereas most affected individuals have the red SNP variants. This suggests that this region contains or is close to a gene that is genetically linked to these red SNP variants and which predisposes individuals to the disease. Using carefully selected controls and thousands of affected individuals, this approach can help track down disease-related genes, even when they confer only a slight increase in the risk of developing the disease.

MBOC7_ptr_ch08_475-562.indd 526 02/12/21 12:42 PM

Genomics Is Accelerating the Discovery of Rare Mutations That Predispose Us to Serious Disease

The polymorphisms that have allowed us to identify some of the genes that increase our risk of disease are common. They arose long ago in our evolutionary past and are now present, in one form or another, in a substantial portion of the population. Such polymorphisms are thought to account for about 90% of the differences between one person's genome and another. But when we try to tie these common variants to differences in disease susceptibility or other heritable traits, such as height, we find that they do not have as much predictive power as we had anticipated: thus, for example, most confer relatively small increases—less than twofold—in the risk of developing a common disease.

Part of the problem is that many of the mutations that are directly responsible for complex human diseases appeared more recently in our evolutionary history—during a period when the human population expanded from the few million individuals who existed 10,000 years ago to the more than 7 billion who exist today. Because recent mutations occur more rarely than the ancient polymorphisms that are common in the human population, they could slip through the genome-wide association studies just described.

In contrast to polymorphisms, rare DNA variants—those much less frequent in humans than SNPs—can have large effects on the risk of developing some common diseases. For example, numerous loss-of-function mutations, each individually rare, have been found to increase greatly the predisposition to autism and schizophrenia. Many of these are *de novo* mutations, which arose spontaneously in the germ-line cells of one or the other parent. The fact that these mutations arise spontaneously with some frequency could help explain why these common disorders—each observed in about 1% of the population—remain with us, even though the affected individuals might leave few or no descendants. These rare mutations can arise in any one of hundreds of different genes, which could explain much of the clinical variability of autism and schizophrenia.

Now that DNA sequencing has become fast and inexpensive, the most efficient way to identify these rare, large-effect mutations is by comparing the genomes of large numbers of affected individuals with those of unaffected controls. When the key variants are identified, the major challenge is then to determine how they affect the individuals who carry them and how small variations in multiple genes produce the disease phenotype.

The Cellular Functions of a Known Gene Can Be Studied with Genome Engineering

As we have seen, classical genetics starts with a mutant phenotype and identifies the mutations, and consequently the genes, responsible for it. Recombinant DNA technology has made possible a different type of genetic approach that is used widely in a variety of species. Instead of beginning with a mutant organism and using it to identify a gene and its protein, an investigator can start with a particular gene and proceed to make mutations in it, creating mutant cells or organisms so as to analyze the gene's function. Because this approach reverses the traditional direction of genetic discovery—proceeding from genes to mutations, rather than vice versa—it is sometimes referred to as *reverse genetics*. And because the genome of the organism is deliberately altered in a particular way, this approach is also called *genome engineering* or *genome editing*. We shall see in this chapter that this approach can be scaled up so that whole collections of organisms can be created, each of which has a different gene altered.

There are several ways a gene of interest can be altered. In the simplest, the gene can simply be deleted from the genome, although in a diploid organism, this requires that both copies—one on each chromosome homolog—be deleted. Such *gene knockouts* are especially useful if the gene is not essential. The gene in question (even if it is essential) can also be replaced by one that is expressed in the wrong tissue or at the wrong time in development; this type of manipulation

MBOC7_ptr_ch08_475-562.indd 527 02/12/21 12:42 PM

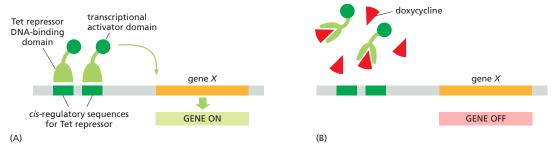

Figure 8–54 Engineered genes can be turned on and off with small molecules. Here, the DNA-binding portion of a bacterial protein (the tetracycline, Tet, repressor) has been fused to a portion of a mammalian transcriptional activator and expressed in cultured mammalian cells. The engineered gene X, present in place of the normal gene, has its usual gene control region replaced by cis-regulatory sequences recognized by the tetracycline repressor. In the absence of doxycycline (a particularly stable version of tetracycline), the engineered gene is expressed; in the presence of doxycycline, the gene is turned off because the drug causes the tetracycline repressor to dissociate from the DNA. This strategy can also be used in mice by incorporating the engineered genes into the germ line. In many tissues, the gene can be turned on and off simply by adding doxycycline to or removing it from the animal's water. If the tetracycline repressor construct is placed under the control of a tissue-specific gene control region, the engineered gene will be turned on and off only in that tissue.

often provides important clues to the gene's normal function. In a particularly powerful approach, a gene of interest can be modified to be expressed at will by the experimenter (Figure 8–54). Finally, genes can also be engineered so that they are expressed normally in most cell types and tissues but deleted in certain cell types or tissues selected by the experimenter (see Figure 5–66). This approach is especially useful when a gene has different roles in different tissues.

It is also possible to make subtler changes to a gene. It is sometimes useful to make slight changes in a protein's structure so that one can begin to dissect which portions of a protein are important for its function. The activity of an enzyme, for example, can be studied by changing a single amino acid in its active site. It is also possible, through genome engineering, to create new types of proteins in an animal. For example, a gene can be fused to the gene for a fluorescent protein. When this altered gene is introduced into the genome, the protein can be tracked in the living organism by monitoring its fluorescence.

Altered genes can be created in several ways. Perhaps the simplest is to chemically synthesize the DNA that makes up the gene. In this way, the investigator can specify any type of variant of the normal gene. It is also possible to construct altered genes using recombinant DNA technology, as described earlier in this chapter. Once obtained, altered genes can be introduced into cells in a variety of ways. DNA can be microinjected into mammalian cells with a glass micropipette or introduced by a virus that has been engineered to carry foreign genes. In plant cells, genes can be introduced by a technique called particle bombardment: DNA samples are painted onto tiny gold beads and then literally shot through the cell wall with a specially modified gun. *Electroporation* is sometimes used for introducing DNA into bacteria and some other cells. In this technique, a brief electric shock renders the cell membrane temporarily permeable, allowing foreign DNA to enter the cytoplasm.

To be most useful to experimenters, the altered gene, once it is introduced into a cell, must recombine with the cell's genome so that the normal gene is replaced. In simple organisms such as bacteria and yeasts, this process occurs with high frequency using the cell's own homologous recombination machinery, as described in Chapter 5. In more complex organisms that have elaborate developmental programs, the procedure is more complicated because the altered gene must be introduced into the germ line, as we next describe.

Animals and Plants Can Be Genetically Altered

Animals and plants that have been genetically engineered by gene deletion or gene replacement are called **transgenic organisms**, and any foreign or modified genes that are added are called **transgenes**. We discuss transgenic plants later

MBOC7_ptr_ch08_475-562.indd 528 02/12/21 12:42 PM

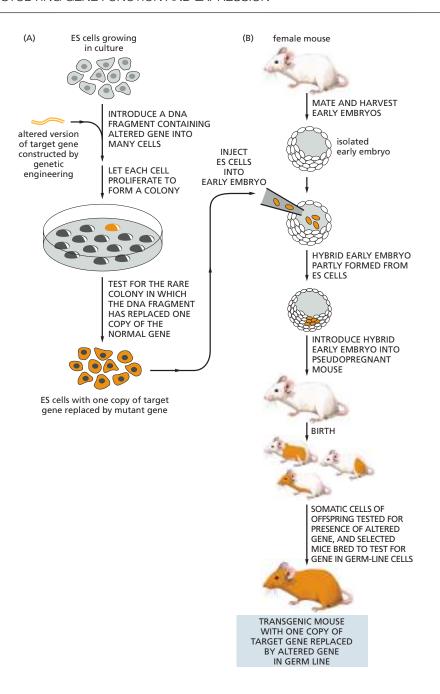

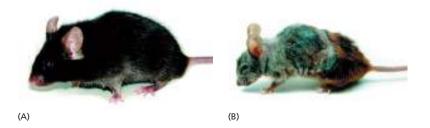

Figure 8-55 Summary of the procedures used for making gene replacements in mice. (A) In the first step, an altered version of the gene is introduced into cultured embryonic stem (ES) cells (described in Chapter 22). Only a few ES cells will have their corresponding normal genes replaced by the altered gene through a homologous recombination event. These cells can be identified by PCR and cultured to produce many descendants, each of which carries an altered gene in place of one of its two normal corresponding genes. (B) In the next step of the procedure, these altered ES cells are injected into a very early mouse embryo: the cells are incorporated into the growing embryo, and a mouse produced by such an embryo will contain some somatic cells (indicated by orange) that carry the altered gene. Some of these mice will also contain germ-line cells that contain the altered gene: when bred with a normal mouse, some of the progeny of these mice will contain one copy of the altered gene in all of their cells.

The mice with the transgene in their germ line are then bred to produce both a male and a female animal, each heterozygous for the gene replacement (that is, they have one normal and one mutant copy of the gene). When these two mice are mated (not shown), one-fourth of their progeny will be homozygous for the altered gene.

in this chapter and, for now, concentrate our discussion on transgenic mice. If a DNA molecule carrying a mutated mouse gene is transferred into a mouse cell, it is possible to direct the mutant gene to replace the normal gene by homologous recombination. By exploiting these gene-targeting events, any specific gene can be altered or inactivated in a mouse cell by a direct gene replacement. In the case in which both copies of the gene of interest are completely inactivated or deleted, the resulting animal is called a *knockout* mouse. The technique is summarized in **Figure 8–55**.

The ability to prepare transgenic mice lacking a known normal gene was a major advance, and the technique has been used to determine the functions of many mouse genes (Figure 8–56). If the gene functions in early development, a knockout mouse will usually die before it reaches adulthood. These lethal defects can be carefully analyzed to help determine the function of the missing gene.

MBOC7_ptr_ch08_475-562.indd 529 02/12/21 12:42 PM

As described in Chapter 5, an especially useful type of transgenic animal takes advantage of a site-specific recombination system to excise—and thus disable—the target gene in a particular place or at a particular time (see Figure 5–66). In this case, the target gene in embryonic stem (ES) cells is replaced by a fully functional version of the gene that is flanked by a pair of the short DNA sequences, called *lox sites*, that are recognized by the *Cre recombinase* protein. The transgenic mice that result are phenotypically normal. They are then mated with transgenic mice that express the Cre recombinase gene under the control of an inducible promoter. In the specific cells or tissues in which Cre is switched on, it catalyzes recombination between the lox sequences—excising a target gene and eliminating its activity (see Figure 22–7).

The Bacterial CRISPR System Has Been Adapted to Edit Genomes in a Wide Variety of Species

One of the difficulties in making transgenic mice by the procedure just described is that the introduced DNA molecule (bearing the experimentally altered gene) often inserts at random in the genome, and many ES cells must therefore be screened individually to find one that has the correct gene replacement.

Creative use of the CRISPR system, discovered in bacteria as a defense against viruses, has largely solved this problem. As described in Chapter 7, the CRISPR system uses a guide RNA sequence to target (through complementary base-pairing) double-stranded DNA, which it then cleaves (see Figure 7-81). The gene coding for the key component of this system, the bacterial Cas9 protein, has been transferred into a variety of organisms, where it greatly simplifies the process of making transgenic organisms (Figure 8-57A and B). The basic strategy is as follows: Cas9 protein is expressed in cultured cells along with a guide RNA designed by the experimenter to target a particular location on the genome. The Cas9 and guide RNA associate, the complex is brought to the matching sequence on the genome, and the Cas9 protein makes a double-strand break. As we saw in Chapter 5, these breaks are usually repaired by nonhomologous end joining, which often results in small sequence errors or deletions that disrupt gene function. In many cases, this repair process is sufficient to inactivate the gene, particularly if it produces a frameshift near the beginning of the coding sequence. If the goal is a precise gene knockout or replacement, then Cas9 and guide RNA can be co-expressed in ES cells with an altered homologous gene sequence, which the cell uses to repair the double-strand break by homologous recombination. In this way, the normal gene can be selectively damaged by the CRISPR system and replaced at high efficiency by an experimentally altered gene.

The CRISPR system has a variety of other uses. Its particular power lies with its ability to target Cas9 to thousands of different positions across a genome through the simple rules of complementary base-pairing. Thus, if a catalytically inactive Cas9 protein is fused to a transcription activator or repressor, it is possible, in principle, to turn any gene on or off by providing a guide RNA that matches a unique sequence in the gene promoter (Figure 8–57C and D; Movie 8.4).

The CRISPR system has several advantages over other strategies for experimentally manipulating gene expression. First, it is relatively easy for the experimenter to design the guide RNA: it simply follows standard base-pairing

Figure 8-56 Transgenic mice engineered to express a mutant DNA helicase show premature aging. The helicase, encoded by the Xpd gene, is involved in both transcription and DNA repair. Compared with a wild-type mouse of the same age (A), a transgenic mouse that expresses a defective version of Xpd (B) exhibits many of the symptoms of premature aging, including osteoporosis, emaciation, early graying, infertility, and reduced life span. The mutation in Xpd used here impairs the activity of the helicase and mimics a mutation that in humans causes trichothiodystrophy, a disorder characterized by brittle hair, skeletal abnormalities, and a very reduced life expectancy. These results indicate that an accumulation of DNA damage can contribute to the aging process in both humans and mice. (From J. de Boer et al., Science 296:1276-1279, 2002. With permission from AAAS.)

MBOC7_ptr_ch08_475-562.indd 530 02/12/21 12:42 PM

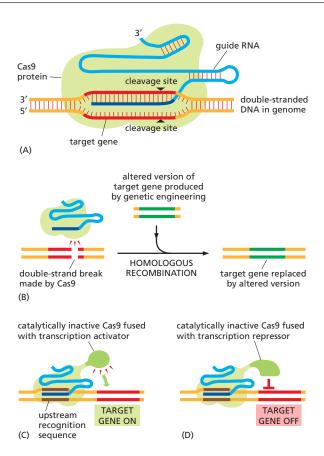

Figure 8-57 Use of CRISPR to study gene function in a wide variety of species. (A) The Cas9 protein (artificially expressed in the species of interest) binds to a guide RNA, designed by the experimenter and also expressed. The portion of RNA in light blue is needed for associations with Cas9; that in dark blue is specified by the experimenter to match a position on the genome. The only other requirement is that the adjacent genome sequence includes a short PAM (protospacer adjacent motif, not shown) that is needed for Cas9 to cleave. As described in Chapter 7, this sequence allows the CRISPR system in a bacterium to distinguish its own genome from that of invading viruses. (B) When Cas9 is directed to make a double-strand break in a gene, the break is generally repaired by nonhomologous end joining (not shown), which introduces local sequence errors that can disrupt gene function. A more precise mutation can be made as shown here, where the double-strand break is repaired by homologous recombination with an altered gene provided by the experimenter. (C, D) By using a mutant form of Cas9 that can no longer cleave DNA, Cas9 can be used to activate a normally dormant gene (C) or turn off an actively expressed gene (D). (Adapted from P. Mali et al., Nat. Methods 10:957-963, 2013.)

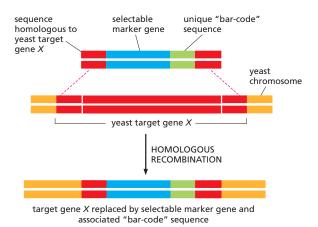

convention. Second, the gene to be controlled does not have to be modified; the CRISPR strategy exploits DNA sequences already present in the genome. Third, numerous genes can be controlled simultaneously. Cas9 has to be expressed only once, but many guide RNAs can be expressed in the same cell; this strategy allows the experimenter to turn on or off a whole set of genes at once.

The export of the CRISPR system from bacteria to virtually all other experimental organisms (including mice, zebrafish, worms, flies, rice, and wheat) has revolutionized the study of gene function. Like the earlier discovery of restriction nucleases, this breakthrough came from scientists studying a fascinating phenomenon in bacteria without—at first—realizing the enormous impact these discoveries would have on all aspects of biology.

Large Collections of Engineered Mutations Provide a Tool for Examining the Function of Every Gene in an Organism

Extensive collaborative efforts have produced comprehensive libraries of mutations in a variety of model organisms, including *S. cerevisiae*, *Caenorhabditis elegans*, *Drosophila*, *Arabidopsis*, and even the mouse. The ultimate aim in each case is to produce a collection of mutant strains in which every gene in the organism—one at a time—has been systematically deleted or altered in such a way that it can be conditionally disrupted. Collections of this type provide an invaluable resource for investigating gene function on a genomic scale. For example, a large collection of mutant organisms can be screened for a particular phenotype. Like the classic genetic approaches described earlier, this is one of the most powerful ways to identify the genes responsible for a particular phenotype. Unlike the classical genetic approach, however, the set of mutants is "pre-engineered," so that there is no need to rely on chance events such as

MBOC7_ptr_ch08_475-562.indd 531 02/12/21 12:42 PM

spontaneous mutations or transposon insertions. In addition, each of the individual mutations within the collection is often engineered to contain a distinct molecular "bar code"—in the form of a unique DNA sequence—designed to make identification of the altered gene rapid and routine (Figure 8–58).

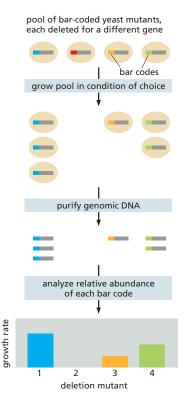

In *S. cerevisiae*, the task of generating a complete set of 6000 mutants, each missing only one gene, was accomplished in the early 2000s. Because each mutant strain has an individual bar-code sequence embedded in its genome, a large mixture of engineered strains can be grown under various selective test conditions—such as nutritional deprivation, a temperature shift, or the presence of various drugs—and the cells that survive can be rapidly identified by the unique sequence tags present in their genomes. By assessing how well each mutant in the mixture fares, one can begin to discern which genes are essential, useful, or irrelevant for growth under the various conditions (Figure 8–59).

Similar methods can be applied to human cells using the CRISPR system described earlier. Using viral expression vectors, a large library of different guide RNAs can be expressed in a cell population, such that only one guide RNA is expressed in each cell, along with Cas9. After growth of the cells under various conditions, surviving cells are subjected to genomic sequencing to measure the abundance of guide RNAs in the population. Guide RNAs that target genes essential for survival will disappear from the population, whereas those that enhance survival will be enriched—providing important clues about the function of those genes under the conditions tested.

The insights generated by examining mutant libraries can be considerable. For example, studies of an extensive collection of mutants in *Mycoplasma genitalium*—the organism with the smallest known genome—have identified the minimum complement of genes essential for cellular life. Growth under laboratory conditions requires about three-quarters of the 480 protein-coding genes in *M. genitalium*. Approximately 100 of these essential genes are of unknown function, which suggests that a surprising number of the basic molecular mechanisms that underlie life have yet to be discovered.

Figure 8–59 Genome-wide screens for fitness using a large pool of bar-coded yeast deletion mutants. A large pool of yeast mutants, each with a different gene deleted and present in equal amounts, is grown under conditions selected by the experimenter. Some mutants (blue) grow normally, but others show reduced growth (orange and green) or no growth at all (red). The fitness of each mutant is experimentally determined in the following way. After the growth phase is completed, genomic DNA (isolated from the mixture of strains) is purified, and the relative abundance of each mutant is determined by quantifying the level of the DNA bar code matched to each deletion. This can be done by sequencing the pooled genomic DNA. In this way, the contribution of every gene to growth under the specified condition can be rapidly ascertained. This type of study has revealed that of the approximately 6000 coding genes in yeast, only about 1000 are essential under standard growth conditions.

Figure 8-58 Making bar-coded collections of mutant organisms. A deletion construct for use in yeast contains DNA sequences (red) homologous to each end of a target gene X, a selectable marker gene (blue), and a unique "bar-code sequence approximately 20 nucleotide pairs in length (green). This DNA is introduced into yeast cells, where it readily replaces the target gene by homologous recombination. Cells that carry a successful gene replacement are identified by expression of the selectable marker gene, typically a gene that provides resistance to a drug. By using a collection of such constructs, each specific for one gene, a library of yeast mutants was constructed containing a mutant for every gene. Essential genes cannot be studied this way, as their deletion from the genome causes the cells to die. In this case, the target gene is replaced by a version of the gene that can be regulated by the experimenter (see Figure 8-54). The gene can then be turned off, and the effect of this can be monitored before the cells die.

MBOC7_ptr_ch08_475-562.indd 532 02/12/21 12:42 PM

Collections of mutant organisms are also available for many animal and plant species. For example, it is possible to "order," by phone or e-mail from a consortium of investigators, a deletion or insertion mutant for almost all coding genes in *Drosophila*. Likewise, a nearly complete set of mutants exists for the model plant *Arabidopsis*. And the adaptation of the CRISPR system for use in mice means that, in the near future, we can expect to be able to turn on or off—at will—each gene in the mouse genome at different stages of development. Although we are still ignorant about the function of most genes in most organisms, these technologies allow an exploration of gene function on a scale that was unimaginable a decade ago.

RNA Interference Is a Simple and Rapid Way to Test Gene Function

Although knocking out (or conditionally expressing) a gene in an organism and studying the consequences is the most powerful approach for understanding the functions of the gene, *RNA interference* (*RNAi*, for short) is an alternative, particularly convenient approach. As discussed in Chapter 7, this method exploits a natural mechanism used in many plants, animals, and fungi to protect themselves against viruses and transposable elements. The technique introduces into a cell or organism a double-strand RNA molecule whose nucleotide sequence matches that of part of the gene to be inactivated. After the RNA is processed, it hybridizes with the target-gene RNA (either mRNA or noncoding RNA) and reduces its expression by the mechanisms shown in Figure 7–78.

RNAi is frequently used to inactivate genes in *Drosophila* and mammalian cell culture lines. Indeed, a set of 15,000 *Drosophila* RNAi molecules (one for every coding gene) allows researchers, in several months, to test the role of every fly gene in any process that can be monitored using cultured cells. RNAi has also been widely used to study gene function in whole organisms, including the nematode *C. elegans*. When working with worms, introducing the double-stranded RNA is quite simple: either the RNA can be injected directly into the intestine of the worm or the worm can be fed with *E. coli* engineered to produce the RNA (**Figure 8–60**). The RNA is amplified and distributed throughout the body of the worm, where it inhibits expression of the target gene in different tissue types. RNAi is being used to help in assigning functions to the entire complement of worm genes (**Figure 8–61**).

A related technique has also been applied to mice. In this case, the RNAi molecules are not injected or fed to the mouse; rather, recombinant DNA techniques are used to make transgenic animals that express the RNAi under the control of an inducible promoter. Often this is a specially designed RNA that can fold back on itself and, through base-pairing, produce a double-strand region that is recognized by the RNAi machinery. In the simplest cases, the process inactivates only the genes that exactly match the RNAi sequence. Depending on the

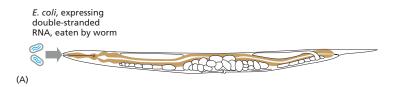

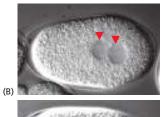

Figure 8–60 Gene function can be tested by RNA interference. (A) Double-stranded RNA (dsRNA) can be introduced into *C. elegans* by feeding the worms *E. coli* that express the dsRNA. (B) In a wild-type worm embryo, the egg and sperm pronuclei (*red arrowheads*) come together in the posterior half of the embryo shortly after fertilization. (C) In an embryo in which a particular gene has been inactivated by RNAi, the pronuclei fail to migrate. This experiment revealed an important but previously unknown function of this gene in embryonic development. (B and C, from P. Gönczy et al., *Nature* 408:331–336, 2000. Reproduced with permission of SNCSC.)

20 μm

MBOC7_ptr_ch08_475-562.indd 533 02/12/21 12:42 PM

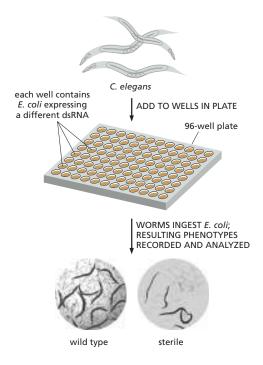

Figure 8-61 RNA interference provides a convenient method for conducting genome-wide genetic screens. In this experiment, each well in this 96-well plate is filled with E. coli that produce a different double-stranded RNA than that produced by E. coli in other wells. Each interfering RNA matches the nucleotide sequence of a single C. elegans gene, thereby inactivating it. About 10 worms are added to each well. where they ingest the genetically modified bacteria. The plate is incubated for several days, which gives the RNAs time to inactivate their target genes-and the worms time to grow, mate, and produce offspring. The plate is then examined in a microscope, which can be controlled robotically, to screen for genes that affect the worms' ability to survive, reproduce, develop, and behave. Shown here are normal worms alongside worms that show an impaired ability to reproduce because of inactivation of a particular "fertility" gene. (From B. Lehner et al., Nat. Genet. 38:896-903, 2006. With permission from Nature.)

inducible promoter used, the RNAi can be produced only in a specified tissue or only at a particular time in development, allowing the functions of the target genes to be analyzed in elaborate detail.

RNAi is a simple and efficient tool for analysis of gene function in many organisms, but it has several potential limitations compared with true genetic knockouts. For unknown reasons, RNAi does not efficiently inactivate all genes. Moreover, within whole organisms, certain tissues may be resistant to the action of RNAi (for example, neurons in nematodes). Another problem arises because many organisms contain large gene families, the members of which exhibit sequence similarity. RNAi therefore sometimes produces "off-target" effects, inactivating related genes in addition to the targeted gene. One strategy to avoid such problems is to use multiple small RNA molecules matched to different regions of the same gene. Ultimately, the results of any RNAi experiment must be viewed as a strong clue to, but not necessarily a proof of, normal gene function.

Reporter Genes Reveal When and Where a Gene Is Expressed

We have just discussed some of the approaches that can be used to assess a gene's function in cultured cells or, even better, in the intact organism. Although this information is crucial to understanding gene function, it does not generally reveal the molecular mechanisms through which the gene product works in the cell. For example, genetics on its own rarely tells us all the places in the organism where the gene is expressed or how its expression is controlled. It does not necessarily reveal whether the gene acts in the nucleus, the cytosol, on the cell surface, or in one of the numerous other compartments of the cell. And it does not reveal how a gene product might change its location or its expression pattern when the external environment of the cell changes. Key insights into gene function can be obtained by simply observing when and where a gene is expressed. A variety of approaches, most involving some form of genetic engineering, can easily provide this critical information.

As discussed in detail in Chapter 7, cis-regulatory DNA sequences, located upstream or downstream of the coding region, control gene transcription. These regulatory sequences, which determine precisely when and where the gene is

MBOC7_ptr_ch08_475-562.indd 534 02/12/21 12:42 PM

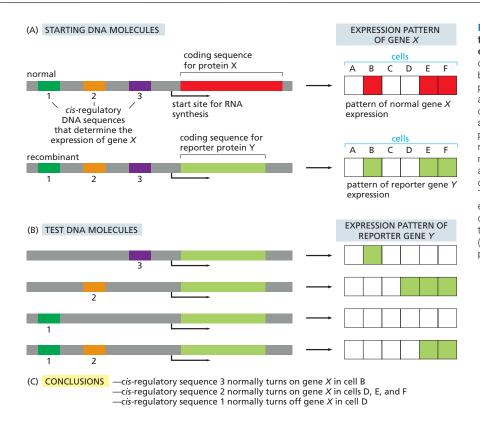

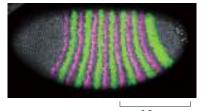

Figure 8-62 Using a reporter protein to determine the pattern of a gene's expression. (A) In this example, the coding sequence for protein X is replaced by the coding sequence for reporter protein Y. The expression patterns for X and Y are the same. (B) Various fragments of DNA containing candidate cis-regulatory sequences are added in combinations to produce test DNA molecules encoding reporter gene Y. These recombinant DNA molecules are then tested for expression after introducing them into a variety of different types of mammalian cells. The results are summarized in (C). For experiments in eukarvotic cells, two commonly used reporter proteins are the enzyme β -galactosidase (β -gal) (see Figure 7-30) and green fluorescent protein (GFP) (see Figure 9-16).

expressed, can be easily studied by placing a reporter gene under their control and introducing these recombinant DNA molecules into cells (Figure 8–62). In this way, the normal expression pattern of a gene can be determined, as well as the contribution of individual *cis*-regulatory sequences in establishing this pattern.

Reporter genes also allow any protein to be tracked over time in living cells. Here, the reporter gene typically encodes a fluorescent protein, often **green fluorescent protein (GFP)**, the molecule that gives luminescent jellyfish their greenish glow. The GFP is simply attached—in the coding frame—to the protein-coding gene of interest. The resulting *GFP fusion protein* often behaves in the same way the normal protein does, and its location can be monitored by fluorescence microscopy, a topic that is discussed in the next chapter (see Figure 9–10). GFP fusion has become a standard strategy for tracking not only the location but also the movement of specific proteins in living cells.

In Situ Hybridization Can Reveal the Location of mRNAs and Noncoding RNAs

It is also possible to directly observe the time and place that an RNA product of a gene is expressed using *in situ hybridization*. For protein-coding genes, this strategy often provides the same general information as the reporter gene approaches described above; however, it is crucial for genes whose final product is RNA rather than protein. We encountered *in situ* hybridization earlier in the chapter (see Figure 8–32); it relies on the basic principles of nucleic acid hybridization. Typically, tissues are gently fixed so that their RNA is retained in an exposed form that can hybridize with a labeled complementary DNA or RNA probe. In this way, the patterns of differential gene expression can be observed in tissues, and the location of specific RNAs can be determined (**Figure 8–63**). An advantage of *in situ* hybridization over other approaches is that genetic engineering is not required. Thus, it is often simpler and faster and can be used for genetically intractable species.

0.2 mm

Figure 8–63 In situ hybridization to mRNAs reveals patterns of gene expression during development.

Expression of specific regulatory genes is localized in the early Drosophila embryo, forming a series of stripes (see Figures 7–29 and 7–30). In this image, expression of the genes eve (magenta) and ftz (green) has been revealed by in situ hybridization with differently colored fluorescent probes. DNA is lightly stained with a white fluorescent dye to label all nuclei in the embryo. (Courtesy of Erik Clark and Angela DePace.)

MBOC7_ptr_ch08_475-562.indd 535 02/12/21 12:42 PM

Figure 8–64 RNA levels can be measured by quantitative RT-PCR. The fluorescence measured is generated by a dye that fluoresces only when bound to the double-strand DNA products of the RT-PCR (see Figure 8–34). The *red sample* has a higher concentration of the mRNA being measured than does the *blue sample*, because it requires fewer PCR cycles to reach the same half-maximal concentration of double-stranded DNA. On the basis of this difference, the relative amounts of the mRNA in the two samples can be precisely determined.

Expression of Individual Genes Can Be Measured Using Quantitative RT-PCR

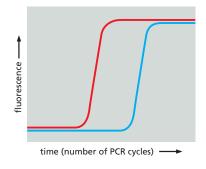

Although reporter genes and in situ hybridization accurately reveal patterns of gene expression, they are not the most powerful methods for quantifying amounts of individual RNAs in cells. A more accurate method is based on the principles of PCR. Called quantitative RT-PCR (reverse transcription-polymerase chain reaction), this method begins with the total population of RNA molecules purified from a tissue or a cell culture. It is important that no DNA be present in the preparation; it must be purified away or enzymatically degraded. Two DNA primers that specifically match the mRNA of interest are added, along with reverse transcriptase, DNA polymerase, and the four deoxyribonucleoside triphosphates needed for DNA synthesis. The first round of synthesis is the reverse transcription of the RNA into DNA using one of the primers. Next, a series of heating and cooling cycles allows the amplification of that DNA strand by PCR (see Figure 8-34). The quantitative part of this method relies on a direct relationship between the rate at which the PCR product is generated and the original concentration of the mRNA species of interest. By adding chemical dyes to the PCR that fluoresce only when bound to double-stranded DNA, a simple fluorescence measurement can be used to track the progress of the reaction and thereby accurately deduce the starting concentration of the mRNA that is amplified (Figure 8-64). This technique is relatively fast and simple to perform in the laboratory and is the preferred method for accurate measurement of mRNA levels from a specific gene or small group of genes. It is also used routinely to detect rare viral RNAs to determine if a person is infected.

Global Analysis of mRNAs by RNA-seq Provides a Snapshot of Gene Expression

As discussed in Chapter 7, a cell expresses only a subset of the many thousands of genes available in its genome; moreover, this subset differs from one cell type to another or, in the same cell, from one extracellular environment to the next. One way to determine which genes are being expressed by a population of cells or a tissue is to measure all of the RNAs that are being produced.

Global sequencing of all RNAs, or *RNA-seq*, provides the most direct approach for cataloging the RNAs produced by a cell or tissue. As mentioned earlier in this chapter, this approach uses reverse transcriptase to copy all RNAs into cDNAs, which are then fragmented and sequenced by next-generation sequencing methods such as Illumina sequencing (see Figure 8–44). More abundant RNAs will have more cDNA copies, resulting in higher numbers of "sequence reads" for those RNAs. Thus, as we have seen in Chapter 7 (see Figure 7–3), RNA-seq does not simply identify the RNAs in a sample but also provides information about their relative abundance. RNA-seq has other important benefits as well: it can detect alternative RNA splicing, RNA editing, and the many noncoding RNAs produced from a complex genome.

Comprehensive studies of gene expression often provide information that is useful for predicting gene function. Earlier in this chapter, we discussed how identifying a protein's interaction partners can yield clues about that protein's function. A similar principle holds true for genes: information about a gene's function can be deduced by identifying genes that share its expression pattern. Using a computational approach called *cluster analysis*, one can identify sets of genes that are coordinately regulated. Genes that are turned on or turned off together under different circumstances are likely to work in concert in the

MBOC7_ptr_ch08_475-562.indd 536 02/12/21 12:43 PM

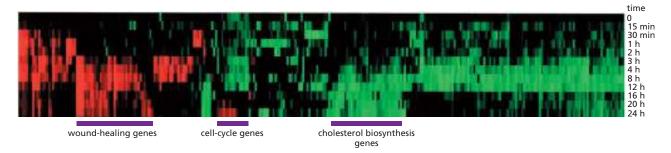

Figure 8–65 Using cluster analysis to identify sets of genes that are coordinately regulated. Genes that have the same expression pattern are likely to be involved in common pathways or processes. To perform a cluster analysis, gene expression data are obtained from cell samples exposed to a variety of different conditions, and genes that show coordinate changes in their expression pattern are grouped together. In this experiment, human fibroblasts were deprived of serum for 48 hours; serum was then added back to the cultures at time 0, and the cells were harvested for mRNA measurements at different time points. Of the 8600 genes depicted here (each represented by a thin vertical line), just over 300 showed threefold or greater variation in their expression patterns in response to serum reintroduction. Here, red indicates an increase in expression; green is a decrease in expression. On the basis of the results of many other experiments, the 8600 genes have been grouped in clusters according to similar patterns of expression. The results of this analysis show that genes involved in wound healing are turned on in response to serum, while genes involved in regulating cell-cycle progression and cholesterol biosynthesis are shut down. (From M.B. Eisen et al., Proc. Natl. Acad. Sci. USA 95:14863–14868, 1998. With permission from National Academy of Sciences.)

cell: they may encode proteins that are part of the same multiprotein machine or proteins that are involved in a complex coordinated activity, such as DNA replication or RNA splicing. Characterizing a gene of unknown function by grouping it with known genes that share its transcriptional behavior is sometimes called "guilt by association." Cluster analyses have been used to analyze the gene expression profiles that underlie many interesting biological processes (Figure 8–65).

Major new insights into gene expression patterns have come from the development of sensitive methods for sequencing RNA from single cells. In this method, a complex tissue, tumor, embryo, or even organism is dissociated into single cells, after which microfluidics systems are used to separate the cell population into individual cells in single droplets that are each processed for RNA-seq. Sophisticated computational methods are then used to process the vast quantities of sequence data. These methods include cluster analysis algorithms that categorize cells into groups with similar gene expression patterns (**Figure 8–66**). The exciting outcome of these methods is a visualization of how individual cells fall into groups with similar expression patterns. In many cases, the cell groups identified in this fashion can be identified as previously known cell types, thereby revealing

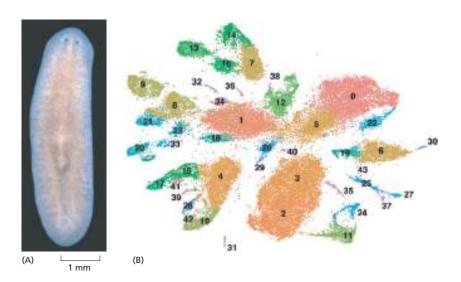

Figure 8-66 Using single-cell RNA-seq to identify the cell types in a whole animal. (A) The planarian flatworm is a small (3-5 mm) model organism used in studies of regeneration (see Figure 22-20). (B) In this experiment, flatworms were cut in small pieces and dissociated into individual cells. About 67,000 cells were analyzed by single-cell RNA sequencing, providing a complete list of all major mRNAs expressed in every cell. Sophisticated computational methods were then used to cluster cells into groups with similar gene expression patterns. These clusters are typically displayed in two dimensions on a plot as shown here, with each dot in a cluster representing a single cell. About 44 distinct cell types, highlighted with distinct colors, were identified in this cluster analysis. The pattern of gene expression in each cluster provides clues about the function of the cells in that cluster. Further insights can be obtained using in situ hybridization of intact flatworms, which reveals the precise location of cells and tissues expressing specific mRNAs from each cluster. Such analyses reveal that cell clusters 2 and 3, for example, represent cells from the epidermis. The end result is a comprehensive catalog of the genes expressed in every major cell type of the animal's body. (From C.T. Fincher et al., Science 360:eaaq1736, 2018. With permission from AAAS.)

MBOC7_ptr_ch08_475-562.indd 537 02/12/21 12:43 PM

new clues about the genes expressed in those cells and even the function of those cells. In other cases, this approach can reveal the existence of cell types that were not previously known. Similar methods can be used to analyze gene expression in distinct cell types during multiple stages of embryonic development, providing comprehensive insights into cell lineage and gene expression patterns during development.

Genome-wide Chromatin Immunoprecipitation Identifies Sites on the Genome Occupied by Transcription Regulators

We have discussed several strategies to measure the levels of individual RNAs in a cell and to monitor changes in their levels in response to external signals. But this information does not tell us how such changes are brought about. We saw in Chapter 7 that transcription regulators, by binding to *cis*-regulatory sequences in DNA, are responsible for establishing and changing patterns of transcription. Typically, these proteins do not occupy all of their potential *cis*-regulatory sequences in the genome under all conditions. For example, in some cell types, the regulatory protein may not be expressed, or it may be present but lack an obligatory partner protein, or it may be excluded from the nucleus until an appropriate signal is received from the cell's environment. Even if the protein is present in the nucleus and is competent to bind DNA, other transcription regulators or components of chromatin can occupy overlapping DNA sequences and thereby occlude some of its *cis*-regulatory sequences in the genome.

Chromatin immunoprecipitation provides a way to experimentally determine all the *cis*-regulatory sequences in a genome that are occupied by a given transcription regulator under a particular set of conditions (Figure 8–67). In this approach, proteins are covalently cross-linked to DNA in living cells, the cells are broken open, and the DNA is mechanically sheared into small fragments. Antibodies directed against a given transcription regulator are then used to purify the DNA that became covalently cross-linked to that protein in the cell. This DNA is then sequenced using the rapid methods discussed earlier; the precise location of each precipitated DNA fragment along the genome is determined by comparing its DNA sequence to that of the whole genome sequence (Figure 8–68). In this way, all of the sites occupied by the transcription regulator in the cell sample can be mapped across the cell's genome. In combination with RNA-seq information, chromatin immunoprecipitation can identify the key transcriptional regulator responsible for specifying a particular pattern of gene expression.

Chromatin immunoprecipitation can also be used to deduce the *cis*-regulatory sequences recognized by a given transcription regulator. Here, all the DNA sequences precipitated by the regulator are lined up (by computer), and features in common are tabulated to produce the spectrum of *cis*-regulatory sequences recognized by the protein (see Figure 7–10A). Chromatin immunoprecipitation is also used routinely to identify the positions along a genome that are bound by the various types of modified histones discussed in Chapter 4. In this case, antibodies specific to the particular histone modification are employed (see Figure 8–68). A variation of the technique can also be used to map positions of chromosomes that are in physical proximity (see Figure 4–53).

Ribosome Profiling Reveals Which mRNAs Are Being Translated in the Cell

We have learned that there are several ways that RNA levels in the cell can be monitored. But for mRNAs, this represents only one step in gene expression, and we are often more interested in the final level of the protein produced by the gene. As described earlier in this chapter, mass spectrometry can be used to monitor the levels of all proteins in the cell, including modified forms of the proteins. However, if we want to understand *how* synthesis of proteins is controlled by the cell, we need to consider the translation step of gene expression.

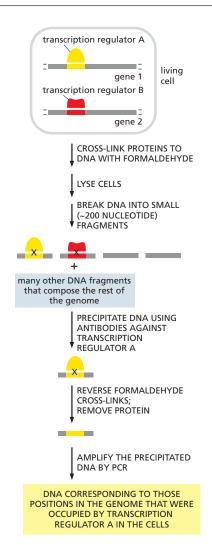

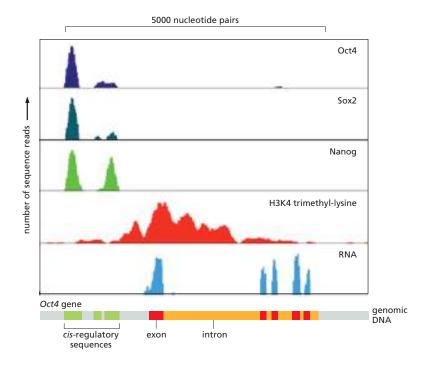

Figure 8–67 Chromatin immunoprecipitation. This method allows the identification of all the sites in a genome that a transcription regulator occupies *in vivo*. The identities of the precipitated, amplified DNA fragments are determined by DNA sequencing.

MBOC7_ptr_ch08_475-562.indd 538 02/12/21 12:43 PM

An approach called *ribosome profiling* provides an instantaneous map of the positions of ribosomes on each mRNA in the cell and thereby identifies those mRNAs that are being actively translated. To accomplish this, total RNA from a cell line or tissue is exposed to ribonucleases under conditions where only those RNA sequences covered by ribosomes are spared. The protected RNAs are released from ribosomes, converted to DNA, and the nucleotide sequence of each is determined (**Figure 8–69**). When these sequences are mapped on the genome, the positions of ribosomes across each mRNA species can be ascertained.

Ribosome profiling has revealed many cases where mRNAs are abundant but are not translated until the cell receives an external signal. It has also shown that many open reading frames (ORFs) that were too short to be annotated as genes are actively translated and probably encode functional, albeit very small, proteins (Figure 8–70). Finally, ribosome profiling has revealed the ways that cells rapidly and globally change their translation patterns in response to sudden changes in temperature, nutrient availability, or chemical stress.

Recombinant DNA Methods Have Revolutionized Human Health

We have seen that nucleic acid methodologies developed in the past 40 years have completely changed the study of cell biology. But they have also had a profound effect on our day-to-day lives. Many pharmaceuticals in routine use (insulin, human growth hormone, blood-clotting factors, and interferon, for example) are based on cloning human genes and expressing the encoded proteins in large amounts. As DNA sequencing continues to drop in cost, more and more individuals will elect to have their genome sequenced; this information can be used to predict susceptibility to diseases (often with the option of minimizing this possibility by appropriate behavior) or to predict the way an individual will respond to a given drug. The genomes of tumor cells from an individual can be sequenced to determine the best type of anticancer treatment. And mutations that cause or greatly increase the risk of disease continue to be identified at an unprecedented pace. Using the recombinant DNA technologies discussed in this chapter, these mutations can then be introduced into animals, such as mice, that can be studied in the laboratory. The resulting transgenic animals, which often mimic some of

Figure 8-68 Chromatin immunoprecipitations showing proteins bound to the genomic region that controls expression of the Oct4 gene. In this series of chromating immunoprecipitation experiments. antibodies directed against a transcription regulator (first three panels) or a particular histone modification (fourth panel) were used to precipitate bound, cross-linked DNA Precipitated DNA was sequenced. and the positions across the genome were mapped. (Only the small part of the mouse genome containing the Oct4 gene is shown.) The results show that, in the embryonic stem cells analyzed in these experiments, Oct4 binds upstream of its own gene, and Sox2 and Nanog are bound in close proximity. Oct4, Sox2, and Nanog are key regulators in embryonic stem cells (discussed in Chapter 22), and this experiment reveals the position on the genome through which they exert their effects on Oct4 expression. In the fourth panel, the positions of a histone modification associated with actively transcribed genes are shown (see Figure 4-35). Finally, the bottom panel shows the RNA produced from the Oct4 gene under the same conditions used for the chromatin immunoprecipitations. Note that the introns and exons are relatively easy to identify from these RNA-seg data.

MBOC7_ptr_ch08_475-562.indd 539 02/12/21 12:43 PM

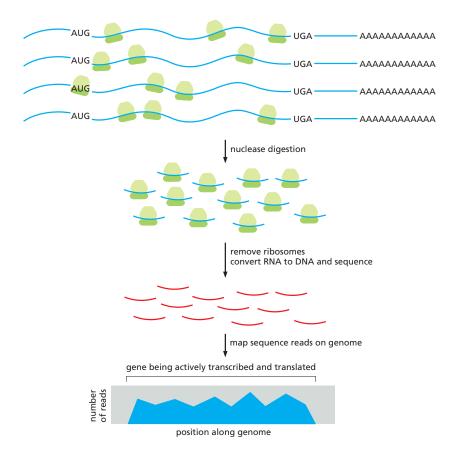

Figure 8–69 Ribosome profiling. RNA is purified from cells and digested with a ribonuclease to leave only those portions of the mRNAs that are protected by a bound ribosome. These short pieces of protected RNA (approximately 20 nucleotides in length) are converted to DNA and sequenced. The resulting information is displayed as the number of sequence reads along each position of the genome. In the diagram here, the data for only one gene, whose mRNA is being efficiently translated, are shown. Ribosome profiling provides this type of information for every mRNA produced by the cell.

the phenotypic abnormalities associated with the condition in humans, can be used to explore the cellular and molecular basis of the disease and to screen for drugs that could potentially be used for human therapy.

Transgenic Plants Are Important for Agriculture

Recombinant DNA technology has had a profound impact on the study of plants. In fact, certain features of plants make them especially amenable to recombinant DNA methods.

When a piece of plant tissue is cultured in a sterile medium containing nutrients and appropriate growth regulators, some of the cells are stimulated to proliferate indefinitely in a disorganized manner, producing a mass of relatively undifferentiated cells called a *callus*. If the nutrients and growth regulators are carefully manipulated, one can induce the formation of a shoot within the callus, and in many species a whole new plant can be regenerated from such shoots. In a

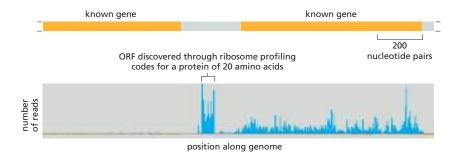

Figure 8-70 Ribosome profiling can identify new genes. This experiment shows the discovery of a previously unrecognized gene-one that encodes a protein of only 20 amino acids. At the top is shown a portion of a viral genome with two previously annotated genes. Below are the results of a ribosome profiling experiment, displayed across the same section of the genome, after human cells were infected by the virus. The results show that the left-hand gene is not expressed under these conditions, the right-hand gene is expressed at low levels, and a previously unrecognized gene that lies between them is expressed at high levels.

MBOC7_ptr_ch08_475-562.indd 540 02/12/21 12:43 PM

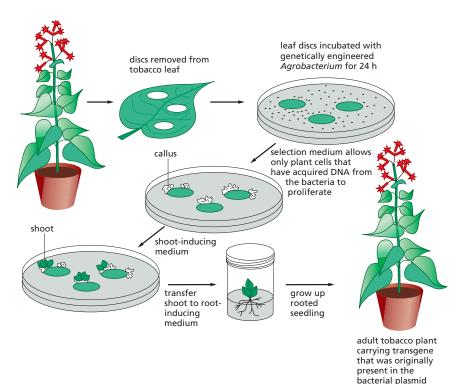

Figure 8-71 Transgenic plants can be made using recombinant DNA techniques optimized for plants. A disc is cut out of a leaf and incubated in a culture of Agrobacterium that carries a recombinant plasmid with both a selectable marker and a desired genetically engineered gene. The wounded plant cells at the edge of the disc release substances that attract the bacteria, which inject their DNA into the plant cells. Only those plant cells that take up the appropriate DNA and express the selectable marker gene survive and proliferate and form a callus. The manipulation of growth factors supplied to the callus induces it to form shoots, which subsequently root and grow into adult plants carrying the engineered gene.

number of plants—including tobacco, petunia, carrot, potato, and *Arabidopsis*—a single cell from such a callus (known as a *totipotent cell*) can be grown into a small clump of cells from which a whole plant can be regenerated (see Figure 7–2B). Just as mutant mice can be derived by the genetic manipulation of embryonic stem cells in culture, so transgenic plants can be created from plant cells transfected with DNA in culture (Figure 8–71).

The ability to produce transgenic plants has greatly accelerated progress in many areas of plant cell biology. It has played an important part, for example, in isolating receptors for growth regulators and in analyzing the mechanisms of morphogenesis and of gene expression. These techniques have also opened up many new possibilities in agriculture that could benefit both the farmer and the consumer. They have made it possible, for example, to modify the ratio of lipid, starch, and protein in seeds, to impart pest and virus resistance to plants, and to create modified plants that tolerate extreme habitats such as salt marshes or water-stressed soil. One variety of rice has been genetically engineered to produce β -carotene, the precursor of vitamin A (Figure 8–72). If it replaced conventional rice, this "golden rice"—so called because of its yellow color—could help to

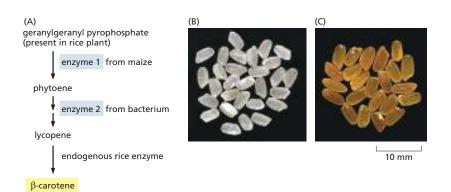

Figure 8-72 DNA technology allows the production of rice grains with high levels of β-carotene. To help reduce vitamin A deficiency in the developing world, a strain of rice, called "golden rice," was developed in which the edible part of the grain (called the endosperm) contains large amounts of B-carotene, which is converted in the human gut to vitamin A. (A) Rice plants, like most other plants, can synthesize β-carotene in their leaves from an abundant precursor (geranylgeranyl pyrophosphate) found in all plant tissues. However, the genes that code for two of the enzymes that act early in this biosynthetic pathway are turned off in the endosperm, preventing the production of β -carotene in rice grains. To produce golden rice, the genes for these two enzymes were obtained from organisms that produce large amounts of β-carotene: one from maize and the other from a bacterium. Using DNA technology, these genes were connected to a promoter that drives gene expression in rice endosperm. Using the method outlined in Figure 8-71, this engineered DNA was then used to generate a transgenic rice plant that expresses these enzymes in endosperm, resulting in rice grains that contain high levels of B-carotene. Compared to the milled grains of wild-type rice (B), the grains of the transgenic rice are a deep yellow/orange due to the presence of B-carotene (C), (B and C, from J.A. Paine et al., Nat. Biotechnol. 23:482-487. 2005. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch08_475-562.indd 541 02/12/21 12:43 PM

alleviate severe vitamin A deficiency, which causes blindness in hundreds of thousands of children in the developing world each year.

Summary

Genetics and genetic engineering provide powerful tools for understanding the function of individual genes in cells and organisms. In the classical genetic approach, random mutagenesis is coupled with screening to identify mutants that are deficient in a particular biological process. These mutants are then used to locate and study the genes responsible for that process.

Gene function can also be ascertained by reverse genetic techniques. DNA engineering methods can be used to alter genes and to reinsert them into a cell's chromosomes so that they become a permanent part of the genome. If the cell used for this gene transfer is a fertilized egg (for an animal) or a totipotent plant cell in culture, transgenic organisms can be produced that express the mutant gene and pass it on to their progeny. Especially important for cell and molecular biology is the ability to alter cells and organisms in highly specific ways—allowing one to discern the effect on the cell or the organism of a designed change in a single protein or RNA molecule. For example, genomes can be altered so that the expression of any gene can be switched on or off by the experimenter.

Many of these methods are being expanded to investigate gene function on a genome-wide scale. The generation of mutant libraries in which every gene in an organism has been systematically deleted, disrupted, or made controllable by the experimenter provides invaluable tools for exploring the role of each gene in the elaborate molecular collaboration that gives rise to life. Technologies such as RNA-seq can monitor the expression of tens of thousands of genes simultaneously, providing detailed, comprehensive snapshots of the dynamic patterns of gene expression that underlie complex cell processes.

MATHEMATICAL ANALYSIS OF CELL FUNCTION

Quantitative experiments combined with mathematical theory mark the beginning of modern science. Galileo, Kepler, Newton, and their contemporaries did more than set out some rules of mechanics and offer an explanation of the movements of the planets around the Sun: they showed how a quantitative mathematical approach could provide a depth and precision of understanding, at least for physical systems, that had never before been dreamed to be possible.

What is it that gives mathematics this almost magical power to explain the natural world, and why has mathematics played so much more important a part in physical sciences than in biology? What do biologists need to know about mathematics?

Mathematics can be viewed as a tool for deriving logical consequences from propositions. It differs from ordinary intuitive reasoning in its insistence on rigorous, accurate logic and the precise treatment of quantitative information. If the initial propositions are correct, then the deductions drawn from them by mathematics will be true. The surprising power of mathematics comes from the length of the chains of reasoning that rigorous logic and mathematical arguments make possible, and from the unexpectedness of the conclusions that can be reached, often revealing connections that one would not otherwise have guessed at. Reversing the argument, mathematics provides a way to test experimental hypotheses: if mathematical reasoning from a given hypothesis leads to a prediction that is not true, then the hypothesis is not true.

Clearly, mathematics is not much use unless we can frame our ideas—our initial hypotheses—about the given system in a precise, quantitative form. A mathematical edifice raised on a rickety or—even worse—a vague or overcomplicated set of propositions is likely to lead us astray. For mathematics to be useful, we must focus our analysis on simple subsystems in which we can pick out key quantitative parameters and frame well-defined hypotheses. This approach has been used with great success in physics for centuries, but it has been less common

MBOC7_ptr_ch08_475-562.indd 542 02/12/21 12:43 PM

in biology. But times are changing, and more and more it is becoming possible for biologists to exploit the power of quantitative mathematical analysis.

In this final section of our methods chapter, we do not attempt to teach readers every way in which mathematics can be fruitfully applied to biological problems. Rather, we simply aim to give a sense of what mathematics and quantitative approaches can do for us in modern biology. We focus primarily on the important principles that mathematics teaches us about the dynamics of molecular interactions and how mathematics can unveil surprising and useful features of complex systems containing feedback. We will illustrate these principles using the regulation of gene expression by transcription regulators like those discussed in Chapter 7. The same principles apply to the post-transcriptional regulatory systems that govern cell signaling (see Chapter 15), cell-cycle control (see Chapter 17), and essentially all cell processes.

Regulatory Networks Depend on Molecular Interactions

Cell function and regulation depend on transient interactions among thousands of different macromolecules in the cell. We often summarize these interactions in this book with schematic cartoons. These diagrams are useful, but a complete picture requires a deeper, more *quantitative* level of understanding. To meaningfully assess the biological impact of any interaction in the cell, we need to know in precise terms how the molecules interact, how they catalyze reactions, and, most important, how the behaviors of the molecules change over time. If a cartoon shows that protein A activates protein B, for example, we cannot judge the importance of this relationship without quantitative details about the concentrations, affinities, and kinetic behaviors of proteins A and B.

Let us begin by defining two different types of regulatory interaction in our cartoons: one designating inhibition and the other designating activation. If the protein product of gene X is a transcription repressor that inhibits the expression of gene Z, we depict the relationship as a *red bar-headed line* (\blacktriangleleft) drawn between genes X and Z (Figure 8-73). If the protein product of gene Y is a transcription activator that induces the expression of gene Z, then a *green arrow* (\rightarrow) is drawn between genes Y and Z.

The regulation of one gene's expression by another is more complicated than a single arrow connecting them, and a complete understanding of this regulation requires that we tease apart the underlying biochemical processes. **Figure 8–74A** sketches some of the biochemical steps in the activation of gene expression by a transcription activator. A gene encoding the activator, designated as gene A, will produce its product, protein A, via an RNA intermediate. This protein A will then bind to p_X , the regulatory *promoter* of gene X, to form the complex $A:p_X$. Once the $A:p_X$ complex forms, it stimulates the production of an RNA transcript that is subsequently translated to produce protein X.

We will focus here on the binding interaction that lies at the heart of this regulatory system: the interaction between protein A and the promoter p_X . This interaction is reversible: any molecule of protein A that is bound to p_X can also dissociate from it. The steps represented by the green activation arrow in Figure 8–74A include both the binding of A to p_X and the dissociation of the complex A: p_X to re-form A and p_X , as illustrated by the notation in Figure 8–74B. This reaction notation is more informative than the diagrams in our figures but has its own limitations. Suppose that the concentration of A increases by a factor of 10 as a response to an environmental input. If A increases, we intuitively know that A: p_X should increase too, but we cannot determine the amount of the increase without additional information. We need to know the affinity of the binding interaction and the concentrations of the two binding partners. With this information in hand, we can rigorously derive the answer.

As discussed earlier and in Chapter 3 (see Figure 3–42), we know that the formation of a complex between two binding partners, such as A and p_X , depends on a rate constant $k_{\rm on}$, which describes how many productive collisions occur per unit time per protein at a given concentration of p_X . The rate of complex

Figure 8–73 Diagrams that summarize biochemical relationships. Here, a simple cartoon indicates that gene *X* represses gene *Z* (*left*) whereas gene *Y* activates gene *Z* (*right*).

MBOC7_ptr_ch08_475-562.indd 543 02/12/21 12:43 PM

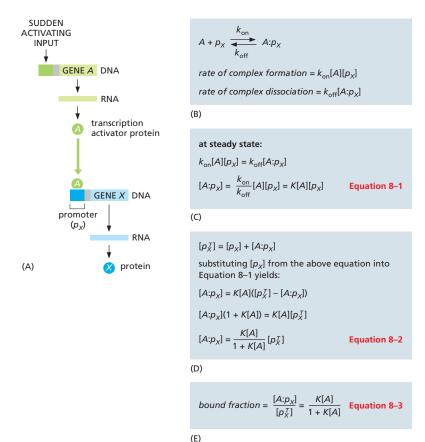

Figure 8-74 A simple transcriptional interaction. (A) Genes A and X each produce a protein, with the product of gene A serving as a transcription activator to stimulate expression of gene X. As indicated by the green arrow, stimulation depends in part on the binding of protein A to the promoter region of gene X, designated as p_X . (B) The binding of protein A to the gene promoter is determined by the concentrations of the two binding partners (denoted as [A] and $[p_X]$, in units of mol/liter, or M), the association rate constant k_{on} (in units of M⁻¹ sec⁻¹), and the dissociation rate constant k_{off} (in units of sec⁻¹). (C) At steady state, the rates of association and dissociation are equal, and the concentration of the bound complex is determined by Equation 8-1, in which the two rate constants are combined in the equilibrium constant K. (D) Equation 8-2 can be derived to calculate the steadystate concentration of bound complex at a known total concentration of the promoter $[p_X^T]$. (E) Rearrangement of Equation 8-2 yields Equation 8-3, which allows calculation of the fraction of promoter p_X that is occupied by protein A.

formation equals the product of this rate constant $k_{\rm on}$ and the concentrations of A and p_X (see Figure 8–74B). Complex dissociation occurs at a rate $k_{\rm off}$ multiplied by the concentration of the complex. The rate constant $k_{\rm off}$ can differ by orders of magnitude for different DNA sequences because it depends on the strength of the noncovalent bonds formed between A and p_X .

We are primarily interested in understanding the amount of bound promoter complex at equilibrium or *steady state*, where the rate of complex formation equals the rate of complex dissociation. Under these conditions, the concentration of the promoter complex is specified by a simple equation that combines the two rate constants into a single equilibrium constant $K = k_{\rm on}/k_{\rm off}$ (Equation 8–1; Figure 8–74C). K is sometimes called the association constant, $K_{\rm a}$. The larger this constant K, the stronger the interaction between K and K0. The reciprocal of K1 is the dissociation constant, K1.

To calculate the steady-state concentration of the promoter complex using Equation 8–1, we need to account for another complication: both A and p_X exist in two forms—free in solution and bound to each other. In most cases, we know the total concentration of p_X and not the free or bound concentrations, so we must find a way to use the total concentration in our calculations. To do this, we first specify that the total concentration of $p_X([p_X^T])$ is the sum of the concentrations of free $([p_X])$ and bound $([A:p_X])$ forms (Figure 8–74D). This leads to a new equation that allows us to use $[p_X^T]$ to calculate the steady-state concentration of the promoter complex $([A:p_X])$ (Equation 8–2; Figure 8–74D).

Protein A also exists in two forms: free ([A]) and bound to $p_X([A:p_X])$. In a cell, there are typically one or two copies of p_X (assuming there is only one gene X per haploid genome) and multiple copies of A. As a result, we can safely assume that from the viewpoint of A, $[A:p_X]$ is negligible relative to the total $[A^T]$. This means $[A] \approx [A^T]$, and we can just plug in the values of total $[A^T]$ in Equation 8–2 without incurring appreciable error in the calculation of $[A:p_X]$.

MBOC7_ptr_ch08_475-562.indd 544 02/12/21 12:43 PM

Now, we are ready to determine the effects of increasing the concentration of A. Suppose that $K=10^8\,\mathrm{M}^{-1}$, which is a typical value for many such interactions. The starting concentration of A is $[A^T]=10^{-9}\,\mathrm{M}$, and $[p_X^T]=10^{-10}\,\mathrm{M}$ (assuming there is one copy of gene X in a haploid yeast cell, for example, with a volume of around $2\times 10^{-14}\,\mathrm{L}$). Using Equation 8–2, we find that a tenfold increase in the concentration of A causes the amount of promoter complex $[A:p_X]$ to increase 5.5-fold, from $0.09\times 10^{-10}\,\mathrm{M}$ to $0.5\times 10^{-10}\,\mathrm{M}$ at steady state. The effects of a tenfold increase in the concentration of A will vary dramatically depending on its starting concentration relative to the equilibrium constant. Only through this mathematical approach can we achieve a thorough understanding of what these effects will be and what impact they will have on the biological response.

To assess the biological impact of a change in transcription activator levels, it is also important in many cases to determine the fraction of the target gene promoter that is bound by the activator, because this number will be directly proportional to the activity of the gene's promoter. In our case, we can calculate the fraction of the gene X promoter, p_X , that has protein A bound to it by rearranging Equation 8–2 (Equation 8–3; Figure 8–74E). This fraction can be viewed as the probability that promoter p_X is occupied, averaged over time. It is also equal to the average occupancy across a large population of cells at any instant in time. When there is no protein A present, p_X is always free, the bound fraction is zero, and transcription is off. When [A] = 1/K, the promoter p_X has a 50% chance of being occupied. When [A] greatly exceeds 1/K, the bound fraction is almost equal to one, meaning that p_X is fully occupied and transcription is maximal.

Differential Equations Help Us Predict Transient Behavior

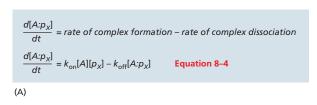

The most important and basic insights for which we, as biologists, depend on mathematics concern the behavior of regulatory systems over time. This is the central theme of dynamics, and it was for the solution of problems in dynamics that the techniques of calculus were developed, by Newton and Leibniz, in the seventeenth century. Briefly, the general problem is this: if we are given the rates of change of a set of variables that characterize the system at any instant, how can we compute its future state? The problem becomes especially interesting, and the predictions often remarkable, when the rates of change themselves depend on the values of the state variables, as in systems with feedback.

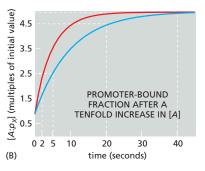

Let us return to Equation 8–2 (Figure 8–74D), which tells us that when [A] changes, $[A:p_X]$ at steady state will also change to a new concentration that we can calculate with precision. However, $[A:p_X]$ does not change instantaneously to this value. If we hope to understand the behavior of this system in detail, we must also ask how long it takes $[A:p_X]$ to get to its new steady-state value inside the cell. Equation 8–2 cannot answer this question. We need calculus.

The most common strategy for solving this problem is to use ordinary differential equations. The equations that describe biochemical reactions have a simple premise: the rate of change in the concentration of any molecular species X (that is, d[X]/dt) is given by the balance of the rate of its appearance with that of its disappearance. For our example, the rate of change in the concentration of the bound promoter complex, $[A:p_X]$, is determined by the rates of complex assembly and disassembly. We can incorporate these rates into the differential equation shown in **Figure 8–75A** (Equation 8–4). When [A] changes, Equation 8–4 can be solved to generate the concentration of $[A:p_X]$ as a function of time. Notice that when $k_{\rm on}[A][p_X] = k_{\rm off}[A:p_X]$, then $d[A:p_X]/dt = 0$ and $[A:p_X]$ stops changing. At this point, the system has reached the steady state.

Calculation of all $[A:p_X]$ values as a function of time, using Equation 8–4, allows us to determine the rate at which $[A:p_X]$ reaches its steady-state value. Because this value is attained asymptotically, it is often most useful to compare the times needed to get to 50%, 90%, or 99% of this new steady state. The simplest way to determine these values is to solve Equation 8–4 with a method called numerical integration, which involves plugging in values for all of the parameters ($k_{\rm on}$, $k_{\rm off}$,

MBOC7_ptr_ch08_475-562.indd 545 02/12/21 12:43 PM

etc.) and then using a computer to determine the values of $[A:p_X]$ over time, starting from given initial concentrations of [A] and $[p_X]$. For $k_{\rm on}=0.5\times 10^7~{\rm M}^{-1}~{\rm sec}^{-1}$, $k_{\rm off}=0.5\times 10^{-1}~{\rm sec}^{-1}$ ($K=10^8~{\rm M}^{-1}$ as above), and $[p_X^T]=10^{-10}$ M, it takes $[A:p_X]$ about 5, 20, and 40 seconds to reach 50%, 90%, and 99% of the new steady-state value after a sudden tenfold change in [A] (Figure 8–75B). Thus, a sudden jump in [A] does not have instantaneous effects, as we might have assumed from looking at the cartoon in Figure 8–74A.

Differential equations therefore allow us to understand the transient dynamics of biochemical reactions. This tool is critical for achieving a deep understanding of cell behavior, in part because it allows us to determine the dependence of the dynamics inside cells on parameters that are specific to the particular molecules involved. For example, if we double the values of both $k_{\rm on}$ and $k_{\rm off}$, then Equation 8–1 (Figure 8–74C) indicates that the steady-state value of $[A:p_X]$ does not change. However, the time it takes to reach 50% of this steady state after a tenfold change in [A] in our example changes from about 5 seconds to 2 seconds (see Figure 8–75B). These insights are not accessible from either cartoons or equilibrium equations. This is an unusually simple example; mathematical descriptions such as differential equations become more indispensable for understanding biological interactions as the number of interactions increases.

Promoter Activity and Protein Degradation Affect the Rate of Change of Protein Concentration

To understand our gene regulatory system further, we also need to describe the dynamics of protein *X* production in response to changes in the amount of transcription activator protein *A*. Here again, we use an ordinary differential equation for the rate of change of protein *X* concentration—determined by the balance of the rate of production of protein *X* through expression of gene *X* and the protein's rate of degradation.

Let us begin with the rate of protein X production, which is determined primarily by the occupancy of the promoter of gene X by protein A. The binding and dissociation of a transcription regulator at a promoter generally occur on a much faster time scale than transcription initiation, causing many binding and unbinding events to occur before transcription proceeds. As a result, we can assume that the binding reaction is at equilibrium on the time scale of transcription, and we can calculate promoter occupancy by protein A using the equilibrium equation discussed earlier (Equation 8–3; Figure 8–74E). To determine the transcription rate, we simply multiply the occupied promoter fraction by a *transcription rate constant*, β , that represents the binding of RNA polymerase and the subsequent

MBOC7_ptr_ch08_475-562.indd 546 02/12/21 12:43 PM

transcription rate =
$$\beta \frac{K[A]}{1 + K[A]}$$

protein production rate = $\beta \cdot m \frac{K[A]}{1 + K[A]}$
protein degradation rate = $\frac{[X]}{\tau_X}$

$$\frac{d[X]}{dt} = protein \ production \ rate - protein \ degradation \ rate$$

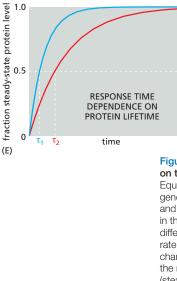

$$\frac{d[X]}{dt} = \beta \cdot m \frac{K[A]}{1 + K[A]} - \frac{[X]}{\tau_X}$$
Equation 8-5

(B)

(C)

$$[X](t) = [X_{st}](1 - \exp(-t/\tau_X))$$
(D)

RESPONSE TIME DEPENDENCE ON

steps that lead to production of mRNA and protein (Figure 8-76A). If each mRNA molecule produces, on average, m molecules of protein product, then we can determine the protein production rate by multiplying the transcription rate by m(Figure 8-76A).

Now let us consider the factors that influence protein X degradation and its dilution due to cell growth. Degradation generally results in an exponential decline in protein levels, and the average time required for a specific protein to be degraded is defined as its mean lifetime, τ . In our current example, the rate of degradation of protein X depends on its mean lifetime τ_X , which takes into account active degradation as well as its dilution as the cell grows. The degradation rate depends on the concentration of protein X and is calculated by dividing this concentration by the lifetime (see Figure 8-76A).

With equations for rates of production and degradation in hand, we can now generate a differential equation to determine the rate of change of protein X as a function of time (Equation 8-5; Figure 8-76B). This equation can be solved by the numerical methods mentioned earlier. According to the solution of this equation, when transcription begins, the concentration of protein *X* rises to a steady-state level at which the concentration of X is not changing anymore; that is, its rate of change is zero. When this occurs, rearrangement of Equation 8-5 yields an equation that can be used to determine the steady-state value of $X_t[X_{st}]$ (Equation 8-6; Figure 8-76C). An important concept emerges from the mathematics: the steadystate concentration of a gene product is directly proportional to its lifetime. If lifetime doubles, protein concentration doubles as well.

The Time Required to Reach Steady State Depends on Protein Lifetime

We can see from Equation 8-6 (see Figure 8-76C) that when the concentration of protein A rises, protein X increases to a new steady-state value, $[X_{st}]$. But this cannot happen instantaneously. Instead, X changes dynamically according to the solution of its differential rate equation (Equation 8-5). The solution of this equation reveals that the concentration of X over time is related to its steady-state

Figure 8-76 Effect of protein lifetime on the timing of the response. (A) Equations for calculation of the rates of gene X transcription, protein X production, and protein X degradation, as explained in the text. (B) Equation 8-5 is an ordinary differential equation for calculating the rate of change in protein X in response to changes in other components. (C) When the rate of change in protein *X* is zero (steady state), its concentration can be calculated with Equation 8-6, revealing a direct relationship with protein lifetime (τ). (D) The solution of Equation 8–5 specifies the concentration of protein X over time as it approaches its steady-state concentration. (E) Response time depends on protein lifetime. As described in the text, the time that it takes a protein to reach a new steady state is greater when the protein is more stable. Here, the blue line corresponds to a protein with a lifetime that is 2.5-fold shorter than the lifetime of the protein in red.

MBOC7_ptr_ch08_475-562.indd 547 02/12/21 12:43 PM concentration according to the equation in Figure 8–76D. Once again, mathematics uncovers a simple but important concept that is not intuitively obvious: after a sudden increase in [A], [X] rises to a new steady state at an exponential rate that is inversely related to its lifetime; the faster X is degraded, the less time it takes it to reach its new steady-state value (Figure 8–76E). The faster response time comes at a higher metabolic cost, however, because proteins with a rapid response time must be produced and degraded at a high rate. For proteins that are not rapidly turned over, the response time is very long, and protein concentration is determined primarily by the dilution that results from cell growth and division.

Quantitative Methods Are Similar for Transcription Repressors and Activators

Positive control is not the only mechanism that cells use to regulate the expression of their genes. As we discussed in Chapter 7, cells also actively shut off genes, often by employing transcription repressor proteins that bind to specific sites on target genes, thereby blocking access to RNA polymerase. We can analyze the function of these repressors by the same quantitative methods described above for transcription activators. If a repressor protein R binds to the regulatory region of gene X and represses its transcription, then the fraction of gene-binding sites occupied by the repressor is specified by the same equation we used earlier for the transcription activator (Figure 8-77A). In this case, however, it is only when the DNA is free that RNA polymerase can bind to the promoter and transcribe the gene. Thus, the quantity of interest is the unbound fraction, which can be viewed as the probability that the site is free, averaged over multiple binding and unbinding events. When the repressor concentration is zero, the unbound fraction is 1 and the promoter is fully active; when the repressor concentration greatly exceeds 1/K, the unbound fraction approaches zero. Figure 8-77B and Figure 8-77C compare these relationships for a transcription activator and a transcription repressor.

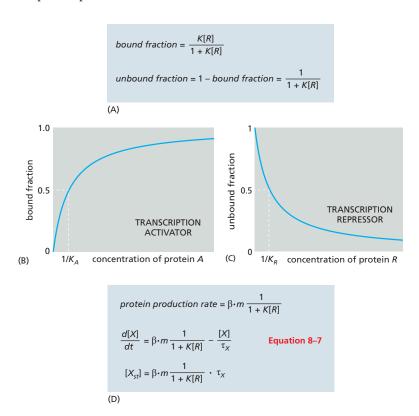

Figure 8-77 How promoter occupancy depends on the binding affinity of a transcription regulator protein. (A) The fraction of a binding site that is occupied by a transcription repressor R is determined by an equation that is similar to the one we used for a transcription activator (see Figure 8-74E), except that in the case of a repressor we are interested primarily in the unbound fraction. (B) For a transcription activator A, half of the promoters are occupied when $[A] = 1/K_A$. Gene activity is proportional to this bound fraction. (C) For a transcription repressor R, gene activity is proportional to the unbound fraction of promoters. As indicated, this fraction is reduced to half of its maximal value when $[R] = 1/K_R$. (D) As in the case of the transcription activator A (see Figure 8-76), we can derive equations to assess the timing of protein X production as a function of repressor concentrations.

MBOC7_ptr_ch08_475-562.indd 548 02/12/21 12:43 PM

We can create a differential equation that provides the rate of change in protein *X* when repressor concentrations change (Equation 8–7; **Figure 8–77D**). As in the case of the transcription activator, the steady-state concentration of protein *X* increases as its lifetime increases, but it decreases as the concentration of the transcription repressor increases.

Negative Feedback Is a Powerful Strategy in Cell Regulation

Thus far, we have considered simple regulatory systems of just a few components. In most of the complex regulatory systems that govern cell behaviors, multiple modules are linked to produce larger circuits that we call *network motifs*, which can produce surprisingly complex and biologically useful responses whose properties become apparent only through mathematical analysis. A particularly common and important network motif is the negative feedback loop, which can have dramatically different functions depending on how it is structured.

We take as a first example a network motif consisting of two linked modules (Figure 8–78A). Here, an input signal initiates the transcription of gene A, which produces a transcription activator protein A. This activates gene R, which synthesizes a transcription repressor protein R. Protein R in turn binds to the promoter of gene A to inhibit its expression. This cyclical organization creates a negative feedback loop that one can intuitively understand as a mechanism to prevent proteins from accumulating to high levels. But what can we learn about negative feedback loops, and their value in biology, by using mathematics to model them?

The negative feedback loop in Figure 8–78A can be modeled using Equation 8–7 (see Figure 8–77D) for the repression of gene A and Equation 8–5 (see Figure 8–76B) for the activation of gene R. Thus, for proteins A and R, we use the set of differential equations (Equation set 8–8) shown in Figure 8–78B. The two equations in this set are coupled, which means that they must be solved together to describe the behavior of A and R over time for any value of the input. As before, we plug in values for the parameters (β_R , τ_R , etc.) and then use a computer to determine the values of [A] and [R] as a function of time after a sudden input activates gene A.

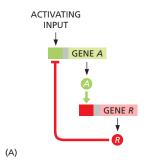

The results reveal several important properties of negative feedback. First, rather surprisingly, negative feedback increases the speed of the response to the activating input. As shown in **Figure 8–78C**, the system with negative feedback reaches its new steady state faster than the system with no feedback.

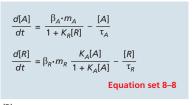

Second, negative feedback is useful for protecting cells from perturbations that continually arise in the cell's internal environment—due either to random variations in the birth and death of molecules or to fluctuations in environmental variables such as temperature and nutritional supplies. Let us imagine, for example, that β_A , the transcription rate constant for gene A, fluctuates by 25% of its value and ask whether and how much the levels of protein R are affected. The results, shown in Figure 8–79, reveal that a change in β_A causes a smaller change in the steady-state value of R when the network has negative feedback.

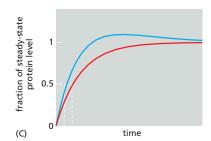

Delayed Negative Feedback Can Induce Oscillations

A beautiful thing happens when a negative feedback loop contains some delay mechanism that slows the feedback signal through the loop: rather than generating a new stable state as in a rapid negative feedback loop, a delayed loop

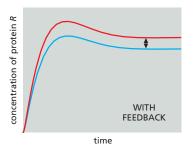

Figure 8–78 A simple negative feedback motif. (A) Gene A negatively regulates its own expression by activating gene R. The product of gene R is a transcription repressor that inhibits gene A. (B) Equation set 8–8 can be solved to determine the dynamics of system components over time. (C) A system with negative feedback (blue) reaches its steady state faster than a system with no feedback (red). The plots indicate the levels of protein A, expressed as a fraction of the steady-state level. The blue line reflects the solution of Equation set 8–8, which includes negative feedback of gene A by the repressor R. The red line represents the solution when the rate of synthesis of A was set to a constant value that is unaffected by the repressor R.

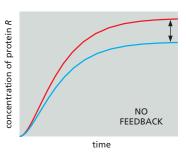

MBOC7_ptr_ch08_475-562.indd 549 02/12/21 12:43 PM

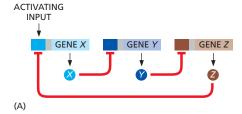

generates pulses, or *oscillations*, in the levels of its components. This can be seen, for example, if the number of components in a negative feedback loop increases, which leads to delays in the amount of time required for the cycle of signals to be completed. Figure 8–80 compares the behavior of two network motifs—one with a three-stage and one with a five-stage negative feedback loop. Using the same kinetic parameters at each stage in the two loops, one finds that stable oscillations arise in the longer loop, while in the shorter loop the same parameters lead to relatively rapid convergence to a stable steady state.

Changes in the parameters of a delayed negative feedback loop—binding affinities, transcription rates, or protein stabilities, for example—can change the amplitude and period of the oscillations, providing a remarkably versatile mechanism for generating all sorts of oscillators that can be used for various purposes in the cell. Indeed, many naturally occurring oscillators, including the calcium oscillators described in Chapter 15 and the cell-cycle network described in Chapter 17, use delayed negative feedback as the basis for biologically important oscillations. Not all of the oscillations observed in cells are thought to have a function, however. Oscillations become inevitable in a highly complex, multicomponent biochemical pathway such as glycolysis, due simply to the large number of feedback loops that appear to be required for its regulation.

Figure 8-79 The effect of fluctuations in kinetic rate constants on a system with negative feedback compared to one without feedback. The plot at left represents the levels of protein R after a sudden activating stimulus, according to the regulatory scheme in Figure 8-78A and determined by the solution of Equation set 8-8 (see Figure 8-78B). A perturbation was induced by changing β_A from 4 M/min (red line) to 3 M/min (blue line). The plot at right shows the results when negative feedback was removed. The system with negative feedback deviates less from its normal operation as β changes than does the system with no feedback. Notice that, as in Figure 8-78C, the system with negative feedback also reaches its steady state more rapidly.

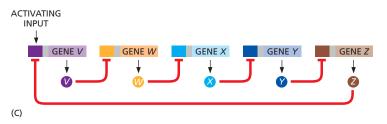

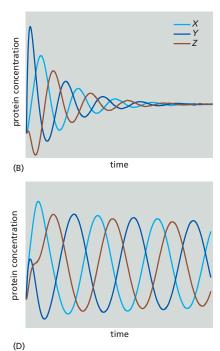

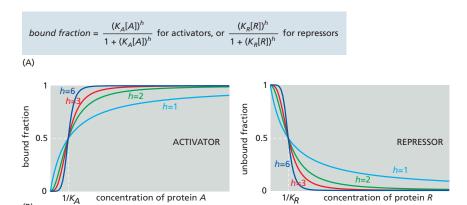

Figure 8–80 Oscillations arising from delayed negative feedback. A transcriptional circuit with three components (A, B) is less likely to oscillate than a transcriptional circuit with five components (C, D). The *X* (*light blue*), *Y* (*dark blue*), and *Z* (*brown*) here represent transcription regulatory proteins. For the simulations in panels B and D, the system was initiated from random initial conditions for *X*, *Y*, and *Z*. Oscillations are produced by a delay induced as the signal propagates through the loop.

MBOC7_ptr_ch08_475-562.indd 550 02/12/21 12:43 PM

DNA Binding by a Repressor or an Activator Can Be Cooperative

We have focused thus far on the binding of a single transcription regulator to a single site in a gene promoter. Many promoters, however, contain multiple adjacent binding sites for the same transcription regulator, and it is not uncommon for these regulators to interact with each other on the DNA to form dimers or larger oligomers. These interactions can result in a *cooperative* form of DNA binding, such that DNA-binding affinity increases at higher concentrations of the transcription regulator. Cooperativity produces a steeper transcriptional response to increasing regulator concentration than the response that can be generated by the binding of a monomeric protein to a single site. A steep transcriptional response of this sort, when present in conjunction with positive feedback, is an important ingredient for producing systems with the ability to switch between different discrete phenotypic states. To begin to understand how this occurs, we need to modify our equations to include cooperativity.

Cooperative binding events can produce steep S-shaped (or *sigmoidal*) relationships between the concentration of regulatory protein and the amount bound on the DNA (see Figure 7-11 and Figure 15-17). In this case, a number called the *Hill coefficient* (*h*) describes the degree of cooperativity, and we can include this coefficient in our equations for calculating the bound fraction of promoter (**Figure 8-81A**). As the Hill coefficient increases, the dependence of binding on protein concentration becomes steeper (**Figure 8-81B**). In principle, the Hill coefficient is similar to the number of molecules that must come together to generate a reaction. In practice, however, cooperativity is rarely complete, and the Hill coefficient does not reach this number.

Positive Feedback Is Important for Switchlike Responses and Bistability

We turn now to positive feedback and its very important consequences. First and foremost, positive feedback can make a system *bistable*, enabling it to persist in either of two (or more) alternative steady states. The idea is simple and can be conveyed by drawing an analogy with a candle, which can exist either in a burning state or in an unlit state. The burning state is maintained by positive feedback: the heat generated by burning keeps the flame alight. The unlit state is maintained by the absence of this feedback signal: so long as sufficient heat has never been applied, the candle will stay unlit.

For the biological system, as for the candle, bistability has an important corollary: it means that the system has a memory, such that its present state depends on its history. If we start with the system in an Off state and gradually rack up the concentration of the activator protein, there will come a point where autostimulation becomes self-sustaining (the candle lights), and the system moves rapidly to an On state. If we now intervene to decrease the level of activator, there will come a point where the same thing happens in reverse, and the system moves rapidly

Figure 8-81 How the cooperative binding of transcription regulatory proteins affects the fraction of promoters bound. (A) Cooperativity is incorporated into our mathematical models by including a Hill coefficient (h) in the equations used previously to determine the fraction of bound promoter (see Figures 8-74E and 8-77A). When h is 1, the equations shown here become identical to the equations used previously, and there is no cooperativity. (B) The left panel depicts a cooperatively bound transcription activator, and the right panel depicts a cooperatively bound transcription repressor. Recall from Figure 8-77B that gene activity is proportional to bound activator (left panel) or unbound repressor (right panel). Note that the plots get steeper as the Hill coefficient increases.

MBOC7_ptr_ch08_475-562.indd 551 02/12/21 12:43 PM

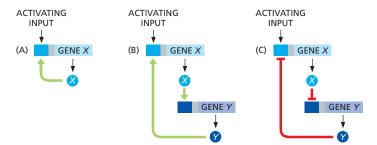

Figure 8–82 Positive feedback of a gene onto itself through serially connected interactions. A sequence of activators and repressors of any length can be connected to produce a positive feedback loop, as long as the overall sign is positive. Because the negative of a negative is positive, not only circuit (A) and (B) but also circuit (C) create positive feedback.

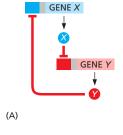

back to an Off state. But the transition points for switching on and switching off are different, and so the current state of the system depends on the route by which it has been taken in the past—a phenomenon called *hysteresis*.

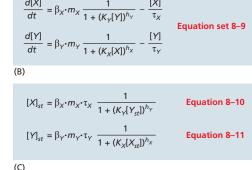

A simple case of positive feedback can be seen in a regulatory system in which a transcription regulator activates (directly or indirectly) its own expression, as in Figure 8–82A. Positive feedback can also arise in a circuit with many intervening repressors or activators, so long as the net overall effect of the interactions is activation (Figure 8–82B and C).

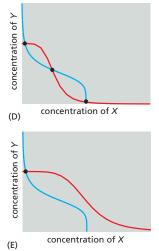

To illustrate how positive feedback can generate stable states, let us focus on a simple positive feedback loop containing two repressors, X and Y, each of which inhibits expression of the other (**Figure 8–83A**). As we saw with Equation set 8–8 (Figure 8–78B) earlier, we can create differential equations describing the rate of change of [X] and [Y] (Equation set 8–9; **Figure 8–83B**). We can further modify these equations to include cooperativity by adding Hill coefficients. As we did earlier, we can then create equations for calculating the concentrations of [X] and [Y] when the system reaches a steady state—that is, when (d[X]/dt) = 0 and (d[Y]/dt) = 0 (Equations 8–10 and 8–11, **Figure 8–83C**).

Equations 8–10 and 8–11 can be used to carry out an intriguing mathematical procedure called a *nullcline* analysis. These equations define the relationships between the concentration of X at steady state, $[X_{st}]$, and the concentration of Y at steady state, $[Y_{st}]$, which must be simultaneously satisfied. We can plug in different values for $[Y_{st}]$ in Equation 8–10 and calculate the corresponding $[X_{st}]$ for each of these values. We can then graph $[X_{st}]$ as a function of $[Y_{st}]$. Next, we repeat the process by varying $[X_{st}]$ in Equation 8–11 to graph the resulting $[Y_{st}]$. The intersections of these two graphs determine the theoretically possible steady states of the system. For systems in which the Hill coefficients h_X and h_Y are much larger than 1, the lines in the two graphs intersect at three locations (Figure 8–83D). In other systems that have the same arrangement of regulators but different parameters, there might only be one intersection, indicating the presence of only a single

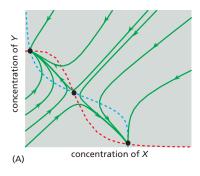

Figure 8-83 A graphical nullcline analysis. (A) X inhibits Y and Y inhibits X, resulting in a positive feedback loop. (B) Equation set 8-9 can be used to determine the rate of change in the concentrations of proteins X and Y. (C) Equations 8-10 and 8-11 provide the concentrations of proteins X and Y, respectively, when these concentrations reach a steady state. (D, E) Blue curves (called nullclines) are plots of $[X_{st}]$ calculated from Equation 8-10 over a range of concentrations of [Y_{st}]. Red curves are nullclines that indicate values of $[Y_{st}]$ calculated from Equation 8-11 over a range of concentrations of $[X_{st}]$. At an intersection of the two lines, both [X] and [Y] are at steady state. For plot D, the binding of both proteins to their target gene promoters was cooperative (h_X and h_Y much larger than 1), resulting in the presence of multiple intersections of the nullclinessuggesting that the system can assume multiple discrete steady states. In plot E, the binding of protein X to the promoter of gene Y was not cooperative (h_X close to 1), resulting in only one nullcline intersection and thus just one likely steady state.

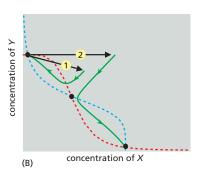

MBOC7_ptr_ch08_475-562.indd 552 02/12/21 12:43 PM

steady state. For example, when there is a low cooperativity of protein X binding to the promoter of gene Y (that is, a small Hill coefficient, h_X , in Equation 8–11), the plot of [Y] is less curved (**Figure 8–83E**), and it is less likely that there will be multiple intersections of the two curves.

We emphasized earlier that positive feedback typically generates a bistable system with two stable steady states. Why does the system modeled in Figure 8–83D have three? This conundrum can be explained by solving the reaction rate equations (Equation set 8–9; Figure 8–83B) for various different starting conditions of [X] and [Y], determining all values of [X] and [Y] as a function of time. Starting with each set of initial concentrations of [X] and [Y], these calculations produce a so-called trajectory of points, each indicated by a curved green line on Figure 8–84A. A fascinating pattern emerges: each trajectory moves across the plot and settles in one of two steady states, but never in the third (middle steady state). We conclude that the middle steady state is unstable because it cannot "attract" any trajectories. The system therefore has only two stable steady states. Thus, the number of stable steady states in a system need not be equal to the total number of its theoretically possible steady states. In fact, stable steady states are usually separated by unstable ones, as in our example.

Once this system adopts a fate by settling in one of the two steady states, does it have the ability to switch to the other state? The numerical solution of Equation set 8–9 can again provide an answer. In **Figure 8–84B**, we show the solution of this equation set for two perturbations from the upper-left steady state. For a small perturbation, the system returns to its original steady state. But the larger perturbation causes the system to switch to the alternate steady state. Thus, this system can be switched from one stable steady state to the other by subjecting it to an input (or a perturbation) that is large enough to make the other steady state more attractive. More generally, every stable steady state has a corresponding *region of attraction*, which can be intuitively thought of as the range of perturbations (of [X] or [Y] in this example) for which the dynamic trajectories converge back to that particular steady state, rather than switch to the other one.

The concept of a region of attraction has interesting implications for the heritability of transcriptional states and the transition rates between them. If the region of attraction around one steady state is large, for example, then most cells in the population will assume this particular state. Furthermore, this state is likely to be inherited by daughter cells, because minor perturbations, like those ensuing from an asymmetric distribution of molecules during cell division, will rarely be sufficient to induce switching to the other steady state. We should expect that the use of positive feedback, coupled to cooperativity, will quite often be associated with systems requiring stable cell memory.

Robustness Is an Important Characteristic of Biological Networks

Biological regulatory systems are exposed to frequent and sometimes extreme variations in external conditions or the concentrations or activities of key components. The ability of these systems to function normally in the face of such perturbations is called **robustness**. If we understand a complex system to the extent that we can reproduce its behavior with a computational model, then the

Figure 8-84 Analysis of the stability of a system's steady states. (A) The dotted lines are the nullclines for the system shown in Figure 8-83. Also shown are dynamic trajectories (green) that show the changes over time in [X] and [Y], starting at a variety of different initial concentrations (determined by solution of Equation set 8-9; see Figure 8-83B). By plotting [X] versus [Y] at each time point, we find that, although there are three possible steady states in this system, the dynamic trajectories converge on only two of them. The middle steady state is avoided: it is unstable, being unable to attract any trajectories. (B) Imagine that the system is at the upper-left steady state and experiences a perturbation (black arrows), such as a random fluctuation in the production rates of X and/or Y. If the perturbation is small (arrow 1), the system will return to the same steady state. On the other hand, a perturbation that drives the system beyond the unstable (middle) steady state (arrow 2) causes it to switch to the lower-right steady state. The set of perturbations that a system can withstand without switching from one steady state to the other is known as the region of attraction of that steady state.

MBOC7_ptr_ch08_475-562.indd 553 02/12/21 12:43 PM

robustness of the system can be assessed by determining how well its normal function persists after changes in various parameters, such as rate constants and component concentrations. We have already seen, for example, how the presence of negative feedback reduces the sensitivity of the steady state to changes in the values of the system's parameters (see Figure 8–79). Considerations of robustness also apply to dynamic behaviors. Thus, for example, when discussing negative feedback, we described how the behavior of a system tends to become more oscillatory as the number of components that constitute the feedback loop increases. If we use different values of the parameters in models derived for systems like those in Figure 8–80, we find that the system with the longer loop tends to exhibit stable oscillations within a much broader range of parameters, indicating that this system provides a more robust oscillator. We can perform similar calculations to determine the ability of different systems to achieve robust bistability arising from positive feedback. Thus, one benefit of computational models is that they allow us to probe the robustness of biological networks in a systematic and rigorous way.

Two Transcription Regulators That Bind to the Same Gene Promoter Can Exert Combinatorial Control

Thus far, we have discussed how one transcription regulator can modulate the expression level of a gene. Most genes, however, are controlled by more than one type of transcription regulator, providing *combinatorial control* that allows two or more inputs to influence the expression of one gene. We can use computational methods to unveil some of the important regulatory features of combinatorial control systems.

Consider a gene whose promoter contains binding sites for two regulatory proteins, A and R, which bind to their individual sites independently. There are four possible binding configurations (**Figure 8–85A**). Suppose that A is a transcription activator, R is a transcription repressor, and the gene is only active when A is bound and R is not bound. We learned earlier that the probability that A is bound and the probability that R is not bound can be determined by the equations in **Figure 8–86A**. The product of these two probabilities gives us the probability of gene activation.

This example illustrates an AND NOT logic function (A and not R) (see Figure 8–85A). Maximal activation of this gene is accomplished when [A] is high and [R] is zero. However, intermediate levels of gene activation are also possible depending on the levels of A and R and also on the binding affinities of A and R for their respective sites (that is, K_A and K_R). When $K_A > K_R$, a small concentration of A is capable of overcoming repression by R. Conversely, if $K_A < K_R$, then much more R is needed to activate the gene (Figure 8–86B and R).

Many other logic functions can govern combinatorial gene regulation. For example, an AND logic gate results when two activators, A1 and A2, are both required for a gene to be transcribed (**Figure 8–85B** and **Figure 8–86D**). In *E. coli* cells, the *AraJ* gene controls some aspects of arabinose sugar metabolism: its

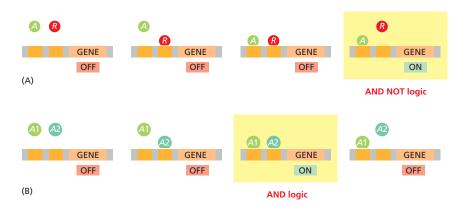

Figure 8-85 Combinatorial control of gene expression. There are many ways in which gene expression can be controlled by two transcription regulators. To define precisely the relationship between the two inputs and the gene expression output, a regulatory circuit is often described as a specific type of logic gate, a term borrowed from electronic circuit design. A simple example is the OR logic gate (not shown here), in which a gene is controlled by two transcription activators, and one or the other can activate gene expression. (A) In a system with an activator A and repressor R, if transcription is turned on only when A is bound and R is not, then the result is an AND NOT logic gate. We saw an example of this logic in Chapter 7 (Figure 7-18). (B) An AND gate results when two transcription activators, A1 and A2, are both required to turn on a gene.

MBOC7_ptr_ch08_475-562.indd 554 02/12/21 12:43 PM

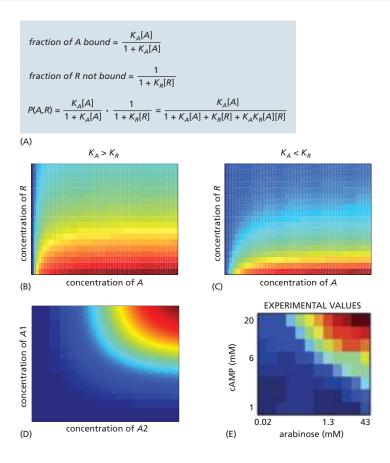

Figure 8-86 How the quantitative output of a gene depends on both its combinatorial logic and the affinities of transcription regulators. (A) In a combinatorial gene regulatory system like that illustrated in Figure 8-85A, the fraction of promoters bound by activator A and the fraction not bound by repressor R are each determined as shown here. The product of these probabilities provides the probability, P(A, R), that a gene promoter is active. (B-E) In these four panels, red indicates high gene expression and blue indicates low gene expression. (B, C) Depictions of gene expression from the system described in panel A. The two panels demonstrate how the system behaves when the relative affinities of the two transcription regulators change as indicated above each panel. (D) Gene expression in a case where the gene turns on only at high levels of both activating inputs (A1 and A2), as shown in Figure 8–85B. (E) Experimental data showing measured expression of a gene in E. coli that is combinatorially regulated by two inputs: arabinose and cAMP. Note the close resemblance to panel D. (E, adapted from S. Kaplan et al., Mol. Cell 29:786-792, 2008. With permission from Elsevier.)

expression requires two transcription regulators, one activated by arabinose and the other activated by the small molecule cAMP (Figure 8-86E).

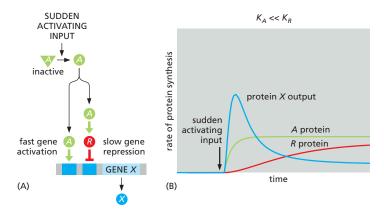

An Incoherent Feed-forward Interaction Generates Pulses

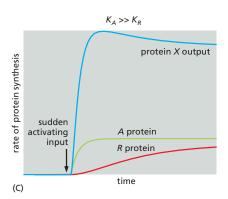

Imagine that a sudden input signal immediately activates a transcription activator A and that the same input signal induces the much slower synthesis of a transcription repressor protein R that acts on the same gene X. If A and R control gene expression by an AND NOT logic function like that described above, our intuition tells us that this system should be able to generate a pulse of transcription: when A is activated (and R is absent), the transcription of gene X will begin and cause an increase in the concentration of protein X, but then transcription will shut off when the concentration of R increases to a sufficiently high value.

Arrangements of this type are common in the cell. In $E.\ coli$, for example, galactose metabolic genes are positively regulated by the catabolite activator protein (CAP), which is activated at high levels of cAMP. The same genes are repressed by the GalS repressor protein, which is encoded by a gene whose transcription is likewise activated by CAP. Thus, an increase in input (cAMP) activates A (CAP), and transcription of the galactose genes begins. But activation of A also causes a subsequent buildup of R (GalS), which causes the same genes to be repressed after a delay. This results in an *incoherent feed-forward motif* (Figure 8–87A).

The response of the incoherent feed-forward motif will vary, depending on the parameters of the system. Suppose, for example, that the transcription activator protein A binds more weakly to the gene regulatory region than does the transcription repressor protein R ($K_A << K_R$). In this case, there will be a transient burst of protein synthesized by the affected gene (gene X) in response to a sudden activating input (**Figure 8–87B**). In contrast, the output will be more sustained if K_A is much larger than K_R , because the repression will be too weak to overcome

MBOC7_ptr_ch08_475-562.indd 555 02/12/21 12:43 PM

the gene activation (Figure 8–87C). Other properties of this network, such as the dependence of the amplitude of the pulse on the various rate constants in the system, can be explored with the same computational tools. Thus, our intuitive guess about how this system would behave was only partially correct; even the simplest of networks depends on precise interaction strengths, demonstrating yet again why mathematics is needed to complement cartoon drawings.

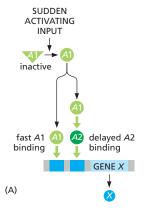

A Coherent Feed-forward Interaction Detects Persistent Inputs

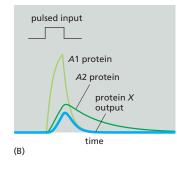

In the bacterium *E. coli*, the sugar arabinose is only consumed when the preferred sugar, glucose, is scarce. The strategy that cells use to assess the presence of arabinose and absence of glucose involves a feed-forward arrangement that is different from the one just described. In this case, depletion of glucose causes an increase of cAMP, which is sensed by the CAP transcription activator protein, as described previously. In this case, however, CAP also induces the synthesis of a second transcription activator, AraC. Both activator proteins are necessary to activate arabinose metabolic genes (the AND logic function in Figure 8–85B).

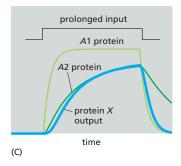

This arrangement, known as a *coherent feed-forward motif*, has the interesting characteristics illustrated in **Figure 8–88**. Imagine that two activators, A1 and A2, are both required to initiate transcription of a gene. The input to the network activates A1 directly, but only activates A2 through this A1 activation. Thus, for a protein to be synthesized from this gene, long-term inputs are required that allow both A1 and A2 to be produced in active form. Brief input pulses are either ignored or produce small outputs. The requirement for a long input is important if assurances about a signal are needed before a costly cellular program is triggered. For example, glucose is the sugar on which E. coli cells grow best. Before cells trigger arabinose metabolism in the example above, it might be beneficial to be sure that glucose has been depleted (a sustained CAP pulse), rather than inducing the arabinose program during a transient glucose fluctuation.

Figure 8–87 How an incoherent feedforward motif can generate a brief pulse of gene activation in response to a sustained input. (A) Diagram of an incoherent feed-forward motif in which the transcription activator A and the repressor R control the expression of gene X using the AND NOT logic of Figure 8–85A. (B) When $K_A << K_R$, this motif generates a pulse of protein X expression, such that the output goes back down even if the input remains high. (C) When $K_A >> K_R$, the same motif responds to a sustained input by generating a sustained output.

Figure 8–88 How a coherent feed-forward motif responds to various inputs. (A) Diagram of a coherent feed-forward motif in which the transcription activators A1 and A2 together activate expression of gene X using the AND logic of Figure 8–85B. (B) The response to a brief input can be either weak (as shown) or nonexistent. This allows the motif to ignore random fluctuations in the concentration of signaling molecules. (C) A prolonged input produces a strong response that can turn off rapidly.

MBOC7_ptr_ch08_475-562.indd 556 02/12/21 12:43 PM

The Same Network Can Behave Differently in Different Cells Because of Stochastic Effects

Up to this point, we have assumed that all cells in a population produce identical behaviors if they contain the same network. It is important, however, to account for the fact that cells often show considerable individuality in their responses. Consider a situation in which a single mother cell divides into two daughter cells of equal volume. If the mother cell has only one molecule of a given protein, then only one daughter will inherit it. The daughters, though genetically identical, are already different. This variability is most pronounced for molecules that are present in small numbers. Nevertheless, even when there are many copies of a particular protein (or RNA), it is very unlikely that both daughter cells will end up with exactly the same number of molecules.

This is just one illustration of a universal feature of cells: their behaviors are often **stochastic**, meaning that they display variability in their protein content and therefore exhibit variations in phenotypes. In addition to the asymmetric partitioning of molecules after cell division, variability can originate from many chemical reactions. Imagine, for example, that our mother cell contains a simple gene regulatory circuit with a positive feedback loop like that shown in Figure 8–82B. Even if both daughter cells receive a copy of this circuit, including one copy of the initial transcription activator protein, there will be variability in the time required for promoter binding—and it will be statistically nearly impossible for the genes in the two daughter cells to become activated at precisely the same time. If the system is bistable and poised near a switching point, then variability in the response might flip the switch in only one daughter cell. Two daughter cells that were born identical can thereby acquire, by chance, a dramatic difference in phenotype.

More generally, isogenic populations of cells grown in the same environment display diversity in size, shape, cell-cycle position, and gene expression. These differences arise because biochemical reactions require probabilistic collisions between randomly moving molecules, with each event resulting in changes in the number of molecular species by integer amounts. The amplified effect of fluctuations in a molecular reactant, or the compounded effects of fluctuations across many molecular reactants, often accumulates as an observable phenotype. This can endow a cell with individuality and generate nongenetic cell-to-cell variability in a population.

Nongenetic variability can be studied in the laboratory by single-cell measurements of fluorescent proteins expressed from genes under the control of a specific promoter. Live cells can be mounted on a slide and viewed through a fluorescence microscope, revealing the striking variability in protein expression levels (Figure 8–89). Another approach is to use flow cytometry, which works by streaming a dilute suspension of cells past an illuminator and measuring the fluorescence of individual cells as they flow past the detector. Fluorescence values can be used to build histograms that reveal the variability in a process across a population of cells, with a broad histogram indicating higher variability.

Several Computational Approaches Can Be Used to Model the Reactions in Cells

We have focused primarily on the use of ordinary differential equations to model the dynamics of simple regulatory circuits. These models are called *deterministic*, because they do not incorporate stochastic variability and will always produce the same result from a specific set of parameters. As we have seen, such models can provide useful insights, particularly in the detailed mechanistic analysis of small regulatory circuits. However, other types of computational approaches are also needed to comprehend the great complexity of cell behavior. *Stochastic models*, for example, attempt to account for the very important problem of random variability in molecular networks. These models do not provide deterministic predictions about the behavior of molecules; instead, they incorporate random

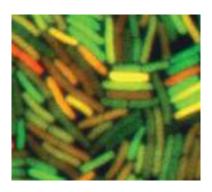

Figure 8-89 Different levels of gene expression in individual cells within a population of E. coli bacteria. For this experiment, two different reporter proteins (one fluorescing green, the other red), controlled by a copy of the same promoter, have been introduced into all of the bacteria. Some cells express only one gene copy, and so appear either red or green. while others express both gene copies, and so appear yellow. This experiment reveals variable levels of fluorescence, indicating variable levels of gene expression within an apparently uniform population of cells. (From M.B. Elowitz et al., Science 297:1183-1186, 2002. With permission from AAAS.)

MBOC7_ptr_ch08_475-562.indd 557 02/12/21 12:43 PM

variation into molecule numbers and interactions, and the purpose of these models is to obtain a better understanding of the probability that a system will exist in a certain state over time.

Numerous other modeling strategies have been or are being developed. *Boolean networks* are used for the qualitative analysis of complex gene regulatory networks containing large numbers of interacting components. In these models, each molecule is a node that can exist in either the active or inactive state, thereby affecting the state of the nodes it is linked to. Models of this sort provide insights into the flow of information through a network, and they were useful in helping us understand the complex gene regulatory network that controls the early development of the sea urchin (see Figure 7–45). Boolean networks therefore reduce complex networks to a highly simplified (and potentially inaccurate) form. At the other extreme are *agent-based simulations*, in which thousands of molecules (or "agents") in a system are modeled individually, and their probable behaviors and interactions with each other over time are calculated on the basis of predicted physical and chemical behaviors, often while taking stochastic variation into account. Agent-based approaches are computationally demanding but have the potential to generate highly life-like simulations of real biological systems.

Statistical Methods Are Critical for the Analysis of Biological Data

Dynamics, differential equations, and theoretical modeling are not the be-all and end-all of mathematics. Other branches of the subject are no less important for biologists. Statistics—the mathematics of probabilistic processes and noisy data sets—is an inescapable part of every biologist's life.

This is true in two main ways. First, imperfect measurement devices and other errors generate experimental noise in our data. Second, all cell-biological processes depend on the stochastic behavior of individual molecules, as we just discussed, and this results in biological noise in our results. How, in the face of all this noise, do we come to conclusions about the truth of hypotheses? The answer is statistical analysis, which shows how to move from one level of description to another: from a set of erratic individual data points to a simpler description of the key features of the data.

Statistics teaches us that the more times we repeat our measurements, the better and more refined the conclusions we can draw from them. Given many repetitions, it becomes possible to describe our data in terms of variables that summarize the features that matter: the mean value of the measured variable, taken over the set of data points; the magnitude of the noise (the standard deviation of the set of data points); the likely error in our estimate of the mean value (the standard error of the mean); and, for specialists, the details of the probability distribution describing the likelihood that an individual measurement will yield a given value. For all these things, statistics provides recipes and quantitative formulas that biologists must understand if they are to make rigorous conclusions on the basis of variable results.

Summary

Quantitative mathematical analysis can provide a powerful extra dimension in our understanding of cell regulation and function. Cell regulatory systems often depend on macromolecular interactions, and mathematical analysis of the dynamics of these interactions can unveil important insights into the importance of binding affinities and protein stability in the generation of transcriptional or other signals. Regulatory systems often employ network motifs that generate useful behaviors: a rapid negative feedback loop dampens the response to input signals; a delayed negative feedback loop creates a biochemical oscillator; positive feedback yields a system that alternates between two stable states; and feed-forward motifs provide systems that generate transient signal pulses or respond only to sustained inputs. The dynamic behavior of these network motifs can be dissected in detail with deterministic and stochastic mathematical modeling.

PROBLEMS 559

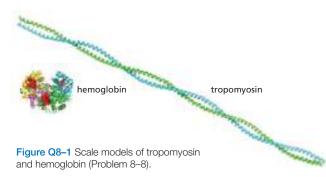

PROBLEMS

Which statements are true? Explain why or why not.

- **8–1** Because a monoclonal antibody recognizes a specific antigenic site (epitope), it binds only to the specific protein against which it was made.
- **8–2** Given the inexorable march of technology, it seems inevitable that the sensitivity of detection of molecules will ultimately be pushed beyond the yoctomole level (10⁻²⁴ mole).
- **8–3** If each cycle of PCR doubles the amount of DNA synthesized in the previous cycle, then 10 cycles will give a 10^3 -fold amplification, 20 cycles will give a 10^6 -fold amplification, and 30 cycles will give a 10^9 -fold amplification.
- **8–4** To judge the biological importance of an interaction between protein *A* and protein *B*, we need to know quantitative details about their concentrations, affinities, and kinetic behaviors.
- 8–5 The rate of change in the concentration of any molecular species X is given by the balance between its rate of appearance and its rate of disappearance.
- **8–6** After a sudden increase in its rate of synthesis, a protein with a slow rate of degradation will reach a new steady-state level more quickly than a protein with a rapid rate of degradation.

Discuss the following problems.

- **8–7** A common step in the isolation of cells from a sample of animal tissue is to treat the tissue with trypsin, collagenase, and EDTA. Why is such a treatment necessary, and what does each component accomplish? And why does this treatment not kill the cells?
- **8–8** Tropomyosin, at 93 kilodaltons, sediments at 2.6S, whereas the 65-kilodalton protein, hemoglobin, sediments at 4.3S. (The sedimentation coefficient S is a linear measure of the rate of sedimentation.) These two proteins are drawn to scale in **Figure Q8–1**. Why does the bigger

protein sediment more slowly than the smaller one? Can you think of an analogy from everyday experience that might help you with this problem?

- **8–9** Hybridoma technology allows one to generate monoclonal antibodies to virtually any protein. Why is it, then, that genetically tagging proteins with epitopes is such a commonly used technique, especially as an epitope tag has the potential to interfere with the function of the protein?
- **8–10** How many copies of a protein need to be present in a cell in order for it to be visible as a band on an SDS gel? Assume that you can load 100 μg of cell extract onto a gel and that you can detect 10 ng in a single band by silver staining the gel. The concentration of protein in cells is about 200 mg/mL, and a typical mammalian cell has a volume of about 1000 μm^3 and a typical bacterium a volume of about 1 μm^3 . Given these parameters, calculate the number of copies of a 120-kilodalton protein that would need to be present in a mammalian cell and in a bacterium in order to give a detectable band on a gel.
- **8–11** You have isolated the proteins from two adjacent spots after two-dimensional polyacrylamide-gel electrophoresis and digested them with trypsin. When the masses of the peptides were measured by MALDI-TOF mass spectrometry, the peptides from the two proteins were found to be identical except for one (**Figure Q8–2**). For this peptide, the mass-to-charge (m/z) values differed by 80, a value that does not correspond to a difference in amino acid sequence. (For example, glutamic acid instead of valine at one position would give an m/z difference of around 30.) Can you suggest a possible difference between the two peptides that might account for the observed m/z difference?

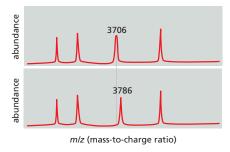

Figure Q8–2 Masses of peptides measured by MALDI-TOF mass spectrometry (Problem 8–11). Only the numbered peaks differ between the two protein samples.

MBOC7_ptr_ch08_475-562.indd 559 02/12/21 12:43 PM

8–12 You want to amplify the DNA between the two stretches of sequence shown in Figure Q8–3. Of the listed primers, choose the pair that will allow you to amplify the DNA by PCR.

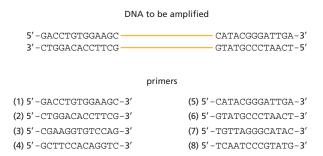

Figure Q8–3 DNA to be amplified and potential PCR primers (Problem 8–12).

- **8–13** In the very first round of PCR using genomic DNA, the DNA primers prime synthesis that terminates only when the cycle ends (or when a random end of DNA is encountered). Yet, by the end of 20–30 cycles—a typical amplification—the only visible product is defined precisely by the ends of the DNA primers. In what cycle is a double-strand fragment of the correct size first generated?
- **8–14** Explain the difference between a gain-of-function mutation and a dominant-negative mutation. Why are both these types of mutation usually dominant?
- **8–15** Discuss the following statement: "We would have no idea today of the importance of insulin as a regulatory hormone if its absence were not associated with the human disease diabetes. It is the dramatic consequences of its absence that focused early efforts on the identification of insulin and the study of its normal role in physiology."
- **8–16** You have received the results from an RNA-seq analysis of mRNAs from liver. You had anticipated counting the number of reads of each mRNA to determine the relative abundance of different mRNAs. But you are puzzled because many of the mRNAs have given you results like those shown in Figure Q8–4. How is it that different parts of an mRNA can be represented at different levels?

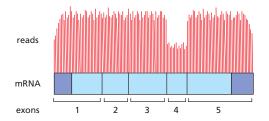

Figure Q8–4 RNA-seq reads for a liver mRNA (Problem 8–16). The exon structure of the mRNA is indicated, with protein-coding segments indicated in *light blue* and untranslated regions in *dark blue*. The numbers of sequencing reads are indicated by the heights of the vertical lines above the mRNA.

8–17 Examine the network motifs in Figure Q8–5. Decide which ones are negative feedback loops and which are positive. Explain your reasoning.

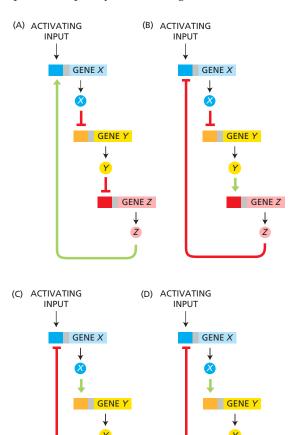

Figure Q8–5 Network motifs composed of transcription activators and repressors (Problem 8–17).

GENE Z

Z

8–18 Imagine that a random perturbation positions a bistable system precisely at the boundary between two stable states (at the *orange dot* in **Figure Q8–6**). How would the system respond?

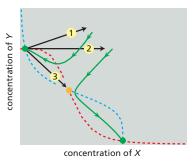

Figure Q8–6 Perturbations of a bistable system (Problem 8–18). As shown by the green lines, after perturbation 1 the system returns to its original stable state (green dot at left), and after perturbation 2, the system moves to the other stable state (green dot at right). Perturbation 3 moves the system to the precise boundary between the two stable states (grange dot).

REFERENCES 561

8–19 Detailed analysis of the regulatory region of the *Lac* operon has revealed surprising complexity. Instead of a single binding site for the Lac repressor, as might be expected, there are three sites termed operators $(O_1, O_2, \text{ and } O_3)$ arrayed along the DNA as shown in Figure Q8–7.

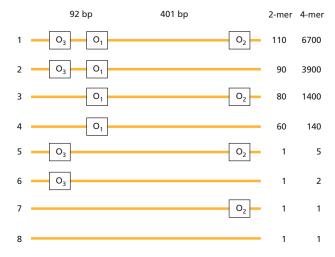

Figure Q8–7 Repression of β-galactosidase by promoter regions that contain different combinations of Lac repressor binding sites (Problem 8–19). The base-pair (bp) separation of the three operator sites is shown. Numbers at *right* refer to the level of repression, with higher numbers indicating more effective repression by dimeric (2-mer) or tetrameric (4-mer) repressors. (From S. Oehler et al., *EMBO J.* 9:973–979, 1990. With permission from John Wiley & Sons.)

To probe the functions of these three sites, you make a series of constructs in which various combinations of operator sites are present. You examine their ability to repress expression of β -galactosidase, using either tetrameric (wild type) or dimeric (mutant) forms of the Lac repressor. The dimeric form of the repressor can bind to a single operator (with the same affinity as the tetramer) with each monomer binding to half the site. The tetramer, the form normally expressed in cells, can bind to two sites simultaneously. When you measure repression of β -galactosidase expression, you find the results shown in Figure Q8–7, with higher numbers indicating more effective repression.

- **A.** Which single operator site is the most important for repression? How can you tell?
- **B.** Do combinations of operator sites (Figure Q8–7, constructs 1, 2, 3, and 5) substantially increase repression by the dimeric repressor? Do combinations of operator sites substantially increase repression by the tetrameric repressor? If the two repressors behave differently, offer an explanation for the difference.
- **C.** The wild-type repressor binds O_3 very weakly when it is by itself on a segment of DNA. However, if O_1 is included on the same segment of DNA, the repressor binds O_3 quite well. How can that be?

Visualizing Cells and Their Molecules

CHAPTER

Understanding the structural organization of cells, and the macromolecules that build and animate them, is essential for learning how they function. In this chapter, we briefly describe some of the principal light and electron microscopy methods used to study cells and molecules. In the past decade or so, there have been major technical developments in both methods that allow us to see biological structures with increasing resolution and clarity. Optical microscopy will be our starting point because cell biology began with the light microscope, and it is still an indispensable tool. The development of methods for the specific labeling and imaging of individual cellular constituents and the reconstruction of their three-dimensional architecture has meant that, far from falling into disuse, optical microscopy continues to increase in importance. One advantage of optical microscopy is that light is relatively nondestructive. By tagging specific cell components with fluorescent probes, such as intrinsically fluorescent proteins, we can watch their movement, dynamics, and interactions in living cells.

Although conventional optical microscopy is limited in resolution by the wavelength of visible light, new methods cleverly bypass this limitation and allow the exact position of even single molecules to be mapped. By using a beam of electrons instead of visible light, electron microscopy can image the interior of cells, and their macromolecular components, at almost atomic resolution and in three dimensions. But all imaging methods involve trade-offs; in this case, the higher resolution means only small objects are imaged and only in fixed, dead cells. There is now a bewildering variety of imaging technologies for the cell biologist to choose from, and when some of these are described later in the chapter, it is worth considering why you might use one rather than another. Trade-offs will always have to be made between thin and thick specimens, living and fixed cells, high and low resolution, fast and slow imaging, signal and noise, or cells and molecules.

This chapter is intended as a companion, rather than an introduction, to the chapters that follow; readers may wish to refer back to it as applications of microscopy to basic biological problems are encountered in other chapters of the book.

LOOKING AT CELLS AND MOLECULES IN THE LIGHT MICROSCOPE

A typical animal cell is $10\text{--}20~\mu m$ in diameter, which is just less than a tenth the size of the smallest object that we can normally see with the naked eye. Only after good light microscopes became available in the early part of the nineteenth century did Matthias Schleiden and Theodor Schwann propose that all plant and animal tissues were aggregates of individual cells. Their proposal in 1838, known as the **cell doctrine**, marks the formal birth of cell biology.

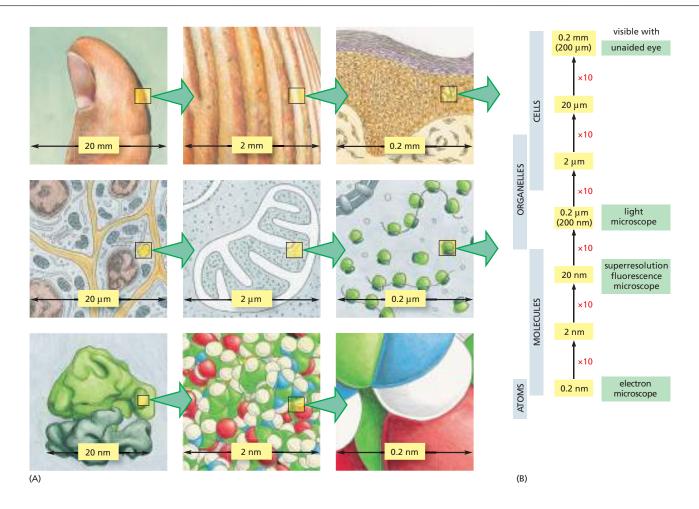

Animal cells are not only tiny, but they are also colorless and translucent. The discovery of their main internal features, therefore, depended on the development, in the late nineteenth century, of a variety of stains that provided sufficient color and contrast to make those features visible. Similarly, the far

Looking at Cells and Molecules in the Electron Microscope

MBOC7_ptr_ch09_563-602.indd 563 02/12/21 2:15 PM

more powerful electron microscope introduced in the early 1940s required the development of new techniques for preserving and staining cells before the full complexities of their internal fine structure could begin to emerge. To this day, microscopy often relies as much on techniques for preparing the specimen as on the performance of the microscope itself. In the following discussions, we therefore consider both instruments and specimen preparation, beginning with the light microscope.

The images in Figure 9–1A illustrate a stepwise progression from a thumb to a cluster of atoms. Each successive image represents a tenfold increase in magnification. The naked eye can see features in the first two panels, the light microscope allows us to see details corresponding to about the fifth panel, and the electron microscope takes us to about the eighth or ninth panel. Figure 9–1B shows the sizes of various cellular and subcellular structures and the ranges of size that different types of microscopes can visualize.

The Conventional Light Microscope Can Resolve Details 0.2 μ m Apart

For well over 100 years, all microscopes were constrained by a fundamental limitation: that a given type of radiation cannot be used to probe structural details much smaller than its own wavelength. A limit to the resolution of a light microscope was therefore set by the wavelength of visible light, which ranges from about 0.4 μm (for violet) to 0.7 μm (for deep red). In practical terms, bacteria and mitochondria, which are about 500 nm (0.5 μm) wide, are generally the smallest objects whose shape we can clearly discern in a standard **light microscope**;

Figure 9-1 A sense of scale between living cells and atoms. (A) Each diagram shows an image magnified by a factor of 10 in an imaginary progression from a thumb, through skin cells, to a ribosome, to a cluster of atoms forming part of one of the many protein molecules in the ribosome. Atomic details of biological macromolecules, as shown in the last two panels, are just within the power of the electron microscope. While color has been used here in all the panels, it is not a feature of objects much smaller than the wavelength of light, so the last five panels should really be in black and white. (B) Sizes of cells and their components are shown on a logarithmic scale, indicating the range of objects that can readily be resolved by the naked eye and in the light and electron microscopes. Note that new superresolution microscopy techniques, discussed in detail later, allow an improvement in resolution by an order of magnitude compared with conventional light microscopy.

MBOC7_ptr_ch09_563-602.indd 564 02/12/21 2:15 PM

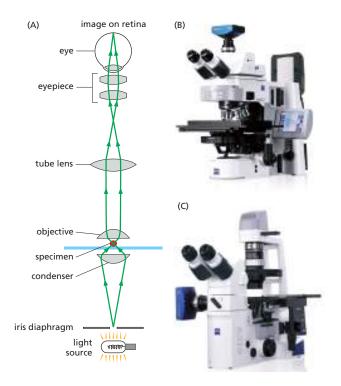

Figure 9-2 A light microscope.

(A) Diagram showing the light path in an upright compound microscope. Light is focused on the specimen by lenses in the condenser. A combination of objective lenses, tube lenses, and eyepiece lenses is arranged to focus an image of the illuminated specimen in the eye. (B) A modern upright research light microscope. (C) A modern inverted microscope, particularly useful for looking at cells in culture. Both microscopes are equipped for fluorescence imaging (B and C, courtesy of Carl Zeiss Microscopy, GmbH.)

details smaller than this are obscured by effects resulting from the wave-like nature of light. Let us follow the behavior of a beam of light as it passes through the lenses of a microscope (Figure 9–2).

Because of its wave nature, light does not follow the idealized straight ray paths that geometrical optics predicts. Instead, light waves travel through an optical system by many slightly different routes, like ripples in water, so that they interfere with one another and cause *optical diffraction* effects. If two trains of waves reaching the same point by different paths are precisely *in phase*, with crest matching crest and trough matching trough, they will reinforce each other so as to increase brightness. In contrast, if the trains of waves are *out of phase*, they will interfere with each other in such a way as to cancel each other partly or entirely (Figure 9-3). The interaction of light with an object changes the phase relationships of the light waves in a way that produces complex interference effects. At high magnification, for example, the shadow of an edge that is evenly illuminated with light of uniform wavelength appears as a set of parallel lines (Figure 9-4A),

The following units of length are commonly employed in microscopy: $\mu m \text{ (micrometer)} = 10^{-6} \text{ m}$ $nm \text{ (nanometer)} = 10^{-9} \text{ m}$ $\text{Å (angstrom)} = 10^{-10} \text{ m}$

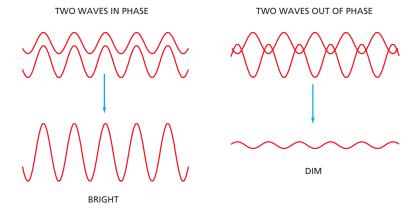

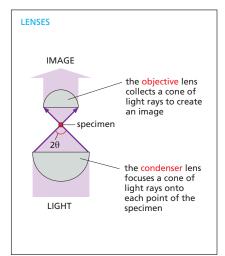

Figure 9–3 Interference between light waves. When two light waves combine in phase, the amplitude of the resultant wave is larger, and the brightness is increased. Two light waves that are out of phase cancel each other partly and produce a wave whose amplitude, and therefore brightness, is decreased.

MBOC7_ptr_ch09_563-602.indd 565 02/12/21 2:15 PM

whereas the smallest focused image of a bright circular aperture appears as a set of concentric rings (Figure 9-4B). For the same reason, a single point seen through a microscope appears as a blurred disc, and two point objects close together give overlapping images and may merge into one. Although no amount of refinement of the lenses can overcome the diffraction limit imposed by the wave-like nature of light, other ways of cleverly bypassing this limit have emerged, creating so-called superresolution imaging techniques that can even detect the position of single molecules. These are discussed later in the chapter.

The limiting separation at which two objects appear distinct—the so-called limit of resolution—depends on both the wavelength of the light and the numerical aperture of the lens system used. The numerical aperture affects the light-gathering ability of the lens and is related both to the angle of the cone of light that can enter it and to the refractive index of the medium the lens is operating in; the wider the microscope opens its eye, so to speak, the more sharply it can see (Figure 9-5). The *refractive index* is the ratio of the speed of light in a vacuum to the speed of light in a particular transparent medium. For example, for water this is 1.33, meaning that light travels 1.33 times slower in water than in a vacuum. Under the best conditions, with violet light (wavelength = $0.4 \mu m$) and a numerical aperture of 1.4, the basic light microscope can theoretically achieve a limit of resolution of about 0.2 µm, or 200 nm. Some microscope makers at the end of the nineteenth century achieved this resolution, but it is routinely matched in contemporary, factory-produced microscopes. Although it is possible to enlarge an image as much as we want-for example, by projecting it onto a screen-it is not possible, in a conventional light microscope, to resolve two objects in the light microscope that are separated by less than about 0.2 µm; they will always appear as a single object. It is important, however, to distinguish between resolution and detection. If a small object, below the resolution limit, itself emits light, then we may still be able to see or detect it. Thus, we can see a single fluorescently labeled microtubule even though it is about 10 times thinner than the resolution limit of the light microscope. Diffraction effects, however, will cause it to appear blurred and at least 0.2 µm thick (see Figure 9-14). In a similar way, we can see the stars in the night sky, even though their diameters are far below the angular resolution of our unaided eyes: they all appear as similar, slightly blurred points of light, differing only in their color and brightness.

NUMERICAL APERTURE: $n \sin \theta$ in the equation above is called the numerical aperture of the lens and is a function of its light-collecting ability. For dry lenses this cannot be more than 1, but for oil-immersion lenses it can be as high as 1.4. The higher the numerical

RESOLUTION: the resolving power of the microscope depends on the width of the cone of illumination and therefore on both the condenser and the objective lens. It is calculated using the formula

resolution =
$$\frac{0.61 \,\lambda}{n \sin \theta}$$

where:

- $\theta=$ half the angular width of the cone of rays collected by the objective lens from a typical point in the central region of the specimen (because the maximum width is 180°, $\sin\theta$ has a maximum value of 1)
- n = the refractive index of the medium (usually air or oil) separating the specimen from the objective and condenser lenses
- λ = the wavelength of light used (for white light a figure of 0.53 μm is commonly assumed)

aperture, the greater the resolution and the brighter the image (brightness is important in fluorescence microscopy). However, this advantage does necessitate very short working distances and a very small depth of field, just as in a conventional camera.

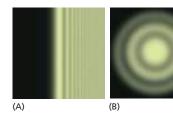

Figure 9-4 Images of an edge and of a point of light. (A) The interference effects, or fringes, seen at high magnification when light of a specific wavelength passes the edge of a solid object placed between the light source and the observer. (B) The image of a point source of light. Diffraction spreads this out into a complex, circular pattern, whose width depends on the numerical aperture of the optical system: the smaller the aperture, the bigger (more blurred) the diffracted image. Two point sources can be just resolved when the center of the image of one lies within the first dark ring in the image of the other: this is used to define the limit of resolution.

Figure 9–5 Basic principles of light microscopy. The path of light rays passing through a transparent specimen in a microscope illustrates the concept of numerical aperture and its relation to the limit of resolution. The higher the numerical aperture of a lens, the brighter the image it forms and the higher its resolution.

MBOC7_ptr_ch09_563-602.indd 566 02/12/21 2:15 PM

Photon Noise Creates Additional Limits to Resolution When Light Levels Are Low

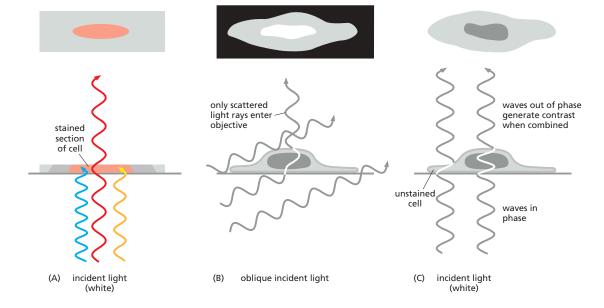

Any image, whether produced by an electron microscope or by an optical microscope, is made by particles—electrons or photons—striking a detector of some sort. But these particles are governed by quantum mechanics, so the numbers reaching the detector are predictable only in a statistical sense. Finite samples, collected by imaging for a limited period of time (that is, by taking a snapshot), will show random variation: successive snapshots of the same scene will not be exactly identical. Moreover, every detection method has some level of background signal or noise, adding to the statistical uncertainty. With bright illumination, corresponding to very large numbers of photons or electrons, the features of the imaged specimen are accurately determined on the basis of the distribution of these particles at the detector. However, with smaller numbers of particles, the structural details of the specimen are obscured by the statistical fluctuations in the numbers of particles detected in each region, which give the image a speckled appearance and limit its precision. The term noise describes this random variability. Because noise in the image is proportional to the square root of the number of photons that are detected (or electrons in electron microscopy), then as the number of photons or electrons recorded increases, the absolute noise also increases, but because of the square root relationship, the percentage of noise decreases, in other words the signal-to-noise ratio improves. A poor signal-to-noise ratio is an important consideration when weak fluorescent light signals are recorded or low, but less damaging, electron doses are required.

Living Cells Are Seen Clearly in a Phase-Contrast or a Differential-Interference-Contrast Microscope

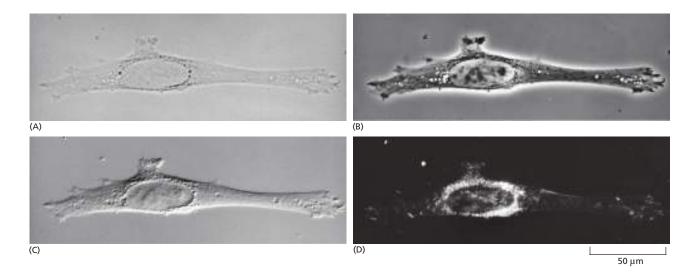

There are many ways in which contrast in a specimen can be generated (Figure 9–6). While fixing and staining a specimen can generate contrast through color (Figure 9–6A), microscopists have always been challenged by the possibility that some components of the cell may be lost or distorted during specimen preparation. The only certain way to avoid the problem is to examine cells while they are alive, without fixing or freezing. For this purpose, light microscopes with special optical systems are especially useful.

In the normal **bright-field microscope**, light passing through a cell in culture forms the image directly. Another system, **dark-field microscopy**, exploits the fact that light rays can be scattered in all directions by small objects in their path.

Figure 9-6 Contrast in light microscopy. (A) The stained portion of the cell will absorb light of some wavelengths, which depends on the stain, but will allow other wavelengths to pass through it. A colored image of the cell is thereby obtained that is visible in the normal bright-field light microscope. (B) In the dark-field microscope, oblique rays of light focused on the specimen do not enter the objective lens, but light that is scattered by components in the living cell can be collected to produce a bright image on a dark background. (C) Light passing through the unstained living cell experiences very little change in amplitude, and the structural details cannot be seen even if the image is highly magnified. The phase of the light, however, is altered by its passage through either thicker or denser parts of the cell, and small phase differences can be made visible by exploiting interference effects using a phase-contrast or a differentialinterference-contrast microscope.

MBOC7_ptr_ch09_563-602.indd 567 02/12/21 2:15 PM

If oblique lighting from the condenser is used, which does not directly enter the objective, unstained objects in a living cell can scatter the rays, some of which then enter the objective to create a bright image against a black background (Figure 9-6B).

When light passes through a living cell, the phase of the light wave is changed according to the cell's refractive index: a relatively thick or dense part of the cell, such as a nucleus, slows the light passing through it. The phase of the light, consequently, is shifted relative to light that has passed through an adjacent thinner region of the cytoplasm (Figure 9–6C). The **phase-contrast microscope** and, in a more complex way, the **differential-interference-contrast microscope** increase these phase differences to produce amplitude differences, or contrast, when the sets of waves recombine, thereby creating an image of the cell's structure. Both types of light microscopy are widely used to look at living cells (see Movie 17.2). Figure 9–7 compares images of the same cell obtained by four kinds of light microscopy.

Phase-contrast, differential-interference-contrast, and dark-field microscopy make it possible to watch the movements involved in such processes as mitosis and cell migration. Because many cellular motions are too slow to be seen in real time, it is often helpful to make time-lapse videos in which the camera records successive frames separated by a short time delay, so that when the resulting picture series is played at normal speed, events appear greatly speeded up.

Images Can Be Enhanced and Analyzed by Digital Techniques

Digital imaging systems, and the associated technology of **image processing**, have had a major impact on light microscopy. Certain practical limitations of microscopes relating to imperfections in their optical components have been largely overcome. Digital imaging systems have also circumvented two fundamental limitations of the human eye: the eye cannot see well in extremely dim light, and it cannot perceive small differences in light intensity against a bright background. To increase our ability to observe cells in these difficult conditions, we can attach a sensitive digital camera to a microscope. These cameras detect light by means of high-sensitivity complementary metal-oxide semiconductor (CMOS) sensors, similar to those now found in digital cameras and smartphones. Such image sensors can count individual photons and are many times more sensitive than the human eye and can detect 100 times more intensity levels. It is therefore possible to observe cells for long periods at very low light levels, thereby avoiding the damaging effects of prolonged bright light (and heat). Such sensitive detectors are especially important for viewing fluorescent molecules in living cells, as explained later.

Because images produced by digital cameras are in electronic form, they can be processed in various ways to extract latent information. Such image processing

Figure 9-7 Four types of light microscopy. Four images are shown of the same fibroblast cell in culture. All images can be obtained with most modern microscopes by interchanging optical components. (A) Bright-field microscopy, in which light is transmitted straight through the specimen. (B) Phase-contrast microscopy, in which phase alterations of light transmitted through the specimen are translated into brightness changes. (C) Differential-interference-contrast microscopy, which highlights edges where there is a steep change of refractive index. (D) Dark-field microscopy, in which the specimen is lit from the side and only the scattered light is seen.

MBOC7_ptr_ch09_563-602.indd 568 02/12/21 2:15 PM

makes it possible to compensate for several aberrations in the lenses of microscopes. Moreover, by digital image processing, contrast can be greatly enhanced to overcome the eye's limitations in detecting small differences in light intensity, and background irregularities in the optical system can be digitally subtracted. This procedure reveals small transparent objects that were previously impossible to distinguish from the background.

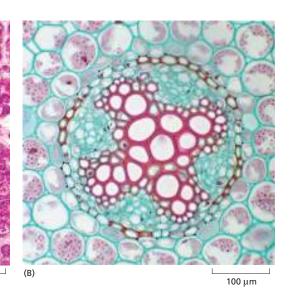

Intact Tissues Are Usually Fixed and Sectioned Before Microscopy

Looking at individual living cells in culture is relatively easy, but most cells are found in complex tissues and organs, and this forces another trade-off when we want to look at them. Because most tissue samples are too thick for their individual cells to be examined directly at high resolution, they are often cut into very thin transparent slices, or *sections*. To preserve the cells within the tissue they must first be treated with a *fixative*. A common fixative is glutaraldehyde, which forms covalent bonds with the free amino groups of proteins, cross-linking them so they are stabilized and locked into position.

Because tissues are generally soft and fragile, even after fixation, they need to be either frozen or embedded in a supporting medium before they can be sectioned. The usual embedding media are waxes or resins. In liquid form, these media both permeate and surround the fixed tissue before being hardened (by cooling or by polymerization) to form a solid block, which is readily sectioned with a microtome. This is a machine with a sharp blade, usually of steel or glass, which operates like a meat slicer (Figure 9–8). The sections (typically 0.5–10 μ m thick) are then laid flat on the surface of a glass microscope slide.

There is little in the contents of most cells (which are 70% water by weight) to impede the passage of light rays. Thus, most cells in their natural state, particularly if fixed and sectioned, are almost invisible in an ordinary light microscope. We have seen that cellular components can be made visible by techniques such as phase-contrast and differential-interference-contrast microscopy, but these methods tell us almost nothing about the underlying chemistry. There are three main approaches to working with thin tissue sections that reveal differences in the types of molecules that are present.

First, and traditionally, sections can be stained with organic dyes that have some specific affinity for particular subcellular components. The dye hematoxylin, for example, has an affinity for negatively charged molecules and therefore reveals the general distribution of DNA, RNA, and acidic proteins in a cell (Figure 9–9). The chemical basis for the specificity of many dyes, however, is not known, although they are used widely in hospital laboratories.

movement of microtome arm specimen embedded in wax or resin fixed blade ribbon of sections on glass slide, stained and mounted under a glass cover slip

Figure 9–8 Making tissue sections. This illustration shows how an embedded tissue is sectioned with a microtome in preparation for examination in the light microscope. Very rapidly frozen samples can also be sectioned, and these better preserve the structure of cells in their native state.

(A) This section of cells in a salivary gland was stained with hematoxylin and eosin, two dyes commonly used in histology. The central duct is made of closely packed cells with nuclei stained *purple* and cytoplasm stained *red*. The duct is surrounded by groups of saliva-secreting cells. (B) This section of a young plant root is stained

Figure 9-9 Staining of cell components.

with nuclei stained *purple* and cytoplasm stained *red*. The duct is surrounded by groups of saliva-secreting cells. (B) This section of a young plant root is stained with two dyes, safranin and fast green. Fast green stains the cellulosic cell walls, while the safranin stains the lignified xylem cell walls *red*. MBOC7_ptr_ch09_563-602.indd 569 02/12/21 2:16 PM

Second, sectioned tissues can be used to visualize specific patterns of differential gene expression. A third and very sensitive approach, generally and widely applicable for localizing proteins of interest, depends on the use of fluorescent probes and markers, as we explain next.

Specific Molecules Can Be Located in Cells by Fluorescence Microscopy

Fluorescent molecules absorb light at one wavelength and emit it at another, longer wavelength (Figure 9-10A and B). If we illuminate such a molecule at its absorbing wavelength and then view it through a filter that allows only light of the emitted wavelength to pass, it will glow against a dark background. Because the background is dark, even a minute amount of the glowing fluorescent dye can be detected. In contrast, the same number of molecules of a nonfluorescent stain, viewed conventionally, would be practically indiscernible because the absorption of light by molecules in the stain would result in only the faintest tinge of color in the light transmitted through that part of the specimen.

The fluorescent dyes used for staining cells are visualized with a **fluorescence microscope**. This microscope is similar to an ordinary upright or inverted light microscope except that the illuminating light, from a very powerful source, is passed through two sets of filters—one to filter the light before it reaches the specimen, and one to filter the light obtained from the specimen. The first filter passes only the wavelengths that excite the particular fluorescent dye, while the second filter blocks out this light and passes only those wavelengths emitted when the dye fluoresces (**Figure 9–10C**).

Fluorescence microscopy is most often used to detect specific proteins or other molecules in cells and tissues. For example, when using fluorescent nucleotide probes, *in situ* hybridization, discussed earlier (see Figure 8–63), can reveal

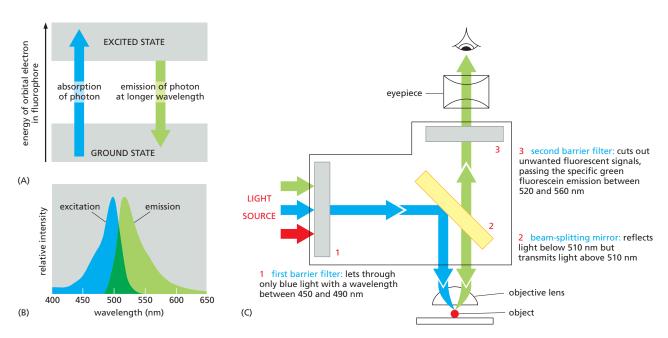

Figure 9–10 Fluorescence and the fluorescence microscope. (A) An orbital electron of a fluorochrome molecule can be raised to an excited state after the absorption of a photon. Fluorescence occurs when the electron returns to its ground state and emits a photon of light at a longer wavelength. Too much exposure to light or too bright a light can destroy the fluorochrome molecule in a process called *photobleaching*. (B) The excitation and emission spectra for the common fluorescent dye fluorescein isothiocyanate (FITC). (C) In the fluorescence microscope, a filter set consists of two barrier filters (1 and 3) and a dichroic (beam-splitting) mirror (2). This example shows the filter set for detection of the fluorescent molecule fluorescein. High-numerical-aperture objective lenses are especially important in this type of microscopy because, for a given magnification, the brightness of the fluorescent image is proportional to the fourth power of the numerical aperture (see also Figure 9–5).

MBOC7_ptr_ch09_563-602.indd 570 02/12/21 2:16 PM

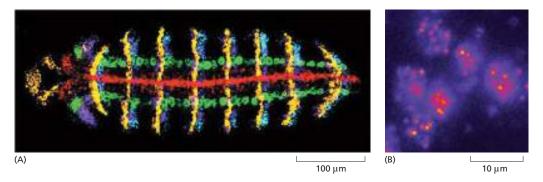

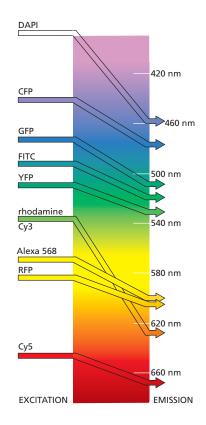

Figure 9–11 RNA in situ hybridization. (A) As described in Chapter 8 (see Figure 8–63), it is possible to visualize the distribution of different RNAs in tissues using in situ hybridization. Here, the transcription pattern of five different genes involved in patterning the early fruit fly embryo is revealed in a single embryo. Each RNA probe has been fluorescently labeled, and the resulting images are displayed each in a different color ("false-colored") and then combined to give an image where different color combinations represent different sets of genes expressed. The genes whose expression pattern is revealed here are wingless (yellow), engrailed (blue), short gastrulation (red), intermediate neuroblasts defective (green), and muscle specific homeobox (purple). (B) Individual RNA transcripts can be detected in a single cell. Each of these six yeast cells is expressing less than 20 transcripts of a particular gene. Using multiple DNA oligonucleotide probes to that particular gene, each labeled with many fluorescent Cy5 molecules, each individual RNA transcript can be detected as a red spot. [A, from D. Kosman et al., Science 305:846, 2004. With permission from AAAS; B, from G.M. Wadsworth, R.Y. Parikh, and H.D. Kim, Single-probe RNA FISH in yeast. Bio Protoc. 8(11):e2868, 2018, doi 10.21769/BioProtoc.2868.]

the cellular distribution and abundance of specific expressed RNA molecules in sectioned material or in whole mounts of small organisms, organs, or cells (Figure 9–11).

A versatile and widely used technique is to couple fluorescent dyes to antibody molecules, which then serve as highly specific and versatile staining reagents that bind selectively to the particular macromolecules they recognize in cells or in the extracellular matrix. Two fluorescent dyes that have been commonly used for this purpose are fluorescein, which emits an intense green fluorescence when excited with blue light, and rhodamine, which emits a deep red fluorescence when excited with green-yellow light (Figure 9-12). By coupling one antibody to fluorescein and another to rhodamine, the distributions of different molecules can be compared in the same cell; the two molecules are visualized separately in the microscope by switching back and forth between two sets of filters, each specific for one dye. As shown in Figure 9-13, multiple fluorescent dyes can be used in the same way to clearly distinguish several different types of molecules in the same cell. Many fluorescent dyes, such as Cy3, Cy5, and the Alexa dyes, have been specifically developed for fluorescence microscopy, but, like many organic fluorochromes, they fade fairly rapidly when continually illuminated. Later in the chapter, additional fluorescence microscopy methods will be discussed that can be used to monitor changes in the concentration and location of specific molecules inside

Figure 9–12 Fluorescent probes. The maximum excitation and emission wavelengths of several commonly used fluorescent probes are shown in relation to the corresponding colors of the spectrum. The photon emitted by a fluorescent molecule is necessarily of lower energy (longer wavelength) than the absorbed photon, and this accounts for the difference between the excitation and emission peaks. CFP, GFP, YFP, and RFP are cyan, green, yellow, and red fluorescent proteins, respectively. DAPI is widely used as a general fluorescent DNA probe, which absorbs ultraviolet light and fluoresces bright blue. FITC is an abbreviation for fluorescein isothiocyanate—a widely used derivative of fluorescein—which fluoresces bright green. The other probes are all commonly used to fluorescently label antibodies and other proteins. Note that although the true fluorescence emission colors are shown here, the actual color seen in the microscope will depend on the second barrier filter used (see Figure 9–10), and these are usually optimized so as to allow as many different non-overlapping colored probes to be seen in the same specimen. Thus although YFP emits in the green spectrum, it actually appears as a yellow-green in the microscope because of the filter used. The use of fluorescent proteins will be discussed later in the chapter.

MBOC7_ptr_ch09_563-602.indd 571 02/12/21 2:16 PM

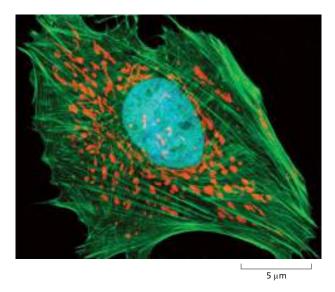

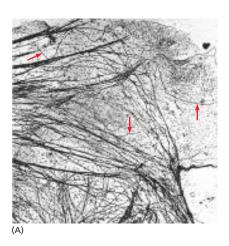

Figure 9–13 Different fluorescent probes can be visualized in the same cell. In this composite micrograph of an epithelial cell in culture, three different fluorescent probes have been used to label three different cellular components. The actin filaments of the cytoskeleton are revealed with a green fluorescent probe, the numerous mitochondria with a red fluorescent dye that accumulates inside the organelles, and the nucleus with a blue fluorescent dye that binds to DNA. (Courtesy of Carl Zeiss Microscopy, GmbH.)

living cells. As with all microscopy methods there are trade-offs to consider. In all fluorescence microscopes, the only molecules that can be imaged are those that are fluorescently labeled; all the other molecules in the cell remain hidden.

Antibodies Can Be Used to Detect Specific Proteins

Antibodies are proteins produced by the vertebrate immune system as a defense against infection (discussed in Chapter 24). They are unique among proteins in that they are made in billions of different forms, each with a different binding site that recognizes a specific target molecule (or *antigen*). The precise antigen specificity of antibodies makes them powerful tools for the cell biologist. When chemically coupled to fluorescent dyes, antibodies are invaluable for locating specific molecules in cells by fluorescence microscopy (Figure 9-14). When labeled with electron-dense particles such as colloidal gold spheres, they are used for similar purposes in the electron microscope (discussed later). The antibodies employed in microscopy are commonly either purified from antiserum so as to remove all nonspecific antibodies or they are specific monoclonal antibodies that only recognize the target molecule.

When we use antibodies as probes to detect and assay specific molecules in cells, we frequently use methods to amplify the fluorescent signal they produce. For example, although a marker molecule such as a fluorescent dye can be linked directly to an antibody—the *primary antibody*—a stronger signal is achieved by

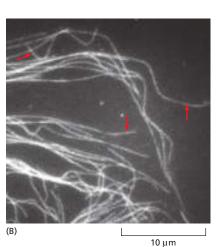

Figure 9–14 Immunofluorescence.

(A) A transmission electron micrograph of the periphery of a cultured epithelial cell showing the distribution of microtubules and other filaments. (B) The same area stained with fluorescent antibodies against tubulin, the protein that assembles to form microtubules, using the technique of indirect immunocytochemistry (see Figure 9-15). Red arrows indicate individual microtubules that are readily recognizable in both images. Note that, because of diffraction effects, the microtubules in the light microscope appear 0.2 μm wide rather than their true width of 0.025 μm. (© 1978 M. Osborn et al. Originally published in J. Cell Biol. doi 10.1083/jcb.77.3.R27. With permission from Rockefeller University Press.)

MBOC7_ptr_ch09_563-602.indd 572 02/12/21 2:16 PM

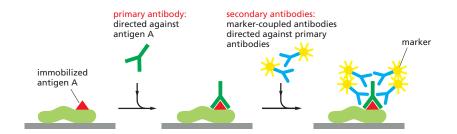

Figure 9–15 Indirect immunocytochemistry. This detection method is very sensitive because many molecules of the secondary antibody recognize each primary antibody. The secondary antibody is covalently coupled to a marker molecule that makes it readily detectable. Commonly used marker molecules include fluorescent dyes (for fluorescence microscopy) and colloidal gold spheres (for electron microscopy).

using an unlabeled primary antibody and then detecting it with a group of labeled *secondary antibodies* that bind to it (Figure 9–15). This process is called *indirect immunocytochemistry*.

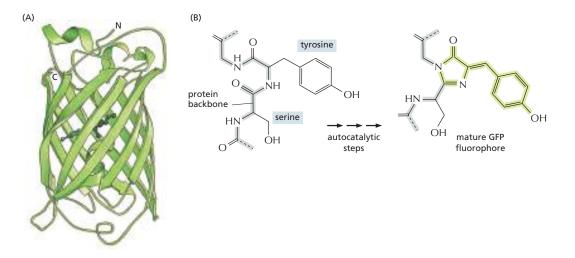

Individual Proteins Can Be Fluorescently Tagged in Living Cells and Organisms

Even the most stable cell structures must be assembled, disassembled, and reorganized during the cell's life cycle. Other structures, often enormous on the molecular scale, rapidly change, move, and reorganize themselves as the cell conducts its internal affairs and responds to its environment. Complex, highly organized pieces of molecular machinery move components around the cell, controlling traffic into and out of the nucleus, from one organelle to another, and into and out of the cell itself.

Various techniques have been developed to visualize the specific components involved in such dynamic phenomena, and many of these methods use fluorescent proteins. All of the fluorescent molecules discussed so far are made outside the cell and then artificially introduced into it. But the use of genes encoding protein molecules that are themselves inherently fluorescent also enables the creation of organisms and cell lines that make their own visible tags and labels, without the introduction of foreign molecules. These cellular exhibitionists display their inner workings in glowing fluorescent color.

Foremost among the fluorescent proteins used for these purposes by cell biologists is the **green fluorescent protein (GFP)**, isolated from the jellyfish *Aequorea victoria*. This protein is encoded by a single gene, which can be cloned and introduced into cells of other species. The freshly translated protein is not fluorescent, but within an hour or so (less for some alleles of the gene, more for others) some of the amino acids undergo a self-catalyzed post-translational modification to generate an efficient fluorochrome, shielded within the interior of a barrel-like protein, which will now fluoresce green when illuminated appropriately with blue light (**Figure 9–16**). Extensive site-directed mutagenesis performed on the

Figure 9–16 Green fluorescent protein (GFP). (A) The structure of GFP, shown here schematically, highlights the eleven β strands that form the staves of a barrel, buried within which is the active chromophore (dark green). (B) The chromophore is formed post-translationally from the protruding side chains of two amino acid residues in a series of autocatalytic steps. (A, PDB code: 1EMA, from M. Ormö et al., Science 273:1392–1395, 1996. With permission from AAAS.)

MBOC7_ptr_ch09_563-602.indd 573 02/12/21 2:16 PM

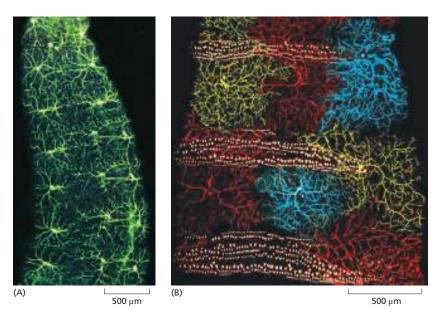

Figure 9-17 Fluorescent proteins as reporter molecules. (A) For this experiment, carried out in the fruit fly, the GFP gene was joined (using recombinant DNA techniques) to a fly promoter that is active only in a specialized set of neurons. This image of a live fly embryo was captured by a fluorescence microscope and shows approximately 20 neurons, each with long projections (axons and dendrites) that communicate with other (nonfluorescent) cells. These neurons are located just under the surface of the animal and allow it to sense its immediate environment. (B) In a variation of this method, three different fluorescent proteins, red, yellow, and cyan, can be expressed at random in neurons of the live fly embryo. The genetic constructs have been arranged such that a strong pulse of blue light will activate the expression of one or other of the three fluorescent proteins at random in neuronal cells, where they are then targeted to the plasma membrane. This noninvasive control of the timing of cell labeling allows the behavior of individual cells to be followed subsequently over time. The fine detail of all the dendrites of individual sensory neurons can be clearly seen. The lines of pale dots arise from the autofluorescence of the bands of denticles in the cuticle that define the segments of the embryo (see Figure 21-24). (A, from W.B. Grueber et al., Curr. Biol. 13:618-626, 2003. With permission from Elsevier; B, from M. Boulina et al., Development 140:1605-1613, 2013, doi 10.1242/dev.088930. © 2013. Published by the Company of Biologists Ltd.)

original gene sequence has resulted in multiple variants that can be used effectively in organisms ranging from animals and plants to fungi and microbes. The fluorescence efficiency has also been improved, and variants have been generated with altered absorption and emission spectra from the blue-green, like blue fluorescent protein (BFP), to the far visible red. Other, related fluorescent proteins have since been discovered (for example, in corals) that also extend the range into the red region of the spectrum, like red fluorescent protein (RFP).

One of the simplest uses of GFP is as a reporter molecule, a fluorescent probe to monitor gene expression. A transgenic organism can be made with the GFP-coding sequence placed under the transcriptional control of the promoter belonging to a gene of interest, giving a directly visible readout of the gene's expression pattern in the living organism (Figure 9–17). In another application, a peptide location signal can be added to the GFP to direct it to a particular cell compartment, such as the endoplasmic reticulum or a mitochondrion (see Figure 9–25B), lighting up these organelles so they can be observed in the living state.

The GFP DNA-coding sequence can also be inserted at the beginning or end of the coding sequence for another protein, yielding a chimeric product consisting of that protein with a new GFP domain attached. In many cases, this GFP fusion protein behaves in the same way as the original protein, directly revealing its location and activities by means of its genetically encoded fluorescence (Figure 9–18). It is often possible to prove that the GFP fusion protein is functionally equivalent

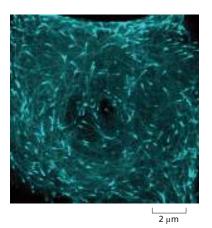

Figure 9–18 GFP-tagged proteins. This cultured mammalian cell is expressing EB3, a plus-end tracking protein that is fused to a GFP-derived blue fluorescent protein (BFP). These proteins associate with the plus ends of growing microtubules (see Figure 16–49), and their dynamics can be followed as they appear to zoom brightly around the cell. (Courtesy of Carl Zeiss Microscopy, GmbH.)

MBOC7_ptr_ch09_563-602.indd 574 02/12/21 2:16 PM

to the untagged protein, for example by using it to rescue a mutant lacking that protein. GFP tagging is the clearest and most unequivocal way of showing the distribution and dynamics of a protein in a living organism (see Movie 16.8).

Protein Dynamics Can Be Followed in Living Cells

Fluorescent proteins are now exploited not just to see where in a cell a particular protein is located, but also to uncover its kinetic properties and to find out whether it might interact with other molecules. We now describe techniques in which fluorescent proteins are used in this way.

First, interactions between one protein and another can be monitored by Förster resonance energy transfer, also called fluorescence resonance energy transfer but both abbreviated to FRET. In this technique, two molecules of interest are each labeled with a different fluorochrome, chosen so that the emission spectrum of one fluorochrome, the donor, overlaps with the absorption spectrum of the other, the acceptor. If the two proteins interact in such a way as to bring their fluorochromes into very close proximity (closer than about 5 nm), one fluorochrome, when excited, can transfer energy from the absorbed light directly (by resonance, nonradiatively) to the other. Thus, when the complex is illuminated at the excitation wavelength of the first fluorochrome, fluorescent light is produced at the emission wavelength of the second (Figure 9-19). This method can be used with two different spectral variants of GFP as fluorochromes to monitor processes such as the interaction of signaling molecules with their receptors (see Figure 15-49) or proteins in macromolecular complexes at specific locations inside living cells. The FRET can be measured by quantifying the reduction of the donor fluorescence in the presence of the acceptor. The efficiency of FRET is inversely proportional to the sixth power of the distance between the donor and acceptor molecules and so is extremely sensitive to small changes

The genes encoding GFP and related fluorescent proteins can be engineered to produce protein variants, usually with one or more amino acid changes, that fluoresce only weakly under normal excitation conditions but can be induced to fluoresce either more strongly or with a color shift (for example, from green to red) by activating them with a strong pulse of light at a different wavelength in a process called **photoactivation**. In principle, the biologist can then follow the local *in vivo* behavior of any protein that can be expressed as a fusion with one of

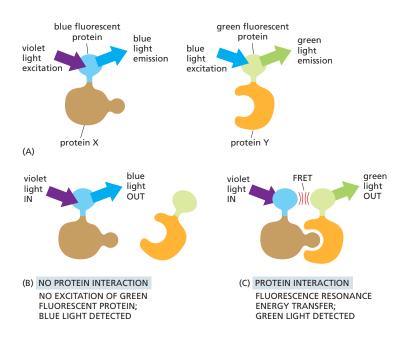

Figure 9-19 Fluorescence resonance energy transfer (FRET). To determine whether (and when) two proteins interact inside a cell, the proteins are first produced as fusion proteins attached to different color variants of green fluorescent protein (GFP). (A) In this example, protein X is coupled to a blue fluorescent protein, which is excited by violet light and emits blue light; protein Y is coupled to a green fluorescent protein, which is excited by blue light and emits green light. (B) If protein X and Y do not interact, illuminating the sample with violet light yields fluorescence only from the blue fluorescent protein. (C) When protein X and protein Y interact, the resonance transfer of energy, FRET, can now occur. Illuminating the sample with violet light excites the blue fluorescent protein, which transfers its energy to the green fluorescent protein, resulting in an emission of green light. The fluorochromes must be quite close together-within about 1-5 nm of one another—for FRET to occur. Because not every molecule of protein X and protein Y is bound at all times, some blue light may still be detected. But as the two proteins begin to interact, emission from the donor blue fluorescent protein falls as the emission from the acceptor GFP rises.

MBOC7_ptr_ch09_563-602.indd 575 02/12/21 2:16 PM

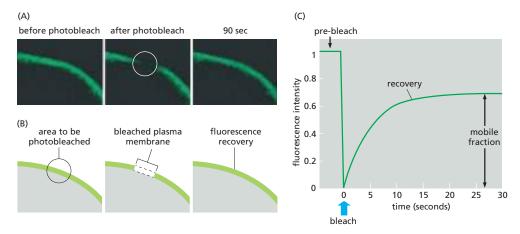

Figure 9–20 Fluorescence recovery after photobleaching (FRAP). A strong focused pulse of laser light will extinguish, or bleach, fluorescent proteins. By selectively photobleaching a set of fluorescently tagged protein molecules within a defined region of a cell, the microscopist can monitor recovery over time, as the remaining fluorescent molecules move into the bleached region (see Movie 10.6). (A) This cultured mammalian cell is expressing an integral membrane protein called CD86, which is fused with a fluorescent protein. CD86 is a co-stimulatory protein present in the plasma membrane of antigen-presenting cells and is required for the activation of T cells (see Figure 24–34). After a small region of the plasma membrane is selectively photobleached, the remaining fluorescent molecules diffuse rapidly within the plane of the membrane and populate the bleached region. This recovery can be followed as a function of time. (B) Schematic diagram of the experiment shown in A. (C) Measurements of the fluorescence intensity in the bleached area as a function of time can be plotted as a fluorescence recovery curve. From such graphs quantitative data can be derived about the rate of recovery and the fraction of fluorescent protein molecules that are either mobile or immobile. (A, from S. Dorsch et al., Nat. Methods 6:225–230, 2009.)

these GFP variants. These genetically encoded, photoactivatable, fluorescent proteins allow the lifetime and behavior of any protein to be studied independently of other newly synthesized proteins.

Another way to exploit GFP fused to a protein of interest is known as **fluorescence recovery after photobleaching (FRAP)**. Here, a strong focused beam of light from a laser is used to extinguish the GFP fluorescence in a specified region of the cell, after which one can analyze the way in which remaining unbleached fluorescent protein molecules move into the bleached area as a function of time. This technique, like photoactivation, can deliver valuable quantitative data about a protein's kinetic parameters, such as diffusion coefficients, active transport rates, or binding and dissociation rates from other proteins (**Figure 9–20**).

Fluorescent Biosensors Can Monitor Cell Signaling

Extracellular signals cause rapid and transient changes in the concentration of intracellular signaling molecules that play an important role in how cells respond. But how to see and measure such dynamic and rapid changes remains a challenge. Changes in the concentration of some of these molecules, for example Ca²⁺ ions, can be analyzed using simple ion-sensitive indicators, whose light emission reflects the local Ca²⁺ ion concentration (Figure 9-21, and see also Figure 15-31). However, the most sensitive indicators available are a range of genetically encoded biosensors, all based on the growing family of fluorescent proteins described earlier. These sensors can be synthesized by the specific cells of interest and easily fused with protein tags that target them to specific destinations within the cell. Here they can act as molecular informants, reporting back like spies on transient signaling events to the careful observer. To convert information about changes in the level of a signaling molecule into changes in observable fluorescence intensity requires two key components: a sensing component that responds to the target signaling event, and a reporting component

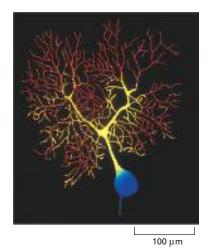

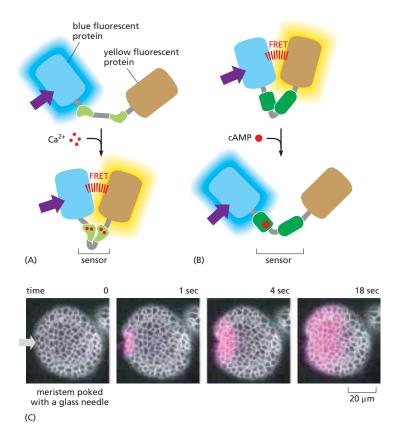

Figure 9-21 Visualizing intracellular Ca2+ concentrations by using a fluorescent indicator. The branching tree of dendrites of a Purkinje cell in the cerebellum receives more than 100,000 synapses from other neurons. The output from the cell is conveyed along the single axon seen leaving the cell body at the bottom of the picture. This image of the intracellular Ca2+ concentration in a single Purkinje cell (from the brain of a guinea pig) was taken with a low-light camera and the Ca²⁺-sensitive fluorescent indicator fura-2. The concentration of free Ca2+ is represented by different colors, red being the highest and blue the lowest. The highest Ca2+ levels are present in the thousands of dendritic branches. (Courtesy of D.W. Tank, J.A. Connor, M. Sugimori, and R.R. Llinas.)

MBOC7_ptr_ch09_563-602.indd 576 02/12/21 2:16 PM

that translates that response into a visible and quantifiable output. Many biosensors use two connected fluorescent proteins that can be brought close enough together to undergo Förster resonance energy transfer (see Figure 9–19). Bringing them together, or indeed moving them apart, is a connecting sensor module. The sensor is usually a protein or protein domain that undergoes a large conformational change on binding to the target molecule. The general principle used to construct a genetically encoded biosensor is shown in **Figure 9–22**. Measuring the ratio of the intensities of light emitted by the two fluorescent proteins in the biosensor provides a quantitative measure of the concentration of the target molecule of interest. Many hundreds of such biosensors have been created. Some can monitor and measure small molecules in living cells, such as Ca^{2+} , cAMP, IP $_3$, NADPH (and hence redox state), H^+ ions (and hence pH), and neurotransmitters such as acetylcholine and glutamate. Others can measure the activity of kinases, phosphatases, active caspases, and even temperature.

Imaging of Complex Three-dimensional Objects Is Possible with the Optical Microscope

For ordinary light microscopy, as we have seen, a tissue has to be sliced into thin sections to be examined; the thinner the section, the crisper the image. Because information about the third dimension is lost upon sectioning, how, then, can we get a picture of the three-dimensional architecture of a cell or tissue, and how can we view the microscopic structure of a specimen that, for one reason or another, cannot first be sliced into sections? Although an optical microscope is focused on a particular focal plane within a three-dimensional specimen, all the other parts of the specimen, above and below the plane of focus, are also illuminated, and the light originating from these regions contributes to the image as out-of-focus blur. This can make it very hard to interpret the image in detail and can lead to fine image structure being obscured by the out-of-focus light.

Figure 9-22 Genetically encoded fluorescent biosensors. (A) Here we show one strategy for constructing a fluorescent biosensor for calcium ions. A sensor, in this case calmodulin (see Figure 15-34). undergoes a large conformational change on binding Ca²⁺. This change brings together the blue and yellow fluorescent proteins to which each end of the sensor is attached, close enough to undergo Förster resonance energy transfer (FRET) and to change the wavelength of the fluorescence emission to yellow in response to a violet excitation light. By measuring the ratio of fluorescence intensity at two wavelengths, blue and yellow, we can determine the concentration ratio of the Ca²⁺-bound indicator to the Ca²⁺-free indicator, thereby providing an accurate measurement of the free Ca²⁺ concentration. (B) This panel illustrates a similar strategy used to construct a biosensor for cAMP. In this case the sensor is a cAMP-regulated guanine nucleotide exchange factor, which again undergoes a large conformational change, enough to move the two attached fluorescent proteins farther apart, thus abolishing their FRET. Hence the emitted light is switched from yellow to blue. (C) A calcium biosensor, similar to that shown in A, is genetically encoded and expressed in an Arabidopsis seedling. When a cell in the epidermis, on the side of the shoot apical meristem, is pricked with a small glass needle, calcium enters the cell from the extracellular environment, and this response is rapidly propagated as a wave of calcium entering cells across the entire surface of the meristem. Mechanical signals help pattern plant morphogenesis, and transient calcium responses affect cell polarity. (C, from T. Li et al., Nat. Commun. 10:726-735, 2019. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch09_563-602.indd 577 02/12/21 2:16 PM

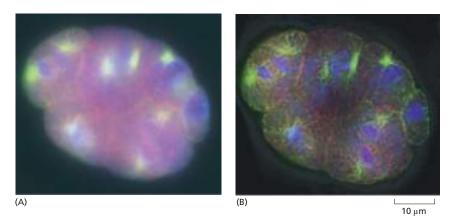

Figure 9–23 Image deconvolution. (A) A light micrograph of a Caenorhabditis elegans embryo, fluorescently labeled for microtubules (green), mitochondria (red), and DNA (blue). Detail at any one level of focus is blurred by light from out-of-focus levels of the specimen. (B) After deconvolution of the three-dimensional stack of images, an optical section at the same level of focus shows a much crisper image with more contrast and much reduced blurring. (A and B, from D. Sage et al., Methods 115:28–41, 2017, doi 10.1016/j.ymeth.2016.12.015. With permission from Elsevier.)

Two distinct but complementary approaches help to solve this problem: one is computational, the other optical. These three-dimensional microscopic imaging methods make it possible to focus on a chosen plane in a thick specimen while rejecting the light that comes from out-of-focus regions above and below that plane. Thus, one sees a crisp, thin *optical section*. From a series of such optical sections taken at different depths and stored in a computer, a three-dimensional image can be reconstructed (Movie 9.1). The methods do for the microscopist what the computed tomography (CT) scanner does (by different means) for the radiologist investigating a human body: both machines give detailed sectional views of the interior of an intact structure.

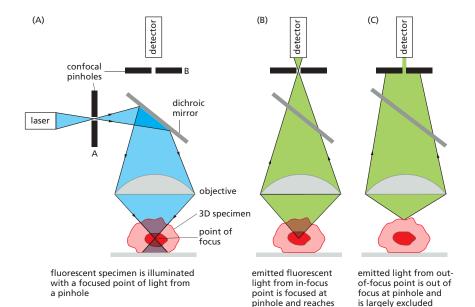

The computational approach is often called *image deconvolution*. To understand how it works, remember that the wave-like nature of light means that the microscope lens system produces a small blurred disc as the image of a point source of light (see Figure 9–4), with increased blurring if the point source lies above or below the focal plane. This blurred image of a point source is called the *point spread function* (see Figure 9–29). An image of a complex object can then be thought of as being built up by replacing each point of the three-dimensional specimen by a corresponding blurred disc, resulting in an image that is blurred overall. For deconvolution, a computer program uses the measured point spread function of a point source of light from that particular microscope to determine what the effect of the blurring would have been on the image, and then applies an equivalent "deblurring" (deconvolution), turning the blurred three-dimensional image into a series of clean optical sections, albeit still constrained by the diffraction limit (Figure 9–23).

The Confocal Microscope Produces Optical Sections by Excluding Out-of-Focus Light

The confocal microscope achieves a result similar to that of deconvolution, but does so by manipulating the light before it is measured; it is an analog technique rather than a digital one. The optical details of the **confocal microscope** are complex, but the basic idea is simple, as illustrated in **Figure 9–24**, and the results are far superior to those obtained by conventional light microscopy.

The confocal microscope is generally used with fluorescence optics (see Figure 9–10C), but instead of illuminating the whole specimen at once, in the usual way, the optical system at any instant focuses a spot of light onto a single point at a specific depth in the specimen. This requires a source of pinpoint illumination

MBOC7_ptr_ch09_563-602.indd 578 02/12/21 2:16 PM

that is usually supplied by a laser whose light has been passed through a pinhole. The fluorescence emitted from the illuminated material is collected at a suitable light detector and used to generate an image. A pinhole aperture is placed in front of the detector, at a position that is *confocal* with the illuminating pinhole; that is, precisely where the rays emitted from the illuminated point in the specimen come to a focus. Thus, the light from this point in the specimen converges on this aperture and enters the detector.

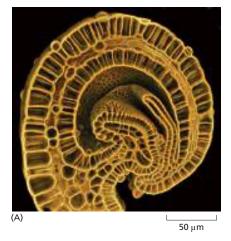

By contrast, the light emitted from regions of the specimen that are out of focus is also out of focus at the pinhole aperture and is therefore largely excluded from the detector. To build up a two-dimensional image, data from each point in the plane of focus are collected sequentially by scanning across the field from one side to the other in a regular pattern of pixels and are displayed on a computer screen. Although not shown in Figure 9–24, the scanning is usually done by deflecting the beam with an oscillating mirror placed between the dichroic (beam-splitting) mirror and the objective lens in such a way that the illuminating spot of light and the confocal pinhole at the detector remain strictly in register. Variations in design now allow the rapid collection of data at video rates.

The confocal microscope has been used to resolve the structures of numerous complex three-dimensional objects (Figure 9-25), from large multicellular

Figure 9-24 The confocal fluorescence microscope. (A) This simplified diagram shows that the basic arrangement of optical components is similar to that of the standard fluorescence microscope shown in Figure 9-10C, except that a laser is used to illuminate a small pinhole whose image is focused at a single point in the threedimensional (3D) specimen. (B) Emitted fluorescence from this focal point in the specimen is focused at a second (confocal) pinhole. (C) Emitted light from elsewhere in the specimen is not focused at the pinhole and therefore does not contribute to the final image. By scanning the beam of light across the specimen, a very sharp two-dimensional image of the exact plane of focus is built up that is not significantly degraded by light from other regions of the specimen. (D) Commercial versions of laser scanning confocal microscopes can be configured for both upright and inverted microscopes. Shown here is a standard upright confocal microscope. (D, courtesy of Andrew Davis.)

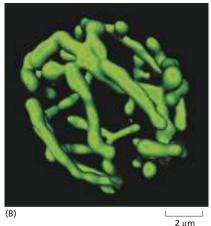

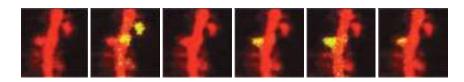

Figure 9-25 Confocal fluorescence microscopy produces clear optical sections and three-dimensional data sets. (A) The elaborate cup-shaped trap of the carnivorous water plant, Utricularia gibba. A stack of 452 separate confocal images using a fluorescent label for the cell walls was assembled to produce the image. (B) A reconstruction of an object can be assembled from a stack of optical sections. In this case, and at a vastly different scale, the complex branching structure of the mitochondrial compartment in a single live yeast cell is shown. structures to subcellular structures; for example, the networks of cytoskeletal fibers, the dynamics of organelles, and the arrangements of chromosomes and genes in the nucleus.

The relative merits of deconvolution methods and confocal microscopy for three-dimensional optical microscopy depend on the specimen being imaged. Confocal microscopes tend to be better for thicker specimens with high levels of out-of-focus light. They are also generally easier to use than deconvolution systems, and the final optical sections can be seen quickly. In contrast, the complementary metal-oxide semiconductor (CMOS) cameras that are used for deconvolution systems are extremely efficient at collecting almost every photon emitted, and they can be used to make detailed three-dimensional images from specimens that are too weakly stained or too easily damaged by the bright light used for confocal microscopy.

Both methods, however, have another drawback; neither is good at coping with very thick specimens. Deconvolution methods quickly become ineffective any deeper than about 40 µm into a specimen, while confocal microscopes can only obtain images up to a depth of about 150 µm. Special microscopes can now take advantage of the way in which fluorescent molecules are excited, to probe even deeper into a specimen. Fluorescent molecules are usually excited by a single high-energy photon, of shorter wavelength than the emitted light, but they can in addition be excited by the absorption of two (or more) photons of lower energy, as long as they both arrive within a femtosecond or so of each other. The use of this longer-wavelength excitation has some important advantages. In addition to reducing background noise, red or near-infrared light can penetrate deeper into a specimen. Multiphoton microscopes, constructed to take advantage of this two-photon effect, can obtain sharp images, sometimes even at a depth of half a millimeter within a specimen. This is particularly valuable for studies of living tissues, notably in imaging the dynamic activity of synapses and neurons just below the surface of living brains (Figure 9-26).

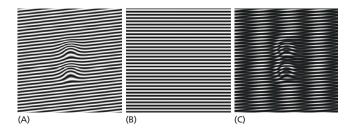

Superresolution Fluorescence Techniques Can Overcome Diffraction-limited Resolution

The variations on light microscopy we have described so far are all constrained by the classic diffraction limit to resolution described earlier; that is, to about 0.2 μm , or 200 nm (see Figure 9–5). Yet many cellular structures—from nuclear pores and ribosomes to nucleosomes and clathrin-coated pits—are much smaller than this and so are unresolvable by conventional light microscopy. However, several approaches are now available that bypass the limit imposed by the diffraction of light, and some can now successfully resolve objects as small as 10 nm, a remarkable, twentyfold improvement.

The first of these so-called **superresolution** approaches, *structured illumination microscopy* (*SIM*), is a fluorescence imaging method with a resolution of about 100 nm, or twice the resolution of conventional bright-field microscopy. SIM overcomes the diffraction limit by using a grated or structured pattern of light to illuminate the sample. The microscope's physical setup and operation are quite complex, but the general principle can be thought of as similar to creating a moiré pattern, an interference pattern created by overlaying two grids with different angles or mesh sizes (**Figure 9-27**). The illuminating grid and the sample features combine into an interference pattern in which features smaller than the grid spacing are transformed into larger patterns. This results in original features

Figure 9-26 Multiphoton imaging. Infrared laser light causes less damage to living cells than does visible light and can also penetrate farther, allowing microscopists to peer deeper into living tissues. The two-photon effect, in which a fluorochrome can be excited by two coincident infrared photons instead of a single high-energy photon, allows us to see nearly 0.5 mm inside the cortex of a live mouse brain. A dye, whose fluorescence changes with the calcium concentration, reveals active synapses (yellow) on the dendritic spines (red) that change as a function of time; in this case, there is a day between each image. (Courtesy of Thomas Oertner and Karel Svoboda.)

MBOC7_ptr_ch09_563-602.indd 580 02/12/21 2:16 PM

beyond the classical limit being transformed so that they can now be imaged by the optical system. Computer image processing can then be used to restore them into an image that has a resolution up to twice the classical limit. Illumination by a grid means that the parts of the sample in the dark stripes of the grid are not illuminated and therefore not imaged, so the imaging is repeated several times (usually three) after translating the grid through a fraction of the grid spacing between each image. As the interference effect is strongest for image components close to the direction of the grid bars, the whole process is repeated with the grid pattern rotated through a series of angles to obtain an equivalent enhancement in all directions. Finally, mathematically combining all these separate images by computer creates an enhanced superresolution image. SIM is versatile because it can be used with any fluorescent dye or protein, and combining SIM images captured at consecutive focal planes can create three-dimensional data sets (Figure 9-28).

To get around the diffraction limit, two other superresolution techniques exploit aspects of the point spread function, a property of the optical system mentioned earlier. The **point spread function** is the distribution of light intensity within the three-dimensional, blurred image that is formed when a single point source of light is brought to a focus with a lens. Instead of being identical to the point source, the image has an intensity distribution that is approximately described by a Gaussian distribution, which in turn determines the resolution of the lens system. Two points that are closer than the width at half-maximum

Figure 9-27 Structured illumination microscopy. The principle, illustrated here, is to illuminate a sample with patterned light and measure the moiré pattern. Shown are (A) the pattern from an unknown structure and (B) a defined grid pattern. (C) When these are combined, the resulting moiré pattern contains more information than is easily seen in A, the original pattern. If the known pattern (B) has higher spatial frequencies, then better resolution will result. However, because the spatial patterns that can be created optically are also diffraction-limited, SIM can only improve the resolution by about a factor of 2. (From B.O. Leung and K.C. Chou, Appl. Spectrosc. 65:967-980, 2011. With permission from SAGE.)

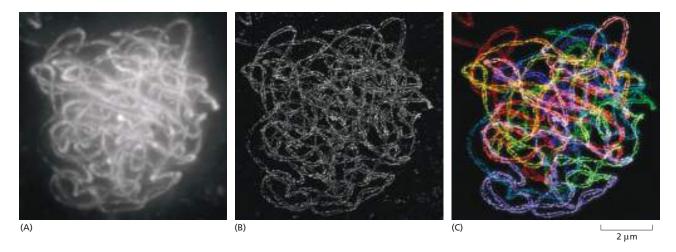

Figure 9–28 Structured illumination microscopy can be used to create three-dimensional data. These three-dimensional projections of the meiotic chromosomes at pachytene in a maize cell show the paired lateral elements of the synaptonemal complexes. (A) The chromosome set has been stained with a fluorescent antibody to cohesin and is viewed here by conventional fluorescence microscopy. Because the distance between the two lateral elements is about 200 nm, the diffraction limit, the two lateral elements that make up each complex are not resolved. (B) In the three-dimensional SIM image, the improved resolution enables each lateral element, about 100 nm across, to be clearly resolved, and the two chromosomes of each separate pair can be seen to coil around each other. (C) Because the complete three-dimensional data set for the whole nucleus is available, the path of each separate pair of chromosomes can be traced and artificially assigned a different color. (Courtesy of C.J. Rachel Wang, Peter Carlton, and Zacheus Cande.)

MBOC7_ptr_ch09_563-602.indd 581 02/12/21 2:16 PM

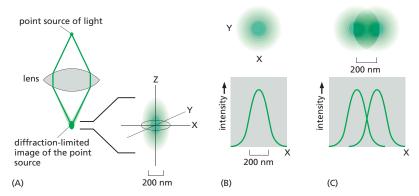

Figure 9–29 The point spread function of a lens determines resolution. (A) When a point source of light is brought to a focus by a lens system, diffraction effects mean that, instead of being imaged as a point, it is blurred in all dimensions. As shown, the point spread function is elongated, meaning that the resolution is better in the XY axes than along the Z axis. (B) In the plane of the image, the distribution of light approximates a Gaussian distribution, whose width at half-maximum height under ideal conditions is about 200 nm. (C) Two separate point sources that are about 200 nm apart can still just be distinguished as separate objects in the image, but if they are any nearer than that, their images will overlap and not be resolvable.

height of this distribution will become hard to resolve because their images overlap too much (Figure 9-29).

In fluorescence microscopy, the excitation light is focused to a spot on the specimen by the objective lens, which then captures the photons emitted by any fluorescent molecule that the beam has raised from a ground state to an excited state. Because the excitation spot is blurred according to the point spread function, fluorescent molecules that are closer than about 200 nm will be imaged as a single blurred spot. One approach to increasing the resolution is to switch all the fluorescent molecules at the periphery of the blurry excitation spot back to their ground state or to a state where they no longer fluoresce in the normal way, leaving only those at the very center to be recorded. This can be done in practice by adding a second, very bright laser beam that wraps around the excitation beam like a torus. The wavelength and intensity of this second beam are adjusted so as to switch the fluorescent molecules off everywhere except at the very center of the point spread function, a region that can be as small as 20 nm across (Figure 9–30).

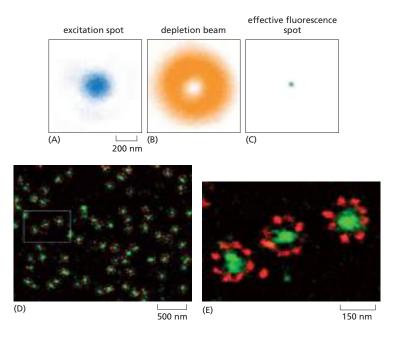

Figure 9-30 Superresolution microscopy can be achieved by reducing the size of the point spread function. (A) The size of a normal focused beam of excitatory light. (B) An extremely strong superimposed laser beam, at a different wavelength and in the shape of a torus, or doughnut. depletes emitted fluorescence everywhere in the specimen except right in the center of the beam, reducing the effective width of the point spread function (C). As the specimen is scanned, this small point spread function can then build up a crisp image in a process called STED (stimulated emission depletion) microscopy. (D) Here STED microscopy is used to examine the structure of the nuclear pore. Fixed samples of the nuclear envelope have been stained by indirect immunofluorescence, using antibodies to different nuclear pore components. Membrane ring proteins (see Figure 12-55) have been stained red while the FC repeat proteins that form fibrils in the center of the pore are stained green. (E) An enlargement of the boxed region shows the clear eightfold symmetry of the membrane ring proteins and the central fibrillar region with a resolution of about 20 nm. [A. B. and C. from G. Donnert et al., Proc. Natl. Acad. Sci. USA 103: 11440-11445, 2006. Copyright 2006 National Academy of Sciences. MBOC7_ptr_ch09_563-602.indd 582 02/12/21 2:16 PM

The fluorescent probes used must be in a special class that is photoswitchable: their emission can be reversibly switched on and off with lights of different wavelengths. As the specimen is scanned with this arrangement of lasers, in much the same way as in a confocal microscope, fluorescent molecules are switched on and off, and the small point spread function at each location is recorded. The diffraction limit is breached because the technique ensures that similar but very closely spaced molecules are in one of two different states, either fluorescing or dark. This approach is called *STED* (*stimulated emission depletion*) *microscopy*, and various microscopes using versions of the general method are now in wide use. Resolutions of 20 nm have been achieved in biological specimens (see Figure 9–30).

Single-Molecule Localization Microscopy Also Delivers Superresolution

If a single fluorescent molecule is imaged, it appears as a circular blurry disc about 200 nm across, but if sufficient photons have contributed to this image, then the precise mathematical center of the disc-like image, and therefore the position of that fluorescent molecule, can be determined very accurately, often to within a few nanometers (Figure 9-31). But the problem with a specimen that contains a large number of adjacent fluorescent molecules, as we saw earlier, is that they each contribute blurry, overlapping point spread functions to the image, making the exact position of any one molecule impossible to resolve. Another way around this limitation is to arrange for only a very few, clearly separated molecules to actively fluoresce at any one moment. The exact position of each of these can then be computed, before subsequent sets of molecules are examined.

In practice, this can be achieved by using lasers to sequentially switch on a sparse subset of fluorescent molecules in a specimen containing switchable fluorescent labels. There are now hundreds of such labels, and they fall into three classes: *photoactivated* labels, which switch for example from dark to green; *photoconvertible* labels, which switch for example from green to red; and *photoswitchable* labels, which switch back and forth. Labels are activated, for example, by illumination with near-ultraviolet light, which modifies a small subset of molecules so that they fluoresce when exposed to an excitation beam at another wavelength. These are then imaged before bleaching quenches their fluorescence, and a new subset is activated. Each molecule emits a few thousand photons in response to the excitation before switching off, and the switching process can be repeated tens or even hundreds of thousands of times, allowing the exact coordinates of a very large set of single molecules to be determined. The full set can be combined and digitally displayed as an image in which the computed

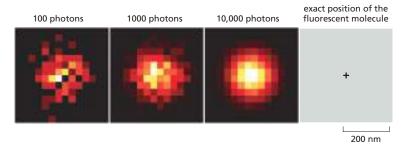

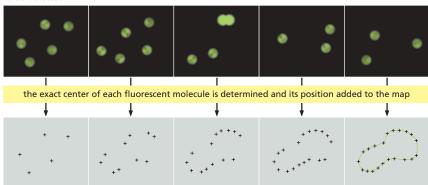

Figure 9–31 Single fluorescent molecules can be located with great accuracy. Determination of the exact mathematical center of the blurred image of a single fluorescent molecule becomes more accurate as more photons contribute to the final image. The point spread function described in the text dictates that the size of the molecular image is about 200 nm across, but in very bright specimens, the position of its center can be pinpointed to within a nanometer or so. (From A.L. McEvoy et al., *BMC Biol.* 8:106, 2010. With permission of the authors.)

successive cycles of activation and bleaching allow well-separated single fluorescent molecules to be detected

a superresolution image of the fluorescent structure is built up as the positions of tens of thousands of successive small groups of molecules are added to the map

(A)

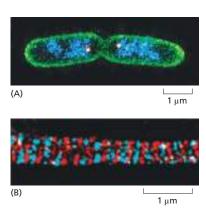

location of each individual molecule is exactly marked (Figure 9-32). The two main methods of single-molecule localization microscopy (SMLM) have been variously termed *photoactivated localization microscopy* (PALM) or stochastic optical reconstruction microscopy (STORM).

By switching the fluorophores off and on sequentially in different regions of the specimen as a function of time, all the superresolution imaging methods described above allow the resolution of molecules that are much closer together than the 200-nm diffraction limit. In STED, the locations of the molecules are determined by using optical methods to define exactly where their fluorescence will be on or off. In PALM and STORM, individual fluorescent molecules are switched on and off at random over a period of time, allowing their positions to be accurately determined. PALM and STORM techniques have depended on the development of novel fluorescent probes that exhibit the appropriate switching behavior. STORM originally relied on photoswitchable dyes, while PALM used photoswitchable fluorescent proteins, but the general principle is the same for both. All these methods can incorporate multicolor imaging (Figure 9–33),

Figure 9–33 Multiple structures that are below the diffraction-limited resolution can be imaged by single-molecule localization microscopy. (A) Two recently divided *Escherichia coli* cells imaged in a STORM microscope with a resolution of about 20 nm. The cells are stained with three separate switchable fluorescent labels: the membrane is labeled green, the recently segregated DNA molecules are blue, and the ends of the two replicated chromosomes are seen as two bright white dots. (B) In this nerve cell, evenly spaced ring-like structures of actin (*red*) are wrapped around the circumference of the axon with a periodicity of about 190 nm, just smaller than the diffraction limit to resolution. In between are similarly spaced structures of spectrin (*blue*). This periodic actin–spectrin cytoskeletal framework helps support the long thin axons of nerve cells. Such images depend heavily on the development of new, very fast-switching, and extremely bright fluorescent probes. (A, from C.K. Spahn et al., *Sci. Rep.* 8:14768, 2018, doi.org/10.1038/s41598-018-33052-3; B, from K. Xu et al., *Science* 339:452–456, 2013, doi 10.1126/science.1232251.)

Figure 9–32 Single-molecule localization microscopy (SMLM). (A) In this imaginary specimen, sparse subsets of fluorescent molecules are individually switched on briefly and then bleached. The exact positions of all these well-spaced molecules can be gradually added together and built up into an image at superresolution. (B) In this portion of a cell, the microtubules have been fluorescently labeled and imaged (left) in a TIRF microscope (see Figure 9-38) and (right) at superresolution in a PALM microscope. The diameter of each microtubule on the right now resembles its true size, about 25 nm, rather than the 250 nm for each microtubule in the blurred diffraction-limited image on the left. (B, courtesy of Shinsuke Niwa.)

MBOC7_ptr_ch09_563-602.indd 584 02/12/21 2:16 PM

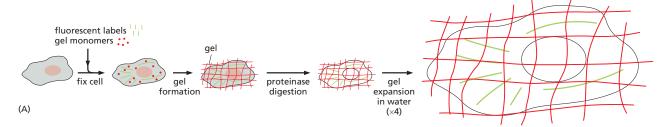

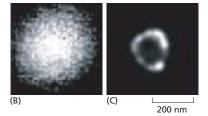

Figure 9–34 Expansion microscopy. (A) Although the technique has numerous variations, the essential features are that the fluorescently labeled sample is embedded in a polymer gel to which the fluorescent labels are covalently attached. After a proteinase digestion step, the gel is immersed in water and everything in the sample expands equally in every direction, usually by between 4 and 10 times, thus allowing details to be seen far more easily. (B) A peroxisome, whose membrane has been labeled with a fluorescent probe, appears in a confocal microscope as a blurred, diffraction-limited disc. (C) After expansion by a factor of 10, the image is captured with a standard epifluorescence microscope and, after deconvolution, shows the peroxisomal membrane well resolved and with a resolution of 25 nm. (From S. Truckenbrodt et al., *EMBO Rep.* 19:e45836, 2018, doi 10.15252/embr.201845836.)

and to some extent live-cell imaging in real time. Ending the long reign of the diffraction limit has reinvigorated light microscopy and its place in cell biology research.

Expanding the Specimen Can Offer Higher Resolution, but with a Conventional Microscope

All the approaches to improvement of resolution that we have discussed so far have centered on increasingly sophisticated and expensive developments of the microscope itself. Looking at the problem from the other end, the specimen end, swelling the sample to physically make it larger would in theory allow higherresolution imaging, while still using a conventional fluorescence microscope. A new specimen preparation technique, called expansion microscopy (ExM), does exactly that. The process starts by staining the fixed sample with fluorescent labels such as antibodies that target the molecules of interest. The labeled specimen is then treated with a chemical cross-linker and incubated with acrylate and acrylamide monomers. These monomers then polymerize to form a polyelectrolyte gel that simultaneously incorporates the cross-linked labels. With the labels covalently cross-linked to the polymer gel, and locked in their original relative positions, cellular material in the sample, predominantly proteins that might hinder subsequent expansion, is then carefully digested away. The gel containing the labeled specimen is now gently swollen by removing the buffer salts with water, so that it expands equally in all directions by between 4 and 10 times (Figure 9-34A). Two fluorochromes that were initially 100 nm apart, and consequently below the diffraction-limited resolution of a standard microscope, will now be $0.4-1.0~\mu m$ apart and are therefore easily resolved (Figure 9-34B and C). "Blowing-up" the sample allows effective superresolution to be enjoyed at up to 25 nm and without costly hardware (Figure 9-35A and B).

Expansion microscopy is proving valuable for detecting and quantitating which RNA transcripts are expressed in which individual cells in the brain. If all RNA molecules present are anchored firmly to the polymer gel before the expansion step, then the sample can be washed and re-probed sequentially with multiple fluorescent RNA probes using *in situ* hybridization (Figure 9–35C and D). Expansion takes place in all directions, and so depth information is also retrievable at higher resolution. Expansion microscopy samples can still be imaged by either confocal or light-sheet microscopy (discussed next), and deconvolution methods can still be used on the images—both help to improve three-dimensional imaging of large specimens.

MBOC7_ptr_ch09_563-602.indd 585 02/12/21 2:16 PM

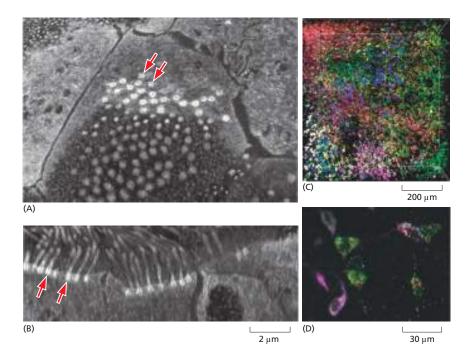

Figure 9-35 Expansion microscopy. (A and B) Two orthogonal views of the same cultured human nasal epithelial cells that have been stained with a fluorescent dve. expanded by ten times. and then imaged by conventional confocal microscopy. The hollow centers of ciliary basal bodies, which are not resolvable by conventional microscopy, are clearly visible in both top view (A) and side view (B) (red arrows) (see Movie 9.1). (C and D) A segment of mouse brain lateral hypothalamus, $800 \times 800 \times 300 \mu m$, that has been expanded by a factor of 2, probed by sequential rounds of in situ RNA hybridization, and imaged by lightsheet microscopy. The cellular expression patterns of six different genes are shown: Gad1 (red), Slc17a6 (green), Hcrt (blue), Trh (yellow), Calb2 (magenta), and Meis2 (cyan). Large Multicellular Structures Can Be Imaged Over Time

Many problems in cell biology involve being able to follow the movement and behavior of cells in multicellular living organisms, in early embryo development for example. Other problems require the ability to disentangle the complexity of cellular interactions in large and dense tissues, for example the millions of connections between the neurons of the brain. The side effects of prolonged exposure to high levels of light in the first case, and depth and out-of-focus fluorescence in the second, mean that most of the techniques we have discussed so far cannot help. One way of eliminating a lot of the out-of-focus fluorescence is to arrange for the beam of light from the excitation laser to illuminate the specimen from a direction perpendicular to the axis from which the emitted fluorescence is viewed. In this arrangement, called *light-sheet microscopy*, a thin sheet of laser light, less than a micrometer thick, is scanned through the specimen, exciting only the labeled molecules at that depth in the sample to emit their fluorescence (Figure 9-36). There are many advantages to this method: it results in high-contrast images with very low photobleaching or photodamage, and three-dimensional information is readily obtained. It is also quick. Variants of the method allow ultrathin light sheets to scan through successive planes of a sample at a rate of hundreds of planes a second. The long-term, three-dimensional observation of living cells is a major application, for example in following early embryonic development in flies or zebrafish over a period of days. In fixed brain samples, the complex architecture of all the cells and their interconnections can be disentangled

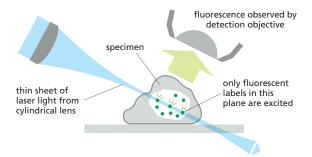

Figure 9–36 Light-sheet microscopy. A simple diagram showing how a very thin sheet of light that is projected (usually from a special cylindrical microscope objective lens) through a large specimen excites only those fluorescent labels in the thin plane that is illuminated. The resulting fluorescence is observed by an objective lens that is placed perpendicular to the light sheet. This means that, by progressively moving the specimen stage, multiple, sequential, and very sharp optical sections can be obtained rapidly and then digitally combined into a three-dimensional image.

MBOC7_ptr_ch09_563-602.indd 586 02/12/21 2:16 PM

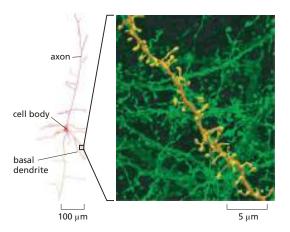

Figure 9-37 Light-sheet microscopy in the brain. A 1-mm-thick portion of a mouse brain has been prepared for expansion microscopy and then imaged with a light-sheet microscope. Reconstructions of thousands of optical sections allow the tracing of individual neurons and all their connections, such as this pyramidal neuron (left) from the visua cortex. On the right is shown the complex cellular context (green) for a short region of one of the neuron's basal dendrites (orange dendrite with its spines shown in yellow). (From R. Gao et al., Science 363:245-261, 2019, doi 10.1126/science.aau8302. With permission from AAAS.)

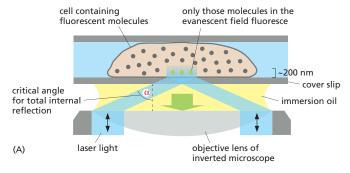

(Figure 9–37 and Movie 9.1). Light-sheet microscopy can also be combined with other techniques. Coupled with STED imaging, for example, superresolution is attainable, and higher-resolution images can also be obtained by preparing the sample for expansion microscopy.

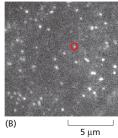

Single Molecules Can Be Visualized by Total Internal Reflection Fluorescence Microscopy

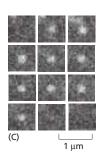

As we have seen, the strong background fluorescence due to light emitted or scattered by out-of-focus molecules tends to blot out the fluorescence from any one particular molecule of interest. This problem can be solved by the use of a special optical technique called total internal reflection fluorescence (TIRF) microscopy. In a TIRF microscope, laser light shines onto the cover-slip surface at the precise critical angle at which total internal reflection occurs (Figure 9-38A). Because of total internal reflection, the light does not enter the sample, and the majority of fluorescent molecules are not, therefore, illuminated. However, electromagnetic energy does extend, as an evanescent field, for a very short distance beyond the surface of the cover slip and into the specimen, allowing just those molecules in the layer closest to the surface to become excited. When these molecules fluoresce, their emitted light is no longer competing with out-of-focus light from the overlying molecules and can now be detected. TIRF has allowed several dramatic experiments, for instance imaging of single motor proteins moving along microtubules or actin filaments. At present, the technique is restricted to a thin layer about 200 nm below the cell surface. Although not strictly TIRF, decreasing the angle of the incident light so that it is almost parallel to the cover slip can increase the depth into the cell that can be examined, albeit not so uniformly, a feature useful in cells with an outer wall, such as those of plants and fungi (Figure 9-38B and C).

Figure 9–38 TIRF microscopy allows the detection of single fluorescent molecules near the cell surface.

(A) TIRF microscopy uses excitatory laser light to illuminate the cover-slip surface at the critical angle at which all the light is reflected by the glass-water interface. Some electromagnetic energy extends a short distance across the interface as an evanescent wave that excites just those molecules that are attached to the cover slip or are very close to its surface. (B) TIRF microscopy is used to follow the formation of an individual clathrin-coated pit and its subsequent endocytosis. In this image of the surface of the plasma membrane of an Arabidopsis root cell, a clathrin adaptor protein is tagged with GFP. Individual pits can be followed over time. (C) The pit ringed in B is shown at 1-second intervals, demonstrating that its appearance and its removal at the plasma membrane by endocytosis takes place in about 10 seconds, (B and C. from A. Johnson and G. Vert, Front. Plant Sci. 8:612, 2017, doi 10.3389 /fpls.2017.00612.)

MBOC7_ptr_ch09_563-602.indd 587 02/12/21 2:16 PM

Summary

Many light-microscope techniques are available for observing cells. Cells that have been fixed and stained can be studied in a conventional light microscope, whereas antibodies coupled to fluorescent dyes can be used to locate specific molecules in cells in a fluorescence microscope. Living cells can be seen with phase-contrast, differential-interference-contrast, dark-field, or bright-field microscopes. All forms of light microscopy are facilitated by digital image-processing techniques, which enhance sensitivity and refine the image. Confocal microscopy and image deconvolution both provide thin optical sections and can be used to reconstruct three-dimensional images.

Techniques are now available for detecting, measuring, and following almost any desired molecule in a living cell. Fluorescent labels can be introduced to measure the concentrations of specific ions or signaling molecules in individual cells or in different parts of a cell. Virtually any protein of interest can be genetically engineered as a fluorescent fusion protein and then imaged in living cells by fluorescence microscopy. The dynamic behavior and interactions of many molecules can be followed in living cells by variations on the use of fluorescent protein tags, in some cases at the level of single molecules. Various superresolution techniques can circumvent the diffraction limit in different ways and resolve molecules separated by distances as small as 20 nm.

LOOKING AT CELLS AND MOLECULES IN THE ELECTRON MICROSCOPE

Light microscopy is limited in the fineness of detail that it can reveal. Microscopes using other types of radiation—in particular, electron microscopes—can resolve much smaller structures than is possible with visible light. This higher resolution comes at a cost: specimen preparation for electron microscopy is complex and it is harder to be sure that what we see in the image corresponds precisely to the original living structure. It is possible, however, to use very rapid freezing to preserve structures faithfully for electron microscopy. Digital image analysis can be used to reconstruct three-dimensional objects by combining information either from many individual particles or from multiple tilted views of a single object. Together, these approaches extend the resolution and scope of electron microscopy to the point at which we can faithfully image the detailed structures of individual macromolecules and the complexes they form, even inside cells.

The Electron Microscope Resolves the Fine Structure of the Cell

The formal relationship between the diffraction limit to resolution and the wavelength of the illuminating radiation (see Figure 9-5) holds true for any form of radiation, whether it is a beam of light or a beam of electrons. With electrons, however, the limit of resolution is very small. The wavelength of an electron decreases as its velocity increases. In an electron microscope with an accelerating voltage of 100,000 V, the wavelength of an electron is 0.004 nm. In theory, the resolution of such a microscope should be about 0.002 nm, which is 100,000 times that of the conventional light microscope. Because the aberrations of an electron lens are considerably harder to correct than those of a glass lens, however, the practical resolving power of modern electron microscopes is, even with careful image processing to correct for lens aberrations, about 0.05 nm (0.5 Å) (Figure 9-39). This is because only the very center of the electron lenses can be used, and the effective numerical aperture is tiny. Furthermore, problems of specimen preparation, contrast, and radiation damage have generally limited the normal effective resolution for biological objects to 1 nm (10 Å). This is nonetheless about 200 times better than the resolution of the light microscope. Moreover, the performance of electron microscopes is improved by electron illumination sources called field-emission guns. These very bright and coherent sources substantially improve the resolution achieved.

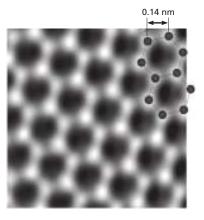

Figure 9-39 The resolution of the electron microscope. This transmission electron micrograph of a monolayer of graphene resolves the individual carbon atoms as bright spots in a hexagonal lattice. Graphene is a single isolated atomic plane of graphite and forms the basis of carbon nanotubes. The distance between adjacent bonded carbon atoms is 0.14 nm (1.4 Å). Such resolution can only be obtained in a specially built transmission electron microscope in which all lens aberrations are carefully corrected. and with optimal specimens; it is rarely achieved with most conventional biological specimens. MBOC7_ptr_ch09_563-602.indd 588 02/12/21 2:16 PM

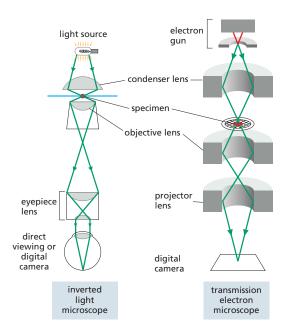

Figure 9–40 The principal features of an inverted light microscope and a transmission electron microscope.

These drawings emphasize the similarities of overall design. Whereas the lenses in the light microscope are made of glass, those in the electron microscope are magnetic coils. The electron microscope requires that the specimen be placed in a vacuum. The inset shows a routine transmission electron microscope in use. (Photograph courtesy of Andrew Davis.)

In overall design, the transmission electron microscope (TEM) is similar to an inverted light microscope, albeit much larger (Figure 9-40). The source of illumination is a filament or cathode that emits electrons at the top of a cylindrical column about 2 m high. Because electrons are scattered by collisions with air molecules, air must first be pumped out of the column to create a vacuum. The electrons are then accelerated from the filament by a nearby anode and allowed to pass through a tiny hole to form an electron beam that travels down the column. Magnetic coils placed at intervals along the column focus the electron beam, just as glass lenses focus the light in a light microscope. The specimen is put into the vacuum, through an airlock, into the path of the electron beam. As in light microscopy, the specimen can be stained—in this case, with electron-dense material. Some of the electrons passing through the specimen are scattered by structures stained with the electron-dense material; the remainder are focused to form an image. The image can be observed on a monitor or is typically recorded with a sensitive CMOS electron detector. Because the scattered electrons are lost from the beam, the dense regions of the specimen show up in the image as areas of reduced electron flux, which look dark.

Biological Specimens Require Special Preparation for Electron Microscopy

In the early days of its application to biological materials, the electron microscope revealed many previously unimagined structures in cells. But before these discoveries could be made, electron microscopists had to develop new procedures for embedding, cutting, and staining tissues.

Because the specimen is exposed to a very high vacuum in the electron microscope, living tissue is usually killed and preserved by chemical fixation. As electrons have very limited penetrating power, the fixed tissues normally have to be cut into extremely thin sections (25–100 nm thick, about 1/200 the thickness of a single cell) before they are viewed. This is achieved by dehydrating the specimen, permeating it with a monomeric resin that polymerizes to form a solid block of plastic, then cutting the block with a fine glass or diamond knife on a special microtome. The resulting *ultrathin sections*, free of water and other volatile solvents, are supported on a small metal grid for viewing in the microscope (Figure 9–41).

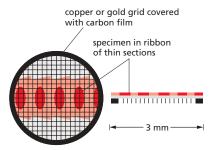

Figure 9–41 Specimen support. The metal grid that supports the thin sections of a specimen in a transmission electron microscope.

MBOC7_ptr_ch09_563-602.indd 589 02/12/21 2:16 PM

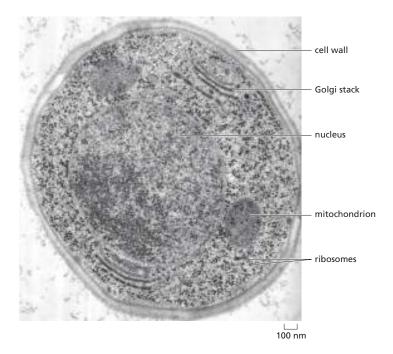

Figure 9–42 Thin section of a cell. This thin section is of a yeast cell that has been very rapidly frozen and the vitreous ice replaced by organic solvents and then by plastic resin (freeze substitution). The nucleus, mitochondria, cell wall, Golgi stacks, and ribosomes can all be readily seen in a state that is presumed to be as lifelike as possible. (Courtesy of Andrew Staehelin.)

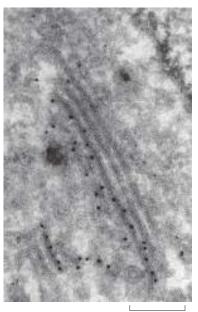

The steps required to prepare biological material for electron microscopy are challenging. How can we be sure that the image of the fixed, dehydrated, resinembedded specimen bears any relation to the delicate, aqueous biological system present in the living cell? The best current approaches to this problem depend on rapid freezing. If an aqueous system is cooled fast enough and to a low enough temperature, the water and other components in it do not have time to rearrange themselves or crystallize into ice. Instead, the water is supercooled into a rigid but noncrystalline state—a "glass"—called vitreous ice. This rapid freezing is usually performed by plunging the sample into a coolant such as liquid ethane or by cooling it at very high pressure.

Some rapidly frozen specimens can be examined directly in the electron microscope using a special cooled specimen holder. In other cases, the frozen block can be fractured to reveal interior cell surfaces or the surrounding ice can be sublimed away to expose external surfaces. However, we often want to examine thin sections, and the frozen tissue can be sectioned directly in a cooled microtome. A compromise is to rapidly freeze the tissue, replace the water with organic solvents, embed the tissue in plastic resin, and finally cut sections. This approach, called *freeze substitution*, stabilizes and preserves the tissue in a condition very close to its original living state (**Figure 9–42**).

Molecules in all kinds of thin sections can be labeled to identify and localize them. We have seen earlier how antibodies can be used in conjunction with fluorescence microscopy to localize specific macromolecules. An analogous method—*immunogold electron microscopy*—can be used in the electron microscope. The usual procedure is to incubate a thin section first with a specific primary antibody, and then with a secondary antibody to which a colloidal gold particle has been attached. The gold particle is electron-dense and can be seen as a black dot in the electron microscope (**Figure 9–43**). Different antibodies can be conjugated to different-sized gold particles so multiple proteins can be localized in a single sample.

Heavy Metals Can Provide Additional Contrast

Although phase contrast can make unstained specimens more visible, image clarity in an electron micrograph usually depends on having a range of electron densities to provide amplitude contrast within the specimen. Electron density in

200 nm

Figure 9-43 Localizing proteins in electron microscopy. Immunogold electron microscopy is used here to find the specific location of a protein that is targeted to the Golgi apparatus. The protein has been tagged with a genetically encoded fluorescent protein and is localized to the trans-Golgi network. The protein is seen in this thin section using an antibody to the fluorescent protein coupled to 10-nm colloidal gold particles, seen in the electron microscope as black dots. The cell has been frozen under high pressure and freeze substituted before embedding and sectioning. (Courtesy of Charlotta Funaya and M. Teresa Alonso.)

MBOC7_ptr_ch09_563-602.indd 590 02/12/21 2:16 PM

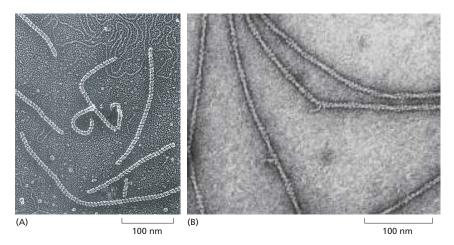

Figure 9–44 Heavy metals provide contrast in the electron microscope. (A) This transmission electron micrograph shows RecA protein together with *E. coli* DNA adsorbed to flakes of mica, frozen, carefully dried, and then shadowed with evaporated platinum atoms. The RecA protein clearly forms tight, right-handed helices around the bacterial DNA molecules, some of which can be seen free at the top of the image (see also Figure 5–48). (B) In this transmission electron micrograph of actin filaments, negatively stained with uranyl acetate, each filament is about 8 nm in diameter and is seen, on close inspection, to be composed of a helical chain of globular actin molecules (see also Figure 16–8). (A, from J. Heuser, *J. Electron Microsc. Tech.* 13:244–263, 1989; B, courtesy of Roger Craig.)

turn depends on the atomic number of the atoms that are present: the higher the atomic number, the more electrons are scattered and the darker that part of the image. Biological tissues are composed mainly of atoms of very low atomic number (primarily carbon, oxygen, nitrogen, and hydrogen). To make them more readily visible, tissues are often impregnated (before or after sectioning) with the salts of heavy metals such as uranium, lead, and osmium. The degree of impregnation, or "staining," with these salts will vary for different cell constituents. Lipids, for example, tend to stain darkly after osmium fixation, revealing the location of cell membranes (see, for example, Figure 12–2 or Figure 12–15).

Alternatively, if isolated molecules are "shadowed" by platinum or other heavy metals evaporated from a heated filament, macromolecules such as DNA or large proteins can be visualized with high contrast in the electron microscope (Figure 9-44A). Negative staining is a similar approach that also allows fine detail to be seen in isolated molecules or macromolecular machines. In this technique, the molecules are supported on the thin film of carbon on a grid and mixed with a solution of a heavy-metal salt such as uranyl formate or acetate. After the sample has dried, a very thin film of metal salt covers the carbon film everywhere except where it has been excluded by the presence of an adsorbed macromolecule. Because the macromolecule allows electrons to pass through it much more readily than does the surrounding heavy-metal stain, a reverse or negative image of the molecule is created. Negative staining is especially useful for quickly and cheaply viewing large macromolecular aggregates such as viruses or ribosomes and for seeing the subunit structure of protein filaments (Figure 9-44B). Shadowing and negative staining can provide high-contrast surface views of small macromolecular assemblies, but the size of the smallest metal particles in the shadow or stain limits the resolution of both techniques to about 2 nm.

Images of Surfaces Can Be Obtained by Scanning Electron Microscopy

A **scanning electron microscope (SEM)** directly produces an image of the three-dimensional structure of the surface of a specimen. The SEM is usually smaller, simpler, and cheaper than a transmission electron microscope. Whereas

MBOC7_ptr_ch09_563-602.indd 591 02/12/21 2:16 PM

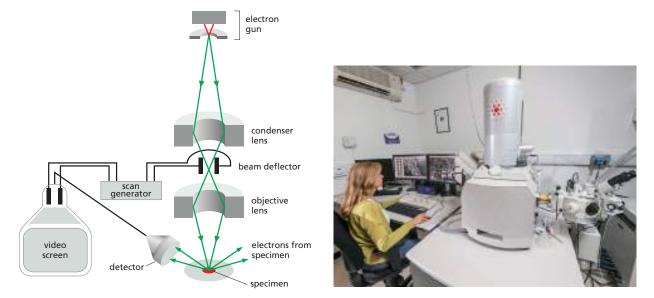

Figure 9–45 The scanning electron microscope. In an SEM, the specimen is scanned by a beam of electrons brought to a focus on the specimen by the electromagnetic coils that act as lenses. The detector measures the quantity of electrons scattered or emitted as the beam bombards each successive point on the surface of the specimen and records the intensity of successive points in an image built up on a screen. The SEM creates striking images of three-dimensional objects with great depth of focus and a resolution between 0.5 nm and 10 nm depending on the kind of instrument. (Photograph courtesy of Andy Davis.)

the TEM uses the electrons that have passed through the specimen to form an image, the SEM uses electrons that are scattered or emitted from the specimen's surface. The specimen to be examined is usually either fixed, dried, and coated with a thin layer of heavy metal or alternatively rapidly frozen and then transferred to a cooled specimen stage for coating and direct examination in the microscope (Figure 9-45). The specimen is scanned with a very narrow beam of electrons. The quantity of electrons scattered or emitted as this primary beam bombards each successive point of the metallic surface is measured and builds up an image on a computer screen. Often an entire plant part or small animal can be put into the microscope with very little preparation (Figure 9-46).

The SEM technique provides great depth of field, thus objects both near and far in the field of view are imaged sharply. Moreover, because the amount of electron scattering depends on the angle of the surface relative to the beam, the image has highlights and shadows that give it a three-dimensional appearance

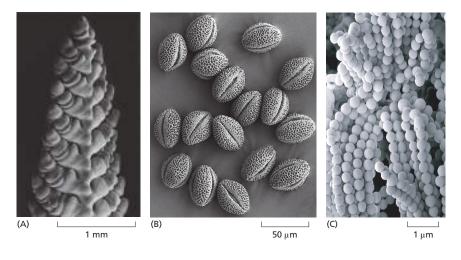

Figure 9-46 The scanning electron microscope produces surface images with great depth of field. SEM micrographs taken at a wide range of magnifications. (A) A developing wheat flower, or spike. This delicate flower spike was rapidly frozen, coated with a thin metal film, and examined in the frozen state with an SEM. This low-magnification micrograph demonstrates the large depth of focus of an SEM, even with a large specimen like this. (B) These pollen grains from a hellebore flower reveal their sculpted cell walls in the SEM. The shapes and patterns are specific for each species of pollen grain. Figure 9–47 Higher-resolution SEM. Macromolecular assemblies, shadowed with a very thin coating of tungsten and imaged in an SEM equipped with a field-emission electron gun. (A) An actin filament showing the helical arrangement of actin monomers. (B) Clathrin-coated vesicles. [A and B, from R. Wepf et al., in Biological Field Emission Scanning Electron Microscopy (R. Fleck and B. Humbel, eds.), pp. 269–298. Hoboken, NJ: Wiley, 2019.]

(see Figure 9–46). Only surface features can be examined, however, and in most forms of SEM, the resolution attainable is not very high (about 10 nm). As a result, the technique is usually used to study whole cells and tissues rather than subcellular organelles (see Movie 21.3). However, very-high-resolution SEMs have been developed with a bright, coherent, field-emission gun as the electron source. As resolution in the SEM depends not on the wavelength of the electron beam but on the size of the electron spot that is scanned across the specimen, this type of SEM can produce images that rival the resolution possible with a negatively stained specimen in a TEM (Figure 9–47).

Electron Microscope Tomography Allows the Molecular Architecture of Cells to Be Seen in Three Dimensions

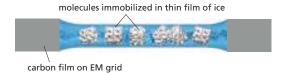

The SEM can only provide a surface view of an object, which tells us little about the important three-dimensional relationships between macromolecules and organelles within a living cell. Moreover, thin sections viewed in a TEM also often fail to convey the three-dimensional arrangement of cellular components, and the images can be misleading. It is possible to reconstruct the third dimension from serial sections, but this is a lengthy and tedious process. But even thin sections have a significant depth compared with the resolution of the electron microscope, so the TEM image can also be misleading in an opposite way, through the superimposition of objects that lie at different depths.

Because of the large depth of field of electron microscopes, all the parts of the three-dimensional specimen are in focus, and the resulting image is a projection (a superimposition of layers) of the structure along the viewing direction. The lost information in the third dimension can be recovered if we have views of the same specimen but from many different directions. The computational methods for this technique are widely used in medical CT scans. In a CT scan, the imaging equipment is moved around the patient to generate the different views. In electron microscope (EM) tomography, the specimen holder is tilted in the microscope, which achieves the same result. The specimen is usually tilted to a maximum of 60° in every direction, and in this way we can arrive at a three-dimensional reconstruction, in a chosen standard orientation, by combining different views of a single object. Each individual view will be very noisy, but by combining them in three dimensions and taking an average, the noise can be significantly reduced. Thick plastic sections of embedded material have been used to create three-dimensional reconstructions, or tomograms (Movie 9.2), of cells, but increasingly microscopists are applying EM tomography to unstained, frozen, hydrated sections, and even to rapidly frozen whole cells or organelles. Individual macromolecular assemblies that

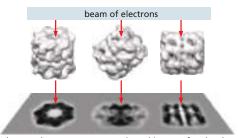

MBOC7_ptr_ch09_563-602.indd 593 02/12/21 2:16 PM

SINGLE-PARTICLE RECONSTRUCTION BY CRYOEM

X-ray crystallography is one way to determine a protein structure. However, large macromolecular machines are often hard to crystallize, as are many integral membrane proteins, and for dynamic proteins and assemblies it is hard to access different conformations through crystallography alone. To get around these problems, investigators are increasingly turning to cryo-electron microscopy (cryoEM) to solve macromolecular structures.

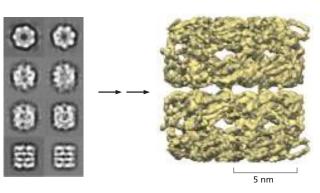

In this technique, a droplet of the pure protein in water is placed on a small EM grid that is plunged into a vat of liquid ethane at -180°C. This freezes the proteins in a thin film of ice and the rapid freezing ensures that the surrounding water molecules have no time to form ice crystals, which would damage the protein's shape.

electron detector captures projected image of molecules

The sample is examined, still frozen, by high-voltage transmission electron microscopy. To avoid damage, it is important that only a few electrons pass through each part of the specimen. Sensitive detectors are therefore deployed to capture every electron that passes through the specimen. Much EM specimen preparation and data collection is now fully automated and many thousands of micrographs are typically captured, each of which will contain hundreds or thousands of individual molecules all arranged in random orientations within the ice.

Algorithms then sort the molecules into sets where each set contains molecules that are all oriented in the same direction. The thousands of images in each set are all then superimposed and averaged to improve the signal-tonoise ratio.

This crisper two-dimensional image set, which represents different views of the particle, are then combined and converted via a series of complex iterative steps into a high-resolution three-dimensional structure.

CRYOEM STRUCTURE OF THE RIBOSOME

60S ribosomal subunits randomly

path of an rRNA loop fitted 60S large ribosomal subunit at into the electron-density map 0.25 nm resolution

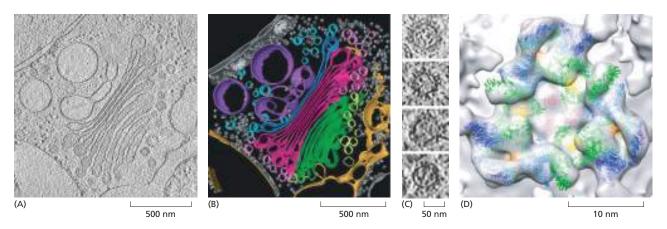

Although by no means routine, big improvements in image-processing algorithms, modeling tools and sheer computing power all mean that structures of macromolecular complexes are now becoming attainable with resolutions in the 0.2- to 0.3-nm range.

100 nm

This resolving power now approaches that of x-ray crystallography, and the two techniques thrive together, each bootstrapping the other to obtain ever more useful and dynamic structural information. A good example is the structure of the ribosome shown here at a resolution of 0.25 nm.

5 nm

MBOC7_ptr_ch09_563-602.indd 594 02/12/21 2:16 PM

appear as multiple copies in the tomogram can be identified, and with a computational process called *subtomogram averaging* to reduce noise and gain structural information, molecular structures inside cells can now be obtained at a resolution of better than 2 nm (**Figure 9-48**). Electron microscopy now provides a robust bridge between the scale of the single molecule and that of its cellular environment.

Cryo-electron Microscopy Can Determine Molecular Structures at Atomic Resolution

As we saw earlier (p. 567), noise is important in light microscopy at low light levels, but it is a particularly severe problem for electron microscopy of unstained macromolecules. A protein molecule can tolerate a dose of only a few hundreds of electrons per square nanometer without damage, and this dose is orders of magnitude below what is needed to define an image at atomic resolution.

The solution is to obtain images of many identical molecules—perhaps hundreds of thousands of images of individual particles—and combine them to produce an averaged image, revealing structural details that are hidden by the noise in the original images. This procedure is called **single-particle reconstruction** (Panel 9–1). Before combining all the individual images, however, they must be aligned with each other. With the help of a computer, the digital images of randomly distributed and unaligned molecules can be processed and combined to yield high-resolution reconstructions (see Movie 13.1). Although structures that have some intrinsic symmetry, such as dimers or helical repeats, are somewhat easier to solve (Figure 9–49), this technique has also been used for huge macromolecular machines, such as ribosomes, that have no symmetry (see Panel 9–1).

Cryo-electron microscopy (cryoEM) depends crucially on very rapidly freezing the aqueous specimen to form vitreous ice, which does not allow ice crystals to form and therefore does not damage the specimen. A very thin (about 100 nm) film of an aqueous suspension of purified macromolecular complex is prepared on a microscope grid and is then rapidly frozen by being plunged into a coolant. A special sample holder keeps this hydrated specimen at -160°C in the vacuum of the microscope, where it can be viewed directly without fixation, staining, or drying. Unlike negative staining, in which what we see is the envelope of stain exclusion around the particle, cryoEM produces an image from the macromolecular structure itself. The specialized transmission electron microscopes required operate with much higher electron accelerating voltages than that of a routine TEM and typically run at 300,000 V. However, as very low electron doses are used to obtain cryoEM images, the intrinsic contrast in the images produced is very low, and to extract the maximum amount of structural information, special image-processing techniques must be used. Huge advances in direct electron detectors and faster, more efficient image-processing techniques that involve image alignment routines, motion correction, and contrast transfer function corrections mean that the structures of molecules as small as 100 kilodaltons can now be solved. The smaller the molecule, the noisier the image, and the main

Figure 9-48 EM tomography. The COP1 coat mediates vesicle traffic within the Golgi apparatus and retrograde traffic to the endoplasmic reticulum (ER) (see Figures 13-4 and 13-5). EM tomography has helped visualize the details of COP1 coats in situ on buds and vesicles in rapidly frozen Chlamydomonas cells. (A) One slice through a three-dimensional tomogram of a complete Golgi apparatus. (The tomogram can be seen in Movie 9.2.) (B) Using the information from several such tomograms, a portion of the Golgi is shown here, color coded to show ER dark vellow, the cis vesicles vellow, the four cis cisternae green, the four medial cisternae red, the trans cisterna blue, medial vesicles pink, trans vesicles light blue, and the trans Golgi network purple. Ribosomes can also be seen as small gray blobs. (C) Individual slices through COP1 vesicles in the tomogram; the bottom one is partially uncoated. (D) By identifying and averaging more than 10,000 COP1 subunits on vesicles in the tomograms, a molecular structure was obtained by subtomogram averaging at a resolution of 2 nm. Structures of the various proteins in the COP1 coat have been solved, and they can be fitted neatly into the electron-density envelope of the EM structure. A surface view of a triad of COP1 subunits on the surface of a vesicle is shown here together with the molecular structures (in color) of the individual components that have been fitted into the EM structure. (Adapted from Y.S. Bykov et al., eLife 6:e32493, 2017, doi 10.7554/eLife.32493.)

MBOC7_ptr_ch09_563-602.indd 595 02/12/21 2:16 PM

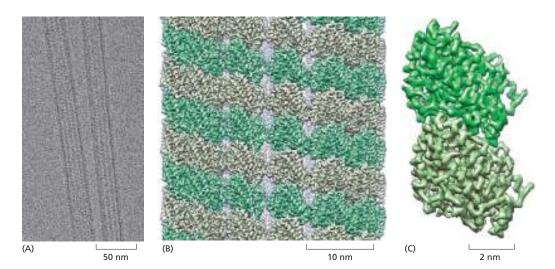

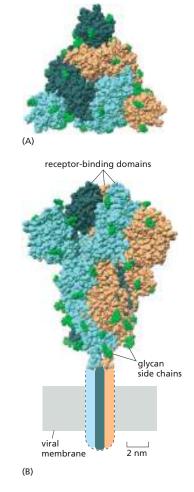

Figure 9–49 CryoEM structure of microtubules. This cryoEM reconstruction of the structure of a microtubule was helped by the intrinsic symmetry of the microtubule itself (see Figure 16–37). This detailed model of the whole microtubule has allowed an examination of the way in which the protofilaments interact and the way in which the whole lattice and associated proteins are assembled. (A) CryoEM image of two intact microtubules embedded in vitreous ice. (B) A reconstruction of the surface lattice of a single microtubule at a resolution of 0.35 nm (3.5 Å). (C) The detailed electron-density map of the tubulin dimer extracted from the structure of the intact microtubule. α-Tubulin is *darker green*, and β-tubulin is *lighter green*. (From E. Nogales, *Mol. Biol. Cell* 27:3202–3204, 2016, doi 10.1091/mbc.E16-06-0372. With permission from Elsevier.)

advantages of the method are best seen with large and sometimes flexible macromolecular complexes such as viruses, ribosomes, and large integral membrane proteins that are hard to crystallize (Figure 9–50).

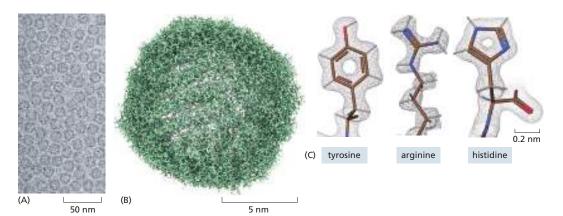

A remarkable resolution of 0.12 nm (1.2 Å) has been achieved in a particularly stable protein by cryoEM, enough to see clearly the detailed atomic structure and to rival x-ray crystallography in resolution (**Figure 9–51**). Electron microscopy, however, also has some very clear additional advantages over x-ray crystallography (discussed in Chapter 8) as a method for macromolecular structure determination. First, it does not require crystalline specimens. Second, it can deal with extremely large complexes—structures that may be too large or too variable to crystallize satisfactorily; for example, membrane proteins. Third, it allows the rapid analysis of different conformations of protein machines; for example, the different states of the F_1 ATPase proton pump shown in Figure 14–31. Fourth, the glycosylation patterns and mobile loops on the surface of proteins, which are often impossible to see in x-ray structures, are more readily resolved in cryoEM structures. And fifth, only a minute amount of sample is required compared with that needed to make crystals.

The analysis of large and complex macromolecular structures is helped considerably if the atomic structure of one or more of the subunits is known, for

Figure 9–50 The spike protein on the SARS-CoV-2 virus. The SARS-CoV-2 virus was responsible for the COVID-19 pandemic. Protructing from the viral membrane are many trimeric spike proteins that mediate binding of the virus to a receptor on cells in our respiratory tract and its subsequent entry into the cell. The trimeric spike protein is a target both of our immune system and of vaccine developers. The closed conformation of the trimeric spike protein shown here, both from the top (A) and from the side (B), was obtained from rapidly frozen intact virus particles. Spike proteins were identified by computer from multiple tilted images of the viruses and subtomogram averaging applied to them. The final electron-density map was determined to a resolution of 0.35 nm, good enough for the molecular model (shown here) to be accurately fitted within its envelope, although the details of the membrane-spanning portion of the trimeric spike protein are not revealed. The proteins are heavily N-glycosylated, and these surface glycans are shown in green, while the three spike proteins are shown in dark green, light blue, and light brown. (PDB code: 6ZWV.)

MBOC7_ptr_ch09_563-602.indd 596 02/12/21 2:16 PM

example from x-ray crystallography (Figure 9–52). Molecular models can then be mathematically "fitted" or docked into the envelope of the structure determined at lower resolution using the electron microscope. X-ray and cryoEM approaches often combine profitably together to determine molecular structures.

Light Microscopy and Electron Microscopy Are Mutually Beneficial

The interior of the cell is a confusing place, with molecules crowded together in the cytosol and intricate and complex membrane-bounded compartments. To discover which molecules are located exactly where and in which tiny vesicles or subcompartments of the cell is not straightforward, even with the genetically encoded labels that can target almost any protein. We have seen that superresolution light microscopy can be used to very accurately locate specific molecules within a cell. A major disadvantage, however, of all fluorescence imaging techniques is that it is only the tagged molecules that are imaged—their cellular context remains invisible. When fluorescence imaging is combined, however, with looking at the same specimen in the electron microscope, this correlative light microscopy and electron microscopy technique, or *CLEM*, can allow specific target molecules to be examined in their full cellular context. Although this can be achieved using fixed and sectioned material, most such approaches now use rapidly frozen material to co-localize target molecules both in the light and in the

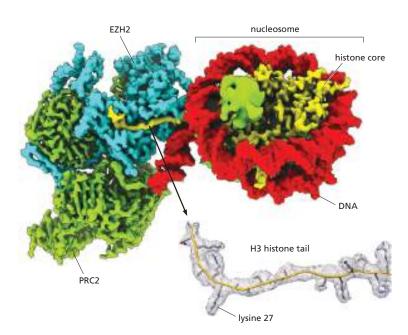

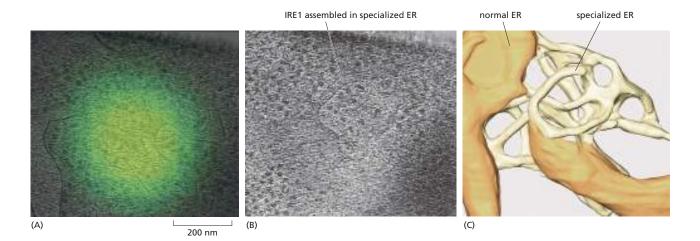

Figure 9-51 Atomic resolution by cryoEM. Apoferritin is a cytosolic protein, present in almost all living organisms, that reversibly stores iron in a nontoxic form. It is a large (474 kilodaltons) and particularly stable molecule. Its hollow globular cage has 24 symmetrical subunits, which means that a structure can be determined with relatively few particles. (A) Cryo-electron micrograph of cage-like apoferritin particles. (B) By use of every possible new technical advance in single-particle reconstruction, the complete cryoEM structure shown here is at the remarkable resolution of 0.12 nm (1.2 Å), (C) When the known amino acid sequence is modeled into the electrondensity map, clear electron densities can be seen associated with hydrogen atoms in the three amino acid side chains. The molecular model is fitted into the final electron-density envelope that is shown as a gray cage. (A, from T. Nakane et al., Nature 587:152-156, 2020, doi 10.1038/s41586-020-2829-0; B, EMD-11668; C, adapted from K.M. Yip et al., Nature 587:157-161, 2020. With permission from Nature.)

Figure 9-52 PRC2, a large macromolecular machine. Polycomb repressive complex 2 (PRC2) is a large protein complex involved in establishing heterochromatin and the epigenetic regulation of gene expression (see Figure 4-40). PRC2 interacts with a nucleosome through the binding of the nucleosomal DNA by one of its subunits, EZH2, which also engages the extended tail of histone H3 to direct its lysine 27 (K27) to the active site for methylation. The density map of PRC2 and two essential cofactors bound to a single nucleosome was produced by single-particle cryoelectron microscopy reconstruction at a resolution of 0.35 nm. The long arm of histone H3 is shown in more detail with the protein backbone modeled into the density map. (Courtesy of Vignesh Kasinath and Eva Nogales and based on EMDB-21707. From V. Kasinath et al., Science 371:eabc3393, 2021. With permission from AAAS.)

MBOC7_ptr_ch09_563-602.indd 597 02/12/21 2:16 PM

electron microscope, and of these two general approaches are common. The first is to freeze the cell or tissue, locate the positions of the target molecule with fluorescence light microscopy, and then, after transferring the frozen specimen to an electron microscope, tilting it, using EM tomography to find the exact point in the tomogram that corresponds to the fluorescent signal (Figure 9–53).

A second approach, and a demanding one too, is again to rapidly freeze the cell and locate fluorescent molecules at high resolution by single-molecule localization microscopy. The frozen cell is then transferred to a modified SEM that incorporates a separate focused ion beam, usually of gallium ions, that can be scanned across the frozen block face like a miniature milling machine, removing about 10 nm of the sample at a time. The SEM records a two-dimensional image of the scattered electrons from the surface of the block face at each step, and a three-dimensional image of the cell is gradually built up that can be correlated with the original localization data, all with a final resolution of about 5 nm (Figure 9-54). The technique is called focused ion beam-scanning electron microscopy, or FIB-SEM for short. The same technique, but without the fluorescent labels, can be used on much larger specimens that have been conventionally fixed, stained with heavy-metal salts, and embedded in plastic. Although the structural preservation may not be so good as with frozen specimens, the approach, although very time consuming, is proving useful in analyzing complex cellular interactions; for example, in mapping the neural connections in brain tissue (see Movie 9.1).

Using Microscopy to Study Cells Always Involves Trade-Offs

The history of cell biology has been tightly interlinked with that of microscopy. What we now know about the structure and function of cells has depended crucially on being able to image cells, organelles, and the molecules they contain—seeing is indeed believing. But for the young biologist today, there is, as we have seen, a bewildering variety of imaging technologies from which to choose, and knowing which is best suited to solve the problem at hand is not easy. All imaging approaches have trade-offs to consider. At an obvious level, the dynamics of cells are only accessible with certain kinds of light microscopies and with living cells. If higher resolution is required, with either electron microscopes or light microscopes, then that comes with increasing cost and complexity. Single-molecule localization microscopy also requires elaborate hardware and also takes many minutes to acquire each image. The cryoEM-derived structures of large protein complexes require the use of high-voltage machines that cost many millions of dollars. Such resources are usually confined to large centralized microscopy facilities that can be shared by many users. The precise localization of molecules within the cell requires the use of fluorescent labels, but, because only the labels themselves can be detected in a fluorescence microscope, the cellular

Figure 9-53 Correlated light and electron microscopy (CLEM). The correct folding of proteins in the endoplasmic reticulum (ER) is sensed by a major transmembrane protein called IRE1 (see Figures 12-36 and 12-37). If IRE1 is activated, it forms oligomers that are visible in fluorescence microscopy as bright foci. Here, stressed cells, expressing fluorescent IRE1 and growing on an EM grid, are rapidly frozen and subsequently imaged by EM tomography. The resulting tomograms can be directly correlated with the light micrographs. (A) A fluorescent spot of labeled IRE1 is shown here precisely superimposed on a slice through its corresponding EM tomogram that contains a network of ER. (B) Another slice through the tomogram at a different level shows IRE1 is localized as aggregates in a complex network of specialized, narrow ER tubules. (C) The outlines of the ER membranes in each slice of the tomogram are manually defined (in a process called segmentation), and the drawing here shows that the oligomers of IRE1 are concentrated in this convoluted network of specialized ER tubules. (A. B. and C. adapted from S.D. Carter et al., 2021. doi 10.1101/2021.02.24.432779.)

MBOC7_ptr_ch09_563-602.indd 598 02/12/21 2:16 PM

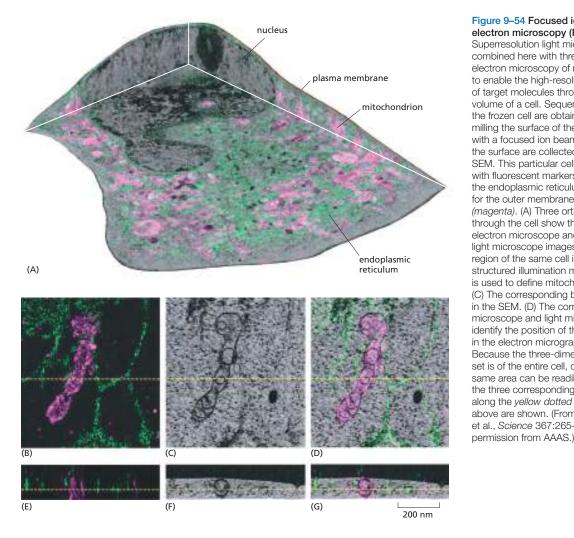

Figure 9-54 Focused ion beam-scanning electron microscopy (FIB-SEM). Superresolution light microscopy is combined here with three-dimensional electron microscopy of rapidly frozen cells to enable the high-resolution localization of target molecules throughout the entire volume of a cell. Sequential slices through the frozen cell are obtained by steadily milling the surface of the frozen block face with a focused ion beam, while images of the surface are collected at each step in an SEM. This particular cell has been labeled with fluorescent markers for the lumen of the endoplasmic reticulum (green) and for the outer membrane of mitochondria (magenta). (A) Three orthogonal slices through the cell show the combined electron microscope and fluorescence light microscope images. (B) A small region of the same cell imaged with a structured illumination microscope (SIM) is used to define mitochondrion and ER. (C) The corresponding block face image in the SEM. (D) The correlated electron microscope and light microscope images identify the position of the fluorescent labels in the electron micrograph. (E, F, and G) Because the three-dimensional SEM data set is of the entire cell, different views of the same area can be readily obtained. Here, the three corresponding vertical sections along the yellow dotted lines on the images above are shown. (From D.P. Hoffman et al., Science 367:265-277, 2020. With

context is sacrificed. Imaging itself involves several trade-offs to be considered. An improvement in any one parameter—image contrast, resolution, signal-to-noise ratio, specimen damage by photons or electrons, the depth of specimen that can be imaged, or the speed of image recording—will inevitably require a sacrifice in one or more of the others, and understanding these trade-offs will help determine which approach is best for the cell biology problem being tackled.

Summary

Discovering the detailed structure of cells and their molecules requires the higher resolution attainable in a transmission electron microscope. Three-dimensional views of the surfaces of cells and tissues are obtained by scanning electron microscopy. Specific macromolecules can be localized by combining electron microscopy with fluorescence light microscopy. EM tomography enables three-dimensional information about cellular architecture to be obtained. The shapes of isolated molecules can be roughly determined by electron microscopy techniques involving negative staining or heavy-metal shadowing, but detailed molecular structures require cryoEM and single-particle reconstruction using computational manipulations of data obtained from multiple images and multiple viewing angles to produce detailed reconstructions of macromolecules and molecular complexes. The resolution obtained with these methods means that atomic structures of individual macromolecules can be "fitted" to the images derived by electron microscopy. CryoEM can often determine the structures of molecules that are inaccessible to x-ray crystallography.

PROBLEMS

Which statements are true? Explain why or why not.

- **9–1** A fluorescent molecule, having absorbed a single photon of light at one wavelength, always emits it at a longer wavelength.
- **9–2** Transmission electron microscopy and scanning electron microscopy can both be used to examine a structure in the interior of a thin section: transmission electron microscopy provides a projection view, while scanning electron microscopy captures electrons scattered from the structure and gives a more three-dimensional view.

Discuss the following problems.

9–3 The diagrams in **Figure Q9–1** show the paths of light rays passing through a specimen into a dry lens or into an oil-immersion lens. Offer an explanation for why oil-immersion lenses should give better resolution. Air, glass, and oil have refractive indices of 1.00, 1.51, and 1.51, respectively.

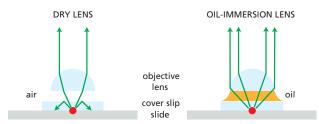

Figure Q9–1 Paths of light rays through dry and oil-immersion lenses (Problem 9–3). The *red circle* at the origin of the light rays is the specimen.

9–4 Figure Q9–2 shows a diagram of the human eye. The refractive indices of the components in the light

path are air, 1.00; cornea, 1.38; aqueous humor, 1.33; crystalline lens, 1.41; and vitreous humor, 1.38. Where does the main refraction—the main focusing—occur? What role do you suppose the lens plays?

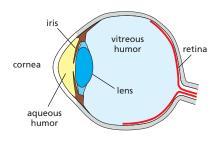

Figure Q9–2 Diagram of the human eye (Problem 9–4).

- **9–5** Why do humans see so poorly under water? And why do goggles help?
- **9–6** Explain the difference between resolution and magnification.
- **9–7 Figure Q9–3** shows a series of modified fluorescent proteins that emit light in a range of colors. Several of these fluorescent proteins contain the same chromophore, yet they fluoresce at different wavelengths. How do you suppose the exact same chromophore can fluoresce at several different wavelengths?

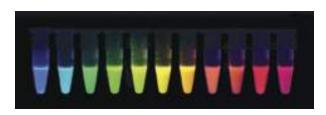

Figure Q9–3 A rainbow of colors produced by modified fluorescent proteins (Problem 9–7). (Courtesy of Nathan Shaner, Paul Steinbach, and Roger Tsien.)

9–8 A fluorescent biosensor was designed to report the cellular location of active Abl protein tyrosine kinase. A blue (cyan) fluorescent protein (CFP) and a yellow fluorescent protein (YFP) were fused to either end of a hybrid protein, which consisted of a substrate peptide recognized by the Abl protein tyrosine kinase and a phosphotyrosine-binding domain (**Figure Q9–4A**). Stimulation of the CFP domain does not cause emission by the YFP domain when the domains are separated. When the CFP and YFP domains are brought close together, however, fluorescence resonance energy transfer (FRET)

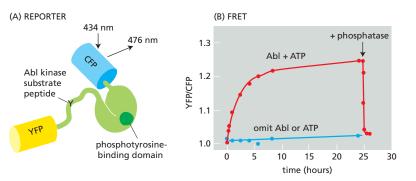

Figure Q9–4 Fluorescent biosensor designed to detect tyrosine phosphorylation (Problem 9–8). (A) Domain structure of the biosensor. Four domains are indicated: CFP, YFP, tyrosine kinase substrate peptide, and a phosphotyrosine-binding domain. (B) FRET assay. YFP/CFP is normalized to 1.0 at time zero. The biosensor was incubated in the presence (or absence) of Abl and ATP for the indicated times. *Arrow* indicates time of addition of a tyrosine phosphatase. (From A.Y. Ting et al., *Proc. Natl. Acad. Sci. USA* 98:15003–15008, 2001. With permission from National Academy of Sciences.)

MBOC7_ptr_ch09_563-602.indd 600 02/12/21 2:16 PM

REFERENCES 601

allows excitation of CFP to stimulate emission by YFP. FRET shows up experimentally as an increase in the ratio of emission at 526 nm (from YFP) versus 476 nm (from CFP) when CFP is excited by 434-nm light.

Incubation of the biosensor protein with Abl protein tyrosine kinase in the presence of ATP gave an increase in the ratio of YFP/CFP emission (Figure Q9-4B). In the absence of ATP or the Abl protein, no FRET occurred. FRET was also eliminated by addition of a tyrosine phosphatase (Figure Q9-4B). Describe as best you can how this biosensor detects active Abl protein tyrosine kinase.

9–9 Under ideal conditions, with the simplest of specimens (a monolayer of carbon atoms, for example) and careful image processing, the practical resolving power of modern electron microscopes is about 0.05 nm, some 25-fold above the theoretical limit of 0.002 nm. This is because only the very center of the electron lens can be used, and the effective numerical aperture ($n \sin \theta$) is limited by θ (half the angular width of rays collected at the objective lens). Assuming that the wavelength (λ) of the electrons is 0.004 nm and that the refractive index (n) is 1.0, calculate the value for θ , where resolution (0.05 nm) = 0.61 $\lambda/n \sin \theta$. How does this value of θ compare with that for a conventional light microscope (60°)?

9–10 Aquaporin water channels in the plasma membrane play a major role in water metabolism and osmoregulation in many cells. To determine their structural organization in the membrane, you use immunogold electron microscopy. You prepare a membrane sample, incubate it with primary antibodies against aquaporin then with gold-tagged secondary antibodies that bind

to the primary antibodies. You then examine it by electron microscopy (Figure Q9–5). Are the gold particles (black dots) consistently associated with any particular structure?

Figure Q9-5 An astrocyte membrane labeled with primary antibodies against aguaporin and then with secondary antibodies to which colloidal gold particles have been attached (Problem 9-10). (From J.E. Rash et al., Proc. Natl. Acad. Sci. USA 95:11981-11986, 1998 With permission from National Academy of Sciences.)

9–11 The technique of negative staining uses heavy metals such as uranium to provide contrast. If these heavy metals do not actually bind to defined biological structures (which they do not), how is it that they can help to make such structures visible?

INTERNAL ORGANIZATION OF THE CELL

Membrane Structure

CHAPTER 1

Cell membranes are crucial to the life of the cell. The **plasma membrane** encloses the cell, defines its boundaries, and maintains the essential differences between the cytosol and the extracellular environment. Without plasma membranes, cells could not have evolved as individual self-replicating units. Inside eukaryotic cells, the membranes of the nucleus, endoplasmic reticulum, Golgi apparatus, mitochondria, and other membrane-enclosed organelles maintain the characteristic differences between the contents of each organelle and the cytosol. Ion gradients across membranes, established by the activities of specialized membrane proteins, can be used to synthesize ATP, to drive the transport of selected solutes across the membrane, or, as in nerve and muscle cells, to produce and transmit electrical signals. In all cells, the plasma membrane also contains proteins that act as sensors of external signals, allowing the cell to change its behavior in response to environmental cues, including signals from other cells; these protein sensors, or *receptors*, transfer information—rather than molecules—across the membrane.

Despite their differing functions, all biological membranes have a common general structure: each is a very thin film of lipid and protein molecules, held together mainly by noncovalent interactions (Figure 10-1). Cell membranes are

IN THIS CHAPTER

The Lipid Bilayer

Membrane Proteins

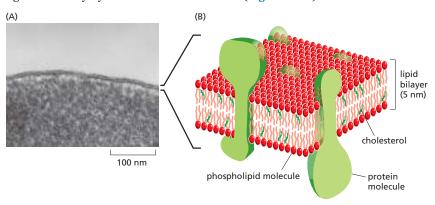

Figure 10–1 Two views of a cell membrane. (A) An electron micrograph of a segment of the plasma membrane of a human red blood cell seen in cross section, showing its bilayer structure. MBOC7_ptr_ch10_603-636.indd 603 02/12/21 12:34 PM

dynamic, fluid structures, and most of their molecules move about in the plane of the membrane. The lipid molecules are arranged as a continuous double layer about 5 nm thick. This *lipid bilayer* provides the basic fluid structure of the membrane and serves as an essentially impermeable barrier to the passage of most water-soluble molecules. Most *membrane proteins* span the lipid bilayer and mediate nearly all of the other functions of the membrane, including the transport of specific molecules across it, and the catalysis of membrane-associated reactions such as ATP synthesis. In the plasma membrane, some transmembrane proteins serve as structural links that connect the cytoskeleton through the lipid bilayer to either the extracellular matrix or an adjacent cell, while others serve as receptors to detect and transduce chemical signals in the cell's environment. It takes many kinds of membrane proteins to enable a cell to function and interact with its environment, and it is estimated that about 30% of the proteins encoded in an animal's genome are membrane proteins.

In this chapter, we consider the structure and organization of the two main constituents of biological membranes—the lipids and the proteins. Although we focus mainly on the plasma membrane, most concepts discussed apply to the various internal membranes of eukaryotic cells as well. The functions of cell membranes are considered in later chapters: their role in energy conversion and ATP synthesis, for example, is discussed in Chapter 14; their role in the transmembrane transport of small molecules in Chapter 11; and their roles in cell signaling and cell adhesion in Chapters 15 and 19, respectively. In Chapters 12 and 13, we discuss the internal membranes of the cell and the protein traffic through and between them.

THE LIPID BILAYER

The **lipid bilayer** provides the basic structure for all cell membranes. It is easily seen by electron microscopy, and its bilayer structure is attributable exclusively to the special properties of the lipid molecules, which assemble spontaneously into bilayers even under simple artificial conditions. In this section, we discuss

Figure 10–2 The parts of a typical phospholipid molecule. This example is phosphatidylcholine, represented (A) by a formula, (B) as a space-filling model (Movie 10.1), (C) schematically, and (D) as a symbol.

MBOC7_ptr_ch10_603-636.indd 604 02/12/21 12:34 PM

THE LIPID BILAYER 605

the different types of lipid molecules found in cell membranes and the general properties of lipid bilayers.

Glycerophospholipids, Sphingolipids, and Sterols Are the Major Lipids in Cell Membranes

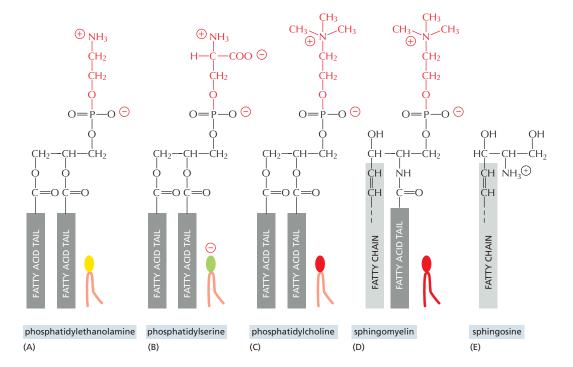

Lipid molecules constitute about 50% of the mass of most animal cell membranes, nearly all of the remainder being protein. There are approximately 5×10^6 lipid molecules in a 1 μ m \times 1 μ m area of lipid bilayer, or about 7×10^8 lipid molecules in the plasma membrane of a red blood cell. All of the lipid molecules in cell membranes are **amphiphilic**; that is, they have a **hydrophilic** ("water-loving") or *polar* end and a **hydrophobic** ("water-fearing") or *nonpolar* end.

The most abundant membrane lipids are the **phospholipids**. These have a polar head group, which includes a phosphate group, and two hydrophobic *hydrocarbon tails*. In animal, plant, and bacterial cells, the tails are usually fatty acids, and they can differ in length (they normally contain between 14 and 24 carbon atoms). One tail typically has one or more *cis*-double bonds (that is, it is *unsaturated*), while the other tail does not (that is, it is *saturated*). As shown in **Figure 10–2**, each *cis*-double bond creates a kink in the tail. Differences in the length and saturation of the fatty acid tails influence how phospholipid molecules pack against one another, thereby affecting the fluidity of the membrane, as we discuss later.

The main phospholipids in most animal cell membranes are the **glycerophospholipids**, which have a three-carbon *glycerol* backbone (see Figure 10–2). Two long-chain fatty acids are linked through ester bonds to adjacent carbon atoms of the glycerol, and the third carbon atom of the glycerol is attached to a phosphate group, which in turn is linked to one of several types of head group. By combining several different fatty acids and head groups, cells make many different glycerophospholipids. *Phosphatidylethanolamine*, *phosphatidylserine*, and *phosphatidylcholine* are the most abundant ones in mammalian cell membranes (**Figure 10–3A**, **B**, and **C**).

Another important class of phospholipids is the *sphingolipids*, which are built from *sphingosine* rather than glycerol (**Figure 10–3D and E**). Sphingosine is a long fatty acid tail with an amino group (NH₂) and two hydroxyl groups (OH) at one end. In sphingomyelin, the most common sphingolipid, a fatty acid tail

Figure 10–3 Four major phospholipids in mammalian plasma membranes. Different head groups are represented by different colors in the symbols. The lipid molecules shown in (A–C) are glycerophospholipids, which are derived from glycerol. The molecule in (D) is sphingomyelin, which is derived from (E) sphingosine and is therefore a sphingolipid. Note that only phosphatidylserine carries a net negative charge, the importance of which we discuss later; the other three are electrically neutral at physiological pH, carrying one positive and one negative charge.

MBOC7_ptr_ch10_603-636.indd 605 02/12/21 12:34 PM

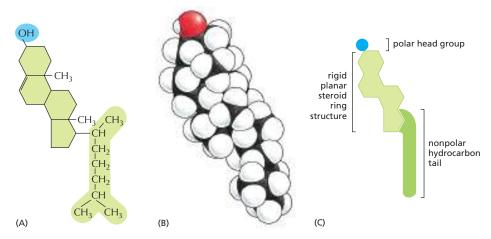

Figure 10-4 The structure of cholesterol. Cholesterol, a sterol, is represented (A) by a formula, (B) as a space-filling model, and (C) by a schematic drawing.

is attached to the amino group, and a phosphocholine group is attached to the terminal hydroxyl group. Together, the phospholipids phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and sphingomyelin constitute more than half the mass of lipid in most mammalian cell membranes (see Table 10–1, p. 610).

In addition to phospholipids, the lipid bilayers in many cell membranes contain *glycolipids* and *sterols*. Glycolipids resemble sphingolipids, but, instead of a phosphate-linked head group, they have sugars attached. We discuss glycolipids later. Sterols are rigid ring structures related to steroids but containing a single polar hydroxyl group and a short nonpolar hydrocarbon chain (Figure 10–4). Different types of sterols, distinguished primarily by the side chain attached to the ringed scaffold, are found in fungi, plants, and animal cells. Eukaryotic plasma membranes contain especially large amounts of sterols—up to one molecule for every phospholipid molecule. **Cholesterol** is the major sterol found in animal cells. The cholesterol molecules orient themselves in the bilayer with their hydroxyl group close to the polar head groups of adjacent phospholipid molecules (Figure 10–5).

Phospholipids Spontaneously Form Bilayers

The shape and amphiphilic nature of the phospholipid molecules cause them to form bilayers spontaneously in aqueous environments. As discussed in Chapter 2, hydrophilic molecules dissolve readily in water because they contain charged groups or uncharged polar groups that can form either favorable electrostatic

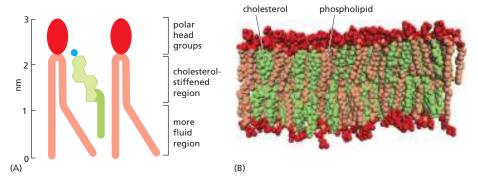

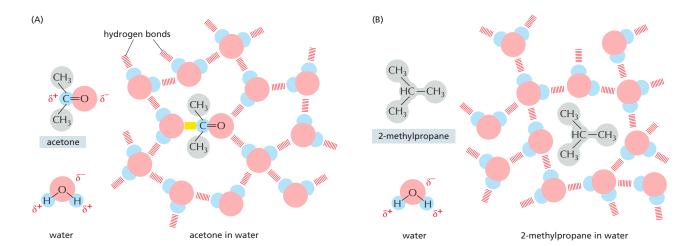

Figure 10–5 Cholesterol in a lipid bilayer. (A) Schematic drawing (to scale) of a cholesterol molecule interacting with two phospholipid molecules in one monolayer of a lipid bilayer shown in (B).

MBOC7_ptr_ch10_603-636.indd 606 02/12/21 12:34 PM

THE LIPID BILAYER 607

interactions or hydrogen bonds with water molecules (Figure 10-6A). Hydrophobic molecules, by contrast, are insoluble in water because all, or almost all, of their atoms are uncharged and nonpolar and therefore cannot form energetically favorable interactions with water molecules. If dispersed in water, this forces the adjacent water molecules to reorganize into icelike cages that surround the hydrophobic molecule (Figure 10-6B). Because these cage structures are more ordered than the surrounding water, their formation increases the free energy. This entropic free-energy cost is minimized, however, if the hydrophobic molecules (or the hydrophobic portions of amphiphilic molecules) cluster together so that the smallest number of water molecules is affected.

When phospholipid molecules are exposed to an aqueous environment, they behave as you would expect from the above discussion. They spontaneously pack together to minimize exposure of their hydrophobic tails to water and maximize exposure of their hydrophilic heads to water. Depending on their shape, the optimal packing arrangement is achieved in either of two ways: they can form spherical *micelles*, with the tails inward, or they can form double-layered sheets, or *bilayers*, with the hydrophobic tails sandwiched between the hydrophilic head groups (Figure 10–7).

The same forces that drive phospholipids to form bilayers also provide a self-sealing property. A small tear in the bilayer creates a free edge exposed to water; because this is energetically unfavorable, the lipids will rearrange spontaneously to eliminate the free edge. The prohibition of free edges has a profound consequence: the only way for a bilayer to avoid having edges is by closing in on

Figure 10-6 How hydrophilic and hydrophobic molecules interact differently with water. (A) Because acetone is polar, it can form hydrogen bonds (red) and favorable electrostatic interactions (yellow) with water molecules, which are also polar. Thus, acetone readily dissolves in water. (B) By contrast, 2-methylpropane is entirely hydrophobic. Because it cannot form favorable interactions with water, it forces adjacent water molecules to reorganize into icelike cage structures, which increases the free energy. This compound is therefore virtually insoluble in water. The symbol $\delta^{\scriptscriptstyle -}$ indicates a partial negative charge, and δ^+ indicates a partial positive charge. Polar atoms are shown in color, and nonpolar groups are shown in gray.

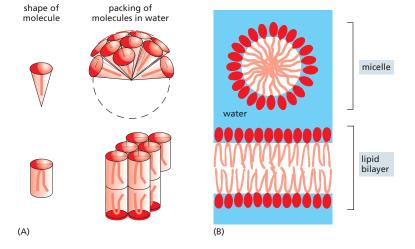

Figure 10–7 Packing arrangements of amphiphilic molecules in an aqueous environment. (A) These molecules spontaneously form micelles or bilayers in water, depending on their shape. Cone-shaped amphiphilic molecules (above) form micelles, whereas cylindershaped amphiphilic molecules such as phospholipids (below) form bilayers. (B) A micelle and a lipid bilayer seen in cross section. Note that micelles of amphiphilic molecules are thought to be much more irregular than drawn here (see Figure 10–26C).

MBOC7_ptr_ch10_603-636.indd 607 02/12/21 12:34 PM

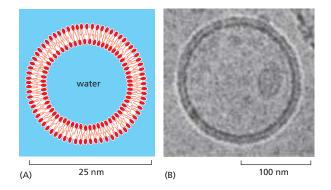

itself and forming a sealed compartment (Figure 10–8). This remarkable behavior, fundamental to the creation of a living cell, follows directly from the shape and amphiphilic nature of the phospholipid molecule.

The Lipid Bilayer Is a Two-dimensional Fluid

A lipid bilayer also has other characteristics that make it an ideal structure for cell membranes. One of the most important of these is its fluidity, which is crucial to many membrane functions (Movie 10.2). Around 1970, researchers first recognized that individual lipid molecules are able to diffuse freely within the plane of a lipid bilayer. The initial demonstration came from studies of synthetic (artificial) lipid bilayers, which can be made in the form of spherical vesicles, called liposomes (Figure 10-9), or planar lipid films. Biophysical studies showed that phospholipid molecules in synthetic bilayers very rarely migrate from the monolayer (also called a *leaflet*) on one side to that on the other. This process, known as "flip-flop," occurs on a time scale of hours for any individual molecule. It is slow because during flip-flop, the hydrophilic head groups must transiently enter and pass through the hydrophobic core of the bilayer, which is energetically disfavored. Cholesterol is an exception to this rule and can flip-flop rapidly, having only a single hydroxyl group to accommodate transiently in the hydrophobic core. By contrast to flip-flop, all lipid molecules rapidly exchange places with their neighbors within a monolayer ($\sim 10^7$ times per second). This gives rise to a rapid lateral diffusion, with a diffusion coefficient (D) of about 10^{-8} cm²/sec, which means that an average lipid molecule diffuses the length of a large bacterial cell (~2 μm) in about 1 second. These studies have also shown that individual lipid molecules rotate very rapidly about their long axis and have flexible hydrocarbon chains. Computer simulations show that lipid molecules in synthetic bilayers are very disordered, presenting an irregular, ragged surface of variously spaced and oriented head groups to the water phase on either side of the bilayer (Figure 10-10). The liquidity of membranes allows lipids to rapidly patch transient holes that may appear in the bilayer through mechanical or other stresses.

Similar mobility studies on labeled lipid molecules in isolated biological membranes and in living cells give results similar to those in synthetic bilayers. They demonstrate that the lipid component of a biological membrane is a two-dimensional liquid in which the constituent molecules are free to move laterally. As in synthetic bilayers, individual phospholipid molecules are normally confined to their own monolayer. This confinement creates a problem for the growth of biological membranes. Phospholipid molecules are manufactured in only one monolayer of a membrane, mainly in the cytosolic monolayer of the endoplasmic reticulum membrane. If none of these newly made molecules could migrate reasonably promptly to the noncytosolic monolayer, the membrane would expand asymmetrically. The problem is solved by a special class of membrane proteins called *phospholipid translocators*, or *flippases* and *scramblases*, which catalyze the rapid flip-flop of phospholipids from one monolayer to the other, as discussed in Chapter 12.

Despite the fluidity of the lipid bilayer, liposomes do not fuse spontaneously with one another when suspended in water. Fusion does not occur because the

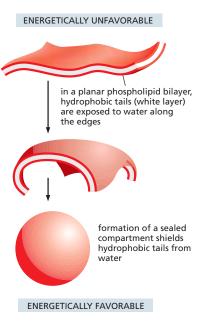

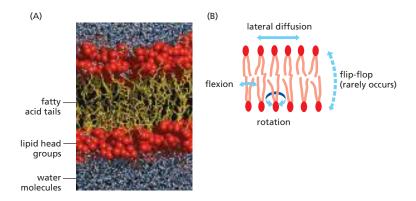

Figure 10–8 The spontaneous closure of a phospholipid bilayer to form a sealed compartment. The closed structure is stable because it avoids the exposure of the hydrophobic hydrocarbon tails to water, which would be energetically unfavorable.

Figure 10–9 Liposomes. (A) A drawing of a small spherical liposome seen in cross section. Liposomes are commonly used as model membranes in experimental studies, especially to study incorporated membrane proteins. (B) An electron micrograph of an unfixed, unstained, synthetic phospholipid vesicle—a liposome—in water, which has been rapidly frozen at liquid-nitrogen temperature. (B, from J. Kotouček et al., Sci. Rep. 10:5595, 2020.)

MBOC7_ptr_ch10_603-636.indd 608 02/12/21 12:34 PM

THE LIPID BILAYER 609

polar lipid head groups bind water molecules and ions that need to be displaced for the bilayers of two different liposomes to come into sufficiently close contact to fuse. Biological membranes have an even larger hydration shell due to the proteins embedded or associated with them. This hydration shell insulates the many internal membranes in a eukaryotic cell and prevents their uncontrolled fusion, thereby maintaining the compartmental integrity of membrane-enclosed organelles. All cell membrane fusion events are catalyzed by tightly regulated tethers that bring appropriate membranes close together and fusion proteins that force out the water layer that keeps the bilayers apart, as we discuss in Chapter 13.

The Fluidity of a Lipid Bilayer Depends on Its Composition

The fluidity of cell membranes has to be precisely regulated. It allows membrane proteins to interact rapidly and transiently, and certain membrane transport processes and enzyme activities, for example, cease when the bilayer viscosity is experimentally increased beyond a threshold level.

The fluidity of a lipid bilayer depends on both its composition and its temperature, as is readily demonstrated in studies of synthetic lipid bilayers. A synthetic bilayer made from a single type of phospholipid changes from a liquid state to a two-dimensional rigid crystalline (or gel) state at a characteristic temperature. This change of state is called a phase transition, and the temperature at which it occurs is lower (that is, the membrane becomes more difficult to freeze) if the hydrocarbon chains are short or have double bonds. A shorter chain length reduces the tendency of the hydrocarbon tails to interact with one another in both the same and opposite monolayer so that the membrane remains fluid at lower temperatures. Fluidity is also favored by cis-double bonds because they produce kinks in the chains that make them more difficult to pack together (Figure 10-11). The makeup of membranes as a complex mix of many different lipid species further adjusts most membranes so that they remain liquids just above the phase-transition point. Bacteria, yeasts, and other organisms whose temperature fluctuates with that of their environment adjust the fatty acid composition of their membrane lipids to maintain a relatively constant fluidity. As the temperature falls, for instance, the cells of those organisms synthesize fatty acids with more cis-double bonds, thereby avoiding the decrease in bilayer fluidity that would otherwise result from the temperature drop.

Sterols, such as cholesterol, modulate the properties of lipid bilayers. When mixed with phospholipids, they enhance the permeability-barrier properties of the lipid bilayer. Cholesterol inserts into the bilayer with its hydroxyl group close to the polar head groups of the phospholipids, so that its rigid, platelike steroid rings interact with—and stiffen—those regions of the hydrocarbon chains closest to the polar head groups (see Figure 10–5 and Movie 10.3). By decreasing the mobility of the first few CH_2 groups of the hydrocarbon chains of the phospholipid molecules, cholesterol makes the lipid bilayer less deformable in this region and thereby decreases the permeability of the bilayer to small water-soluble molecules. Although cholesterol tightens the packing of the lipids in a bilayer, it does

Figure 10-10 The mobility of phospholipid molecules in an artificial lipid bilayer. (A) Starting with a model of 100 phosphatidylcholine molecules arranged in a regular bilayer, a computer calculated the position of every atom after 300 picoseconds of simulated time. From these theoretical calculations, a model of the lipid bilayer emerges that accounts for almost all of the measurable properties of a synthetic lipid bilayer. including its thickness, number of lipid molecules per membrane area, depth of water penetration, and unevenness of the two surfaces. Note that the tails in one monolayer can interact with those in the other monolayer, if the tails are long enough. (B) The different motions of a lipid molecule in a bilayer. (A, based on S.W. Chiu et al., Biophys. J. 69:1230-1245, 1995.)

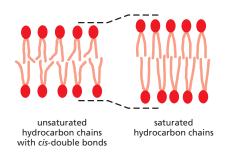

Figure 10–11 The influence of cis-double bonds in hydrocarbon chains. The double bonds make it more difficult to pack the chains together, thereby making the lipid bilayer more difficult to freeze. In addition, because the hydrocarbon chains of unsaturated lipids are more spread apart, lipid bilayers containing them are thinner than bilayers formed exclusively from saturated lipids.

not make membranes any less fluid because it also prevents the hydrocarbon chains from coming together and crystallizing.

Table 10–1 compares the lipid compositions of several biological membranes. Note that bacterial plasma membranes are often composed of one main type of phospholipid and contain no cholesterol. In archaea, lipids usually contain 20- to 25-carbon-long prenyl chains instead of fatty acids; prenyl and fatty acid chains are similarly hydrophobic and flexible (see Figure 10–18F). In thermophilic archaea, the longest lipid chains span both leaflets, making the membrane particularly stable to heat. Thus, lipid bilayers can be built from molecules with similar features but different molecular designs. The plasma membranes of most eukaryotic cells are more varied than those of prokaryotes and archaea, not only in containing large amounts of sterols but also in containing a mixture of different phospholipids.

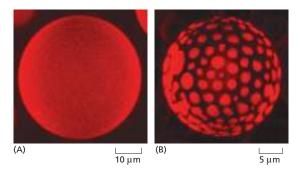

Analysis of membrane lipids by mass spectrometry has revealed that the lipid composition of a typical eukaryotic cell membrane is much more complex than originally thought. These membranes contain a bewildering variety of perhaps 500-2000 different lipid species with even the simple plasma membrane of a red blood cell containing well over 150. Lipid heterogeneity antagonizes phase transitions and may help membrane-spanning proteins to fit better in the bilayer, avoiding leaks. While some of this complexity reflects the combinatorial variation in head groups, hydrocarbon chain lengths, and desaturation of the major phospholipid classes, some membranes also contain many structurally distinct minor lipids, at least some of which have important functions. The inositol phospholipids, for example, are present in small quantities in animal cell membranes and have crucial functions in guiding membrane traffic and in cell signaling (discussed in Chapters 13 and 15, respectively). Their local synthesis and destruction are regulated by a large number of enzymes, which create both small intracellular signaling molecules and lipid docking sites on membranes that recruit specific proteins from the cytosol, as we discuss later.

Despite Their Fluidity, Lipid Bilayers Can Form Domains of Different Compositions

Because a lipid bilayer is a two-dimensional fluid, we might expect most types of lipid molecules in it to be well mixed and randomly distributed in their own monolayer. The van der Waals attractive forces between neighboring hydrocarbon tails are not selective enough to hold groups of phospholipid molecules together. With certain lipid mixtures in artificial bilayers, however, one can observe phase transitions that lead to the lateral segregation of lipids with specific lipids coming

MBOC7_ptr_ch10_603-636.indd 610 02/12/21 12:34 PM

THE LIPID BILAYER 611

together in separate domains (Figure 10–12). In these cases, attractive forces between lipid molecules must outweigh the entropic cost associated with concentrating them. Phase transitions thus break the homogeneity of the bilayer into a patchwork of domains with different properties.

There has been a long debate among cell biologists about whether the lipid molecules in the plasma membrane of living cells similarly segregate into specialized domains, called **lipid rafts**. Although many lipids and membrane proteins are not distributed uniformly, large-scale lipid phase segregations are seen rarely in living cell membranes. Instead, specific membrane proteins and lipids are seen to concentrate in a more temporary, dynamic fashion facilitated by protein-protein interactions that allow the transient formation of specialized membrane regions (**Figure 10–13**). Such clusters can be tiny nanoclusters on a scale of a few molecules or larger assemblies that can be seen with electron microscopy, such as the *caveolae* (discussed in Chapter 13). The tendency of mixtures of lipids to undergo phase transitions, as seen in artificial bilayers (see Figure 10–12), may help create rafts in living cell membranes—organizing and concentrating membrane proteins either for transport in membrane vesicles (discussed in Chapter 13) or for working together in protein assemblies, such as when they convert extracellular signals into intracellular ones (discussed in Chapter 15).

Lipid Droplets Are Surrounded by a Phospholipid Monolayer

Most eukaryotic cells store an excess of lipids in **lipid droplets**, from where they can be retrieved as building blocks for membrane synthesis or as a food source fueling metabolic energy generation. Fat cells, or *adipocytes*, are specialized for lipid storage. They contain a giant lipid droplet that fills up most of their cytoplasm. Most other cells have many smaller lipid droplets, the number and size varying with the cell's metabolic state. Fatty acids can be liberated from lipid droplets on demand and exported to other cells through the bloodstream. Lipid droplets store neutral lipids, such as triacylglycerols and cholesterol esters, which are synthesized from fatty acids and cholesterol by enzymes in the endoplasmic reticulum membrane. Because these lipids do not contain hydrophilic head groups, they are exclusively hydrophobic molecules, and therefore aggregate into three-dimensional droplets rather than into bilayers.

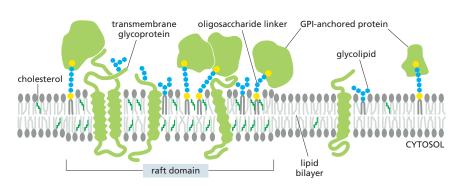

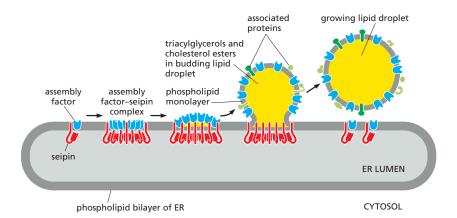

Figure 10–12 Lateral phase separation in artificial lipid bilayers. (A) Giant liposomes produced from a 1:1 mixture of phosphatidylcholine and sphingomyelin form uniform bilayers. (B) By contrast, liposomes produced from a 1:1:1 mixture of phosphatidylcholine, sphingomyelin, and cholesterol form bilayers with two separate phases. The liposomes are stained with trace concentrations of a fluorescent dye that preferentially partitions into one of the two phases. The average size of the domains formed in these giant artificial liposomes is much larger than that expected in cell membranes, where lipid rafts (see text) may be as small as a few nanometers in diameter. (A, from N. Kahya et al., J. Struct. Biol. 147:77-89, 2004. With permission from Elsevier, B, courtesy of Schwille Lab, MPG.)

Figure 10–13 A model of a raft domain. Weak protein–protein, protein–lipid, and lipid–lipid interactions reinforce one another to partition the interacting components into raft domains. Cholesterol, sphingolipids, glycolipids, glycosylphosphatidylinositol (GPI)-anchored proteins, and some transmembrane proteins are enriched in these domains. Note that because of their composition, raft domains are thought to have an increased membrane thickness. We discuss glycolipids, GPI-anchored

proteins, and oligosaccharide linkers later. (Adapted from D. Lingwood and K.

Simons, Science 327:46-50, 2010.)

MBOC7_ptr_ch10_603-636.indd 611 02/12/21 12:34 PM

In order for these hydrophobic droplets to reside in the aqueous cytosol of the cell, their surface is covered by phospholipids oriented with their hydrophobic acyl chains facing the lipid droplet and hydrophilic head groups facing the cytosol. This is why lipid droplets are surrounded by a monolayer of phospholipids rather than the bilayer that defines all other membrane-bounded compartments of the cell. The surface of lipid droplets contains a large variety of proteins, some of which are enzymes involved in lipid metabolism. Lipid droplets form rapidly when cells are exposed to high concentrations of fatty acids. They form from the endoplasmic reticulum membrane where many enzymes of lipid metabolism are localized. Figure 10–14 shows one model of how lipid droplets form and acquire their surrounding monolayer of phospholipids and proteins. In some specialized cells, such as liver cells and enterocytes (the absorptive cells of the gut), droplets bud into the lumen of the endoplasmic reticulum from where they are secreted as lipoprotein particles that move metabolic energy in the form of triglycerides through the body.

The Asymmetry of the Lipid Bilayer Is Functionally Important

The lipid compositions of the two monolayers of the lipid bilayer in many membranes are strikingly different. In the human red blood cell (erythrocyte) membrane, for example, almost all of the phospholipid molecules that have choline— $(CH_3)_3N^+CH_2CH_2OH$ —in their head group (phosphatidylcholine and sphingomyelin) are in the outer monolayer, whereas almost all that contain a terminal primary amino group (phosphatidylethanolamine and phosphatidylserine) are in the inner monolayer (Figure 10–15). Because the negatively charged phosphatidylserine is located in the inner monolayer, there is a significant difference in charge between the two halves of the bilayer. We discuss in Chapter 12 how membrane-bound phospholipid translocators generate and maintain lipid asymmetry.

Lipid asymmetry is functionally important, especially in converting extracellular signals into intracellular ones (discussed in Chapter 15). Many cytosolic proteins bind to specific lipid head groups found in the cytosolic monolayer of the lipid bilayer. The enzyme $protein\ kinase\ C\ (PKC)$, for example, which is

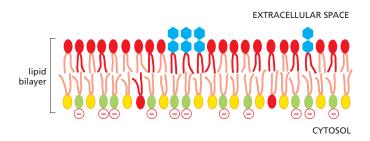

Figure 10-14 A model for the formation of lipid droplets. Neutral lipids are deposited between the two monolayers of the endoplasmic reticulum (ER) membrane forming a lenslike structure between the two monolayers. The lens forms as triacylglycerides and cholesterol esters are made and accumulate in the ER membrane and self-aggregate. Multiple copies of the transmembrane protein seipin assemble into a ring together with a lipid droplet assembly factor. In the presence of triacylglycerides, seipin dissociates from the assembly factor, which migrates to the cytosolic monolayer of the ER membrane where it facilitates a process in which the droplet buds, fills up with nonpolar lipids, and pinches off as a unique organelle that is surrounded by a single monolayer of phospholipids and associated proteins. In some cells, such as adipocytes, droplets fuse and can reach a gigantic size. (Adapted from J. Chung et al., Dev. Cell 51:551-563, 2019.)

Figure 10–15 The asymmetric distribution of phospholipids and glycolipids in the lipid bilayer of human red blood cells. The colors used for the phospholipid head groups are those introduced in Figure 10–3. In addition, glycolipids are drawn with hexagonal polar head groups (blue). Cholesterol (not shown) is distributed roughly equally in both monolayers.

MBOC7_ptr_ch10_603-636.indd 612 02/12/21 12:34 PM

THE LIPID BILAYER 613

activated in response to various extracellular signals, binds to the cytosolic face of the plasma membrane, where phosphatidylserine is concentrated, and requires this negatively charged phospholipid for its activity.

In other cases, specific lipid head groups must first be modified to create protein-binding sites at a particular time and place. One example is *phosphatidylinositol* (*PI*), one of the minor phospholipids that are concentrated in the cytosolic monolayer of cell membranes (see Figure 13–10A, B, and C). Various lipid kinases can add phosphate groups at distinct positions on the inositol ring, creating binding sites that recruit specific proteins from the cytosol to the membrane. An important example of such a lipid kinase is *phosphoinositide 3-kinase* (*PI 3-kinase*), which is activated in response to extracellular signals and helps to recruit specific intracellular signaling proteins to the cytosolic face of the plasma membrane (see Figure 15–53). Similar lipid kinases phosphorylate inositol phospholipids in intracellular membranes and thereby help to recruit proteins that guide membrane transport.

Phospholipids in the plasma membrane are used in yet another way to convert extracellular signals into intracellular ones. The plasma membrane contains various *phospholipases* that are activated by extracellular signals to cleave specific phospholipid molecules, generating fragments of these molecules that act as short-lived intracellular messengers. *Phospholipase C*, for example, cleaves an inositol phospholipid in the cytosolic monolayer of the plasma membrane to generate two fragments, one of which remains in the membrane and helps activate protein kinase C, while the other is released into the cytosol and stimulates the release of Ca^{2+} from the endoplasmic reticulum (see Figure 15–29).

Animals exploit the phospholipid asymmetry of their plasma membranes to distinguish between live and dead cells. When animal cells undergo apoptosis (discussed in Chapter 18), phosphatidylserine, which is normally confined to the cytosolic (or inner) monolayer of the plasma membrane lipid bilayer, rapidly translocates to the extracellular (or outer) monolayer. The phosphatidylserine exposed on the cell surface signals neighboring cells, such as macrophages, to phagocytose the dead cell and digest it. The translocation of the phosphatidylserine in apoptotic cells occurs because the active mechanisms that generate and maintain lipid bilayer asymmetry are impaired.

Glycolipids Are Found on the Surface of All Eukaryotic Plasma Membranes

Sugar-containing lipid molecules called **glycolipids** have the most extreme asymmetry in their membrane distribution: these molecules, whether in the plasma membrane or in intracellular membranes, are found exclusively in the monolayer facing away from the cytosol. In animal cells, they are made from sphingosine, just like sphingomyelin (see Figure 10–3). These intriguing molecules tend to self-associate, partly through hydrogen bonds between their sugars and partly through van der Waals forces between their long and straight hydrocarbon chains, which causes them to partition preferentially into lipid raft phases (see Figure 10–13). The asymmetric distribution of glycolipids in the bilayer results from the addition of sugar groups to the lipid molecules in the lumen of the Golgi apparatus. Thus, the compartment in which they are manufactured is topologically equivalent to the exterior of the cell (discussed in Chapter 12). As they are delivered to the plasma membrane, the sugar groups are exposed at the cell surface (see Figure 10–15), where they have important roles in interactions of the cell with its surroundings.

Glycolipids probably occur in all eukaryotic cell plasma membranes, where they generally constitute about 5% of the lipid molecules in the outer monolayer. They are also found in some intracellular membranes. The most complex of the glycolipids, the **gangliosides**, contain oligosaccharides with one or more sialic acid moieties, which give gangliosides a net negative charge (**Figure 10–16**). The most abundant of the more than 40 different gangliosides that have been identified are in the plasma membrane of nerve cells, where gangliosides constitute 5–10% of the total lipid mass; they are also found in much smaller quantities in other cell types.

MBOC7_ptr_ch10_603-636.indd 613 02/12/21 12:34 PM

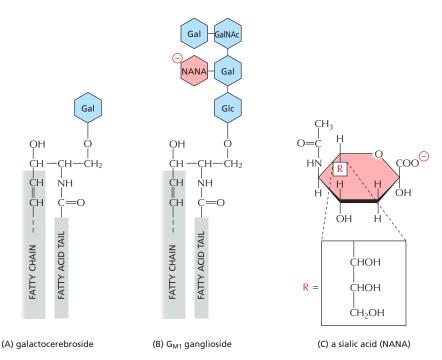

Figure 10-16 Glycolipid molecules. (A) Galactocerebroside is called a neutral glycolipid because the sugar that forms its head group is uncharged. (B) A ganglioside always contains one or more negatively charged sialic acid moieties. There are various types of sialic acid; in human cells, it is mostly N-acetylneuraminic acid, or NANA, whose structure is shown in (C). Whereas in bacteria and plants almost all alvcolipids are derived from glycerol, as are most phospholipids, in animal cells almost all glycolipids are based on sphingosine, as is the case for sphingomyelin (see Figure 10-3). Gal = galactose, Glc = glucose, GalNAc = N-acetylgalactosamine; these three sugars are uncharged.

Hints as to the functions of glycolipids come from their localization. In the plasma membrane of epithelial cells, for example, glycolipids are confined to the exposed apical surface, where they may help to protect the membrane against the harsh conditions frequently found there (such as low pH and high concentrations of degradative enzymes). Charged glycolipids, such as gangliosides, may be important because of their electrical effects: their presence alters the electrical field across the membrane and the concentrations of ions—especially ${\rm Ca^{2^+}-at}$ the membrane surface. Glycolipids also function in cell-recognition processes, in which membrane-bound carbohydrate-binding proteins (*lectins*) bind to the sugar groups on both glycolipids and glycoproteins in the process of cell-cell adhesion (discussed in Chapter 19). Mutant mice that are deficient in all of their complex gangliosides show abnormalities in the nervous system, including axonal degeneration and reduced myelination.

The ubiquitous presence of glycolipids on the cell surface has been exploited by a number of bacterial toxins and viruses as a means to enter cells. For example, influenza virus interacts with sialic acid sugars on gangliosides during its entry into cells (see Figure 10–16). Polyomaviruses also enter the cell after binding initially to gangliosides. Similarly, the ganglioside $G_{\rm M1}$ acts as a cell-surface receptor for the bacterial toxin that causes the debilitating diarrhea of cholera. Cholera toxin binds to and enters only those cells that have $G_{\rm M1}$ on their surface, including intestinal epithelial cells. Its entry into a cell leads to a prolonged increase in the concentration of intracellular cyclic AMP (discussed in Chapter 15), which in turn causes a large efflux of Cl⁻, leading to the secretion of Na⁺, K⁺, HCO₃⁻, and water into the intestine.

Summary

Biological membranes consist of a continuous double layer of lipid molecules in which membrane proteins are embedded. This lipid bilayer is fluid, with individual lipid molecules able to diffuse rapidly within their own monolayer. The membrane lipid molecules are amphiphilic. When placed in water, they assemble spontaneously into bilayers, which form sealed compartments.

Although cell membranes can contain hundreds of different lipid species, the plasma membrane in animal cells contains three major classes—phospholipids,

MBOC7_ptr_ch10_603-636.indd 614 02/12/21 12:34 PM

cholesterol, and glycolipids. Because of their different backbone structure, phospholipids fall into two subclasses—glycerophospholipids and sphingolipids. The lipid compositions of the inner and outer monolayers are different, reflecting the different functions of the two faces of a cell membrane. Different mixtures of lipids are found in the membranes of cells of different types, as well as in the various membranes of a single eukaryotic cell. Inositol phospholipids are a minor class of phospholipids, which in the cytosolic leaflet of the plasma membrane lipid bilayer play an important part in cell signaling: in response to extracellular signals, specific lipid kinases phosphorylate the head groups of these lipids to form docking sites for cytosolic signaling proteins, whereas specific phospholipases cleave certain inositol phospholipids to generate small intracellular signaling molecules.

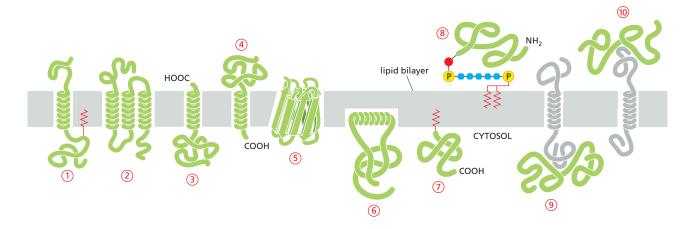

MEMBRANE PROTEINS

Although the lipid bilayer provides the basic structure of biological membranes, the membrane proteins perform most of the membrane's specific tasks and therefore give each type of cell membrane its characteristic functional properties. Accordingly, the amounts and types of proteins in a membrane are highly variable. In the myelin membrane, which serves mainly as electrical insulation for nerve-cell axons, less than 25% of the membrane mass is protein. By contrast, in the membranes involved in ATP production (such as the internal membranes of mitochondria and chloroplasts), approximately 75% is protein. A typical plasma membrane is somewhere in between, with protein accounting for about half of its mass. Because lipid molecules are small compared with protein molecules, however, there are always many more lipid molecules than protein molecules in cell membranes—about 50 lipid molecules for each protein molecule in cell membranes that are 50% protein by mass. Membrane proteins vary widely in structure and in the way they associate with the lipid bilayer, which reflects their diverse functions.

Membrane Proteins Can Be Associated with the Lipid Bilayer in Various Ways

Figure 10–17 shows the different ways in which proteins can associate with the membrane. Like their lipid neighbors, **membrane proteins** are amphiphilic, having hydrophobic and hydrophilic regions. Many membrane proteins extend through the lipid bilayer, and hence are called **transmembrane proteins**, with part of their mass extruding from the membrane on both sides (Figure 10–17, examples 1, 2, and 5). Other transmembrane proteins are inserted with the bulk of their mass exposed almost exclusively on one or the other side of the membrane (Figure 10–17, examples 3 and 4). In all cases their hydrophobic regions pass through the membrane and interact with the hydrophobic tails of the lipid molecules in the interior of the bilayer, where they are sequestered away from water. Their hydrophilic regions are exposed to water on either side of the membrane.

Figure 10-17 Various ways in which proteins associate with the lipid bilaver. Most membrane proteins are thought to extend across the bilayer as (1) a single α helix, (2) as multiple α helices, or (5) as a rolled-up β sheet (a β barrel). Some of these single-pass and multipass proteins have a covalently attached fatty acid chain inserted in the cytosolic lipid monolayer (1). Other membrane proteins are exposed at only one side of the membrane (3, 4). These classes include glycosyltransferases that carry out glycosylation reactions in the Golgi apparatus (3) and SNARE proteins that catalyze membrane fusion (4), both discussed in Chapter 13. (6) Some of these are anchored to the cytosolic surface by an amphiphilic α helix that partitions into the cytosolic monolayer of the lipid bilayer through the hydrophobic face of the helix. (7) Others are attached to the bilayer solely by a covalently bound lipid chain-either a fatty acid chain or a prenyl group (see Figure 10-18) -- in the cytosolic monolayer or, (8) via an oligosaccharide linker, to phosphatidylinositol in the noncytosolic monolayer-called a GPI anchor. (9, 10) Finally, membrane-associated proteins are attached to the membrane only by noncovalent interactions with other membrane proteins. The way in which the structure in (7) is formed is illustrated in Figure 10-18, while the way in which the GPI anchor shown in (8) is formed is illustrated in Figure 12–30. The details of how membrane proteins become associated with the lipid bilayer are discussed in Chapter 12.

MBOC7_ptr_ch10_603-636.indd 615 02/12/21 12:34 PM

Other membrane proteins are located entirely in the cytosol and are attached to the cytosolic monolayer of the lipid bilayer, either by an amphiphilic α helix exposed on the surface of the protein (Figure 10–17, example 6) or by one or more covalently attached lipid chains (Figure 10–17, example 7). The lipid-linked proteins in example 7 in Figure 10–17 are made as soluble proteins in the cytosol and are subsequently anchored to the membrane by the covalent attachment of the lipid group. Lipids can also be attached to the cytosolic facing domains of transmembrane proteins as an additional means of anchoring them to the membrane (see Figure 10–17, example 1).

Yet other membrane proteins are entirely exposed at the external cell surface, being attached to the lipid bilayer only by a covalent linkage (via a specific oligosaccharide) to a lipid anchor in the outer monolayer of the plasma membrane (Figure 10–17, example 8). These proteins are initially made and inserted into the endoplasmic reticulum (ER) by a single transmembrane segment at the C-terminus (similar to example 4 in Figure 10-17). While still in the ER, the transmembrane segment of the protein is cleaved off and a *glycosylphosphatidylinositol* (*GPI*) anchor is added, leaving the protein bound to the noncytosolic surface of the ER membrane solely by this anchor (discussed in Chapter 12); transport vesicles eventually deliver the protein to the plasma membrane (discussed in Chapter 13).

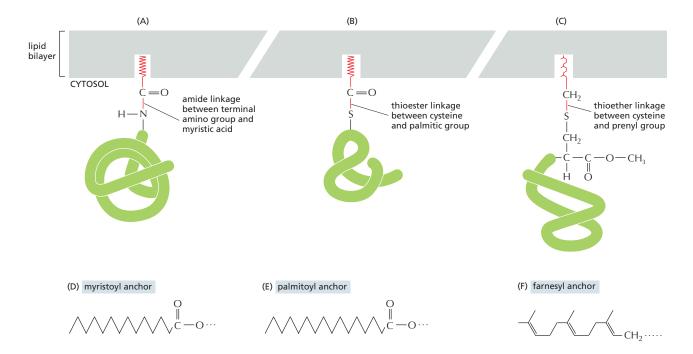

By contrast to these examples, **membrane-associated proteins** do not extend into the hydrophobic interior of the lipid bilayer at all; they are instead bound to either face of the membrane by noncovalent interactions with other membrane proteins (Figure 10–17, examples 9 and 10). Many of the proteins of this type can be released from the membrane by relatively gentle extraction procedures, such as exposure to solutions of very high or low ionic strength or of extreme pH, which interfere with protein-protein interactions but leave the lipid bilayer intact; these proteins are often referred to as *peripheral membrane proteins*, and their association with membranes is often regulated by the cell as we discuss next. Transmembrane proteins and many proteins held in the bilayer by lipid groups or hydrophobic polypeptide regions that insert into the hydrophobic core of the lipid bilayer cannot be released in these ways.

Lipid Anchors Control the Membrane Localization of Some Signaling Proteins

How a membrane protein is associated with the lipid bilayer reflects the function of the protein. Only transmembrane proteins can function on both sides of the bilayer or transport molecules across it. Cell-surface receptors, for example, are usually transmembrane proteins that bind signal molecules in the extracellular space and generate different intracellular signals on the opposite side of the plasma membrane, as we discuss in Chapter 15. To transfer small hydrophilic molecules across a membrane, a membrane transport protein must provide a path for the molecules to cross the hydrophobic permeability barrier of the lipid bilayer; the molecular architecture of multipass transmembrane proteins (Figure 10–17, examples 2 and 5) is ideally suited for this task, as we discuss in Chapter 11.

Proteins that function on only one side of the lipid bilayer, by contrast, are often associated exclusively with either the lipid monolayer or a protein domain on that side. Some intracellular signaling proteins, for example, that help relay extracellular signals into the cell interior are bound to the cytosolic half of the plasma membrane by one or more covalently attached lipid groups, which can be fatty acid chains or *prenyl groups* (Figure 10–18). In some cases, myristic acid is added to the N-terminal amino group of the protein during its synthesis on a ribosome. All members of the *Src family* of cytoplasmic protein tyrosine kinases (discussed in Chapter 15) are myristoylated in this way. Membrane attachment through a single lipid anchor is not very strong, however, and a second lipid group is often added to anchor proteins more firmly to a membrane. For most Src kinases, the second lipid modification is the attachment of palmitic acid to a cysteine side chain of the protein. This modification occurs in response to

MBOC7_ptr_ch10_603-636.indd 616 02/12/21 12:34 PM

an extracellular signal and helps recruit the kinases to the plasma membrane. When the signaling pathway is turned off, the palmitic acid is removed, allowing the kinase to return to the cytosol. Other intracellular signaling proteins, such as the Ras family small GTPases (discussed in Chapter 15), use a combination of prenyl group and palmitic acid attachment to recruit the proteins to the plasma membrane.

Many proteins attach to membranes transiently. Some are classical peripheral membrane proteins that associate with membranes by regulated protein-protein interactions. Others undergo a transition from soluble to membrane protein by a conformational change that exposes a hydrophobic peptide or covalently attached lipid anchor. Many of the small GTPases of the Rab protein family that regulate intracellular membrane traffic (discussed in Chapter 13), for example, switch depending on the nucleotide that is bound to the protein. In their GDP-bound state they are soluble in the cytosol, often stabilized by binding to a GDP dissociation inhibitor, or GDI, whereas in their GTP-bound state their lipid anchor is exposed and tethers them to membranes. They are membrane proteins at one moment and soluble proteins at the next. Such highly dynamic interactions greatly expand the repertoire of membrane functions.

In Most Transmembrane Proteins, the Polypeptide Chain Crosses the Lipid Bilayer in an α -Helical Conformation

A transmembrane protein always has a unique orientation in the membrane. This reflects both the asymmetric manner in which it is inserted into the lipid bilayer in the ER during its biosynthesis (discussed in Chapter 12) and the different functions of its cytosolic and noncytosolic domains. These domains are separated by the membrane-spanning segments of the polypeptide chain, which contact the hydrophobic environment of the lipid bilayer and are composed largely of amino acids with nonpolar side chains. Because the peptide bonds themselves are polar and because water is absent in the bilayer, all peptide bonds in the membrane-spanning segments of a polypeptide are driven to form hydrogen bonds with one another (discussed in Chapter 3).

There are two ways that hydrogen-bonding between peptide bonds can be maximized. The most common way, found in the majority of transmembrane

Figure 10-18 Membrane protein attachment by a fatty acid chain or a prenyl group. The covalent attachment of either type of lipid can help localize a water-soluble protein to a membrane after its synthesis in the cytosol. (A) A fatty acid chain (myristic acid) is attached via an amide linkage to an N-terminal glycine. (B) A fatty acid chain (palmitic acid) is attached via a thioester linkage to a cysteine. (C) A prenyl chain (either farnesyl or a longer geranylgeranyl chain) is attached via a thioether linkage to a cysteine residue that is initially located four residues from the protein's C-terminus. After prenylation, the terminal three amino acids are cleaved off, and the new C-terminus is methylated before insertion of the anchor into the membrane (not shown). The structures of the lipid anchors are shown below: (D) a myristoyl anchor (derived from a 14-carbon saturated fatty acid chain), (E) a palmitoyl anchor (a 16-carbon saturated fatty acid chain), and (F) a farnesyl anchor (a 15-carbon unsaturated hydrocarbon chain composed of three 5-carbon isoprenoid repeats).

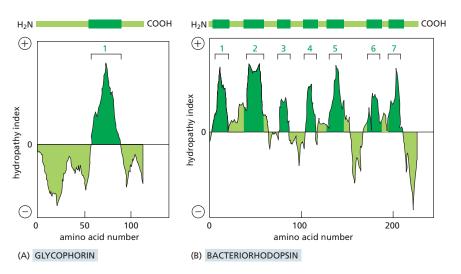

MBOC7_ptr_ch10_603-636.indd 617 02/12/21 12:34 PM

Figure 10–19 A segment of a membrane-spanning polypeptide chain crossing the lipid bilayer as an α helix. Only the α -carbon backbone of the polypeptide chain is shown, with the hydrophobic amino acids in *green* and the hydrophilic amino acids in *yellow*. The polypeptide segment shown is part of the single membrane-spanning protein glycophorin, which is found abundantly in the red blood cell plasma membrane. Glycophorin normally is a dimer of two identical subunits whose transmembrane segments cross in the hydrophobic interior of the bilayer. Only a single transmembrane segment is shown. (PDB code: 5EH4.)

proteins, is if the polypeptide chain forms a regular α helix as it crosses the bilayer (Figure 10–19). In single-pass transmembrane proteins, the polypeptide chain crosses only once (see Figure 10–17, example 1), whereas in multipass transmembrane proteins, the polypeptide chain crosses multiple times (see Figure 10–17, example 2). An alternative way for the peptide bonds in the lipid bilayer to satisfy their hydrogen-bonding requirements is for multiple transmembrane strands of a polypeptide chain to be arranged as a β sheet that is rolled up into a cylinder (a so-called β barrel; see Figure 10–17, example 5, and Figure 3–7). This protein architecture is seen in the porin proteins that we discuss later.

Progress in x-ray crystallography and single-particle cryo-electron microscopy of membrane proteins has enabled the determination of the three-dimensional structure of many of them. The structures confirm that it is often possible to predict from the protein's amino acid sequence which parts of the polypeptide chain extend across the lipid bilayer. Segments containing about 20–30 amino acids, with a high degree of hydrophobicity, are long enough to span a lipid bilayer as an α helix, and they can often be identified in $hydropathy\ plots$ (Figure 10–20). From such plots, it is estimated that about 30% of an organism's proteins are transmembrane proteins, emphasizing their importance. Hydropathy plots cannot identify the membrane-spanning segments of a β barrel, as 10 amino acids or fewer are sufficient to traverse a lipid bilayer as an extended β strand, and only every other amino acid side chain is hydrophobic.

The strong drive to maximize hydrogen-bonding in the absence of water means that most transmembrane helices span the membrane completely. But multipass transmembrane proteins can also contain regions that fold into the membrane from either side, squeezing into spaces between transmembrane α helices without contacting the hydrophobic core of the lipid bilayer. Because such regions interact only with other polypeptide regions, they do not need to maximize hydrogen-bonding; they can therefore have a variety of secondary structures, including helices that extend only partway across the lipid bilayer (Figure 10–21). Such regions are important for the function of some membrane proteins, including water channel and ion channel proteins, in which the regions contribute to the walls of the pores traversing the membrane and confer substrate specificity on the channels, as we discuss in Chapter 11. These regions cannot be identified

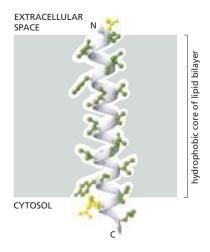

Figure 10-20 Using hydropathy plots to localize potential α-helical membranespanning segments in a polypeptide chain. The free energy needed to transfer successive segments of a polypeptide chain from a nonpolar solvent to water is calculated from the amino acid composition of each segment using data obtained from model compounds. This calculation is made for segments of a fixed size (usually around 10-20 amino acids), beginning with each successive amino acid in the chain. The hydropathy index of the segment is plotted on the Y axis as a function of its location in the chain. A positive value indicates that free energy is required for transfer to water (that is, the segment is hydrophobic), and the value assigned is an index of the amount of energy needed. Peaks in the hydropathy index appear at the positions of hydrophobic segments in the amino acid sequence. (A and B) Hydropathy plots for two membrane proteins that are discussed later in this chapter. Glycophorin (A) has a single membrane-spanning α helix and one corresponding peak in the hydropathy plot. Bacteriorhodopsin (B) has seven membrane-spanning α helices and seven corresponding peaks in the hydropathy plot. (A, adapted from D. Eisenberg, Annu. Rev. Biochem. 53:595-624, 1984.)

MBOC7_ptr_ch10_603-636.indd 618 02/12/21 12:34 PM

in hydropathy plots and are only revealed by determining the protein's threedimensional structure or by sequence alignment with homologous proteins whose structures are known.

Transmembrane α Helices Often Interact with One Another

The transmembrane α helices of many single-pass membrane proteins do not contribute to the folding of the protein domains on either side of the membrane. As a consequence, it is often possible to engineer cells to produce just the cytosolic or extracellular domains of these proteins as water-soluble molecules. This approach has been invaluable for studying the structure and function of these domains, especially the domains of transmembrane receptor proteins (discussed in Chapter 15). A transmembrane α helix, even in a single-pass membrane protein, however, often does more than just anchor the protein to the lipid bilayer. Many single-pass membrane proteins form homodimers or heterodimers that are held together by noncovalent, but strong and highly specific, interactions between the two transmembrane α helices; the sequence of the amino acids of these helices contains the information that directs the protein-protein interaction.

Similarly, the transmembrane α helices in multipass membrane proteins occupy specific positions in the folded protein structure that are determined by interactions between the neighboring helices (Figure 10-22). These interactions are crucial for the structure and function of the many receptors, channels, and transporters that communicate or move molecules across cell membranes. In these proteins, each transmembrane helix shields regions of neighboring transmembrane helices from membrane lipids. When all the helices are packed together into the final folded structure, the outer surface of the helical bundle that is exposed to lipids is composed primarily of hydrophobic amino acids. By contrast, the interior of the helical bundle, which is not exposed directly to lipids, can contain polar and even charged amino acids that would ordinarily be disfavored in the membrane. The ability to accommodate hydrophilic amino acids within a bundle of transmembrane helices means that multipass membrane proteins can contain binding sites and channels across the membrane for hydrophilic molecules. This property affords multipass membrane proteins considerable functional diversity and probably explains why they represent the majority of membrane proteins.

Some B Barrels Form Large Channels

Unlike a bundle of α helices that can be arranged in numerous ways, β -barrel membrane proteins are always arranged as a cylinder. This is because all hydrogen bonds must be satisfied, so a sheet that exposes an edge is energetically

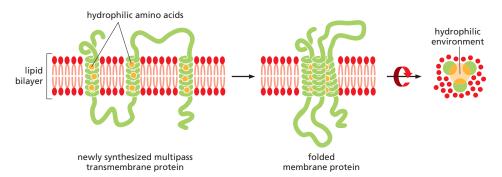

Figure 10–22 Steps in the folding of a multipass transmembrane protein. Polar and charged amino acids contained in transmembrane helices are energetically disfavored in the hydrophobic environment of the lipid bilayer. They become buried in the interface between spatially adjacent helices in folded membrane proteins. In membrane protein complexes, these contacts can occur between helices from different protein subunits, as is the case for many ion channels as discussed in Chapter 11. In this way, multipass membrane proteins can provide a hydrophilic path across the hydrophobic barrier of the bilayer.

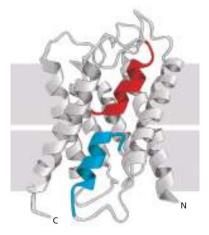

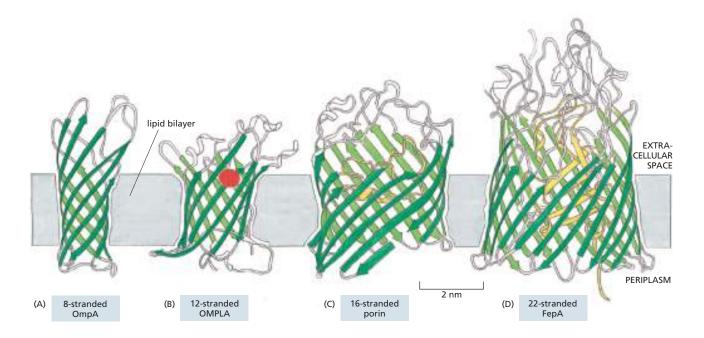

Figure 10–21 Two short α helices in the aquaporin water channel, each of which spans only halfway through the lipid bilayer. In the plasma membrane, four monomers, one of which is shown here, form a tetramer. Each monomer has a hydrophilic pore at its center, which allows water molecules to cross the membrane in single file (see Figure 11–20 and Movie 11.6). The two short, colored helices are buried at an interface formed by protein–protein interactions. The mechanism by which the channel allows the passage of water molecules is discussed in more detail in Chapter 11. (PDB code: 1H6I.)

MBOC7_ptr_ch10_603-636.indd 619 02/12/21 12:34 PM

disfavored in the membrane. This means that β barrels all share the same overall architecture in which the amino acids facing the outside of the cylinder are hydrophobic. By contrast, the size of the barrel, and the content inside the barrel, are highly variable and suited to the function of each β -barrel membrane protein. For example, the number of β strands in a β barrel varies widely, from as few as 8 strands to as many as 22 (Figure 10–23).

 β -Barrel proteins are abundant in the outer membranes of bacteria, mitochondria, and chloroplasts. Some are pore-forming proteins, which create water-filled channels that allow selected small hydrophilic molecules to cross the membrane. The porins are well-studied examples (Figure 10–23C). Many porin barrels are formed from a 16-strand, antiparallel β sheet rolled up into a cylindrical structure. Polar amino acid side chains line the aqueous channel on the inside, while nonpolar side chains project from the outside of the barrel to interact with the hydrophobic core of the lipid bilayer. Loops of the polypeptide chain often protrude into the **lumen** of the channel, narrowing it so that only certain solutes can pass. Some porins are therefore highly selective: *maltoporin*, for example, preferentially allows maltose and maltose oligomers to cross the outer membrane of *E. coli*.

The FepA protein is a more complex example of a β -barrel transport protein (Figure 10–23D). It transports iron ions across the bacterial outer membrane. It is constructed from 22 β strands, and a large globular domain completely fills the inside of the barrel. Iron ions bind to this domain, which changes its conformation to transfer the iron across the membrane.

Not all β -barrel proteins are transporters. Some form smaller barrels that are completely filled by amino acid side chains that project into the center of the barrel. These proteins function as receptors or enzymes (Figure 10–23A and B); the barrel serves as a rigid anchor, which holds the protein in the membrane and orients the cytosolic loops that form binding sites for specific intracellular molecules.

Most multipass membrane proteins in eukaryotic cells and in the bacterial plasma membrane are constructed from transmembrane α helices. The helices can slide against each other, allowing conformational changes in the protein that can open and shut ion channels, transport solutes, or transduce extracellular signals into intracellular ones. In β -barrel proteins, by contrast, hydrogen bonds bind each β strand rigidly to its neighbors, making conformational changes within the wall of the barrel unlikely. This rigidity makes β barrels remarkably

Figure 10-23 β barrels formed from different numbers of β strands. (A) The Escherichia coli OmpA protein serves as a receptor for a bacterial virus. (B) The E. coli OMPLA protein is an enzyme (a lipase) that hydrolyzes lipid molecules. The amino acids that catalyze the enzymatic reaction (indicated in red) protrude from the outside surface of the barrel. (C) A porin from the bacterium Rhodobacter capsulatus forms a water-filled pore across the outer membrane. The diameter of the channel is restricted by loops (shown in *yellow*) that protrude into the channel. (D) The E. coli FepA protein transports iron ions. The inside of the barrel is completely filled by a globular protein domain (shown in yellow) that contains an iron-binding site (not shown).

MBOC7_ptr_ch10_603-636.indd 620 02/12/21 12:35 PM

stable, allowing them to be more easily purified and crystallized than α -helical membrane proteins. This is one reason why β -barrel proteins were among the first multipass proteins whose structures were determined.

Many Membrane Proteins Are Glycosylated

The plasma membrane of a cell is exposed to the often harsh and constantly changing extracellular environment. How are the membrane and its embedded proteins protected from damage? One answer is that many cells have a layer of oligosaccharide and polysaccharide chains that are attached to the lipids and protein domains facing the outside. Most transmembrane proteins in animal cells are glycosylated. As in glycolipids, the sugar residues are added in the lumen of the endoplasmic reticulum and the Golgi apparatus (discussed in Chapters 12 and 13). For this reason, the oligosaccharide chains are always present on the noncytosolic side of the membrane. Another important difference between proteins (or parts of proteins) on the two sides of the membrane results from the reducing environment of the cytosol. This environment decreases the likelihood that intrachain or interchain disulfide (S–S) bonds will form between cysteines on the cytosolic side of membranes. These bonds form on the noncytosolic side, where they can help stabilize either the folded structure of the polypeptide chain or its association with other polypeptide chains (Figure 10–24).

Because the extracellular parts of most plasma membrane proteins are glycosylated, carbohydrates extensively coat the surface of all eukaryotic cells. These carbohydrates occur as oligosaccharide chains covalently bound to membrane proteins (glycoproteins) and lipids (glycolipids). They also occur as the polysaccharide chains of integral membrane *proteoglycan* molecules. Proteoglycans, which consist of long polysaccharide chains linked covalently to a protein core, are found mainly outside the cell, as part of the extracellular matrix (discussed in Chapter 19). But, for some proteoglycans, the protein core either extends across the lipid bilayer or is attached to the bilayer by a glycosylphosphatidylinositol (GPI) anchor.

The terms *cell coat* or *glycocalyx* are sometimes used to describe the carbohydrate-rich zone on the cell surface. This **carbohydrate layer** can be visualized by various stains, such as ruthenium red (**Figure 10–25A**), as well as by its affinity for carbohydrate-binding proteins called **lectins**, which can be labeled with a fluorescent dye or some other visible marker. Although most of the sugar groups are attached to intrinsic plasma membrane molecules, the carbohydrate layer also contains both glycoproteins and proteoglycans that have been secreted into the extracellular space and then adsorbed onto the cell surface (**Figure 10–25B**). Many of these adsorbed macromolecules are components of the extracellular matrix, so that the boundary between the plasma membrane and the extracellular matrix is often not sharply defined. One of the many functions of a slippery carbohydrate layer is to protect cells against mechanical and chemical damage; it also keeps various other cells at a distance, preventing unwanted cell-cell interactions.

The oligosaccharide side chains of glycoproteins and glycolipids are enormously diverse in their arrangement of sugars. Although they usually contain fewer than 15 sugars, the chains are often branched, and the sugars can be bonded together by various kinds of covalent linkages—unlike the amino acids in a polypeptide chain, which are all linked by identical peptide bonds. Even three sugars can be put together to form hundreds of different trisaccharides. How sugars can form such a vast variety of different structures is discussed in Chapter 2. Both the diversity and the exposed position of the oligosaccharides on the cell surface make them especially well suited to function in specific cell-recognition processes. Plasma-membrane-bound lectins that recognize specific oligosaccharides on cell-surface glycolipids and glycoproteins mediate a variety of transient cell-cell adhesion processes, including those occurring in lymphocyte recirculation and inflammatory responses (see Figure 19–28).

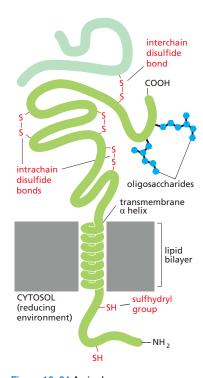

Figure 10-24 A single-pass transmembrane protein. Note that the polypeptide chain traverses the lipid bilayer as a right-handed α helix and that the oligosaccharide chains and disulfide bonds are all on the noncytosolic surface of the membrane. As shown, sulfhydryl groups within a transmembrane protein can form either intrachain disulfide bonds with each other or interchain disulfide bonds with sulfhydryl groups in other proteins. The sulfhydryl groups in the cytosolic domain of the protein do not normally form disulfide bonds because the reducing environment in the cytosol maintains these groups in their reduced (-SH) form.

MBOC7_ptr_ch10_603-636.indd 621 02/12/21 12:35 PM

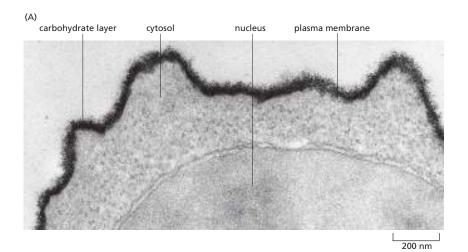

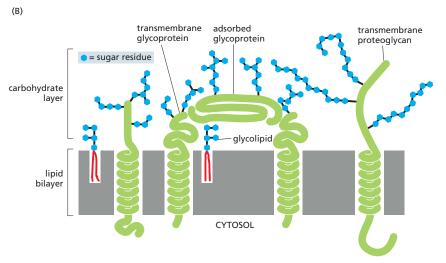

Figure 10-25 The carbohydrate layer on the cell surface. (A) This electron micrograph of the surface of a lymphocyte stained with ruthenium red emphasizes the thick carbohydrate-rich layer surrounding the cell. (B) The carbohydrate layer is made up of the oligosaccharide side chains of membrane glycolipids and membrane glycoproteins and the polysaccharide chains on membrane proteoglycans. In addition, adsorbed glycoproteins, and adsorbed proteoglycans (not shown), contribute to the carbohydrate layer in many cells. Note that all of the carbohydrate is on the extracellular surface of the membrane. (A, courtesy of Audrey M. Gluaert and G.M.W. Cook.)

Membrane Proteins Can Be Solubilized and Purified in Detergents

In general, only agents that disrupt hydrophobic associations and disassemble the lipid bilayer can liberate membrane proteins in a soluble form. The most useful of these for the membrane biochemist are detergents, which are small amphiphilic molecules of variable structure (Movie 10.4). Detergents are much more soluble in water than in lipids. Their polar (hydrophilic) ends can be either charged (ionic), as in sodium dodecyl sulfate (SDS), or uncharged (nonionic), as in β -octylglucoside and Triton X-100 (Figure 10–26A). At low concentration, detergents are monomeric in solution, but when their concentration is increased above a threshold, called the *critical micelle concentration (CMC)*, they aggregate to form micelles (Figure 10-26B, C, and D). Above the CMC, detergent molecules rapidly diffuse in and out of micelles, keeping the concentration of monomer in the solution constant, no matter how many micelles are present. Because of this dynamic behavior, the structure of a micelle changes constantly: at any moment most, but not all, of the hydrophilic ends of the detergent molecules will be external facing the water phase and most, but not all, of the hydrophobic ends will be internal to the micelle. Both the CMC and the average number of detergent molecules in a micelle are characteristic properties of each detergent, but they also depend on the temperature, pH, and salt concentration. Detergent solutions are therefore complex systems and are difficult to study.

MBOC7_ptr_ch10_603-636.indd 622 02/12/21 12:35 PM

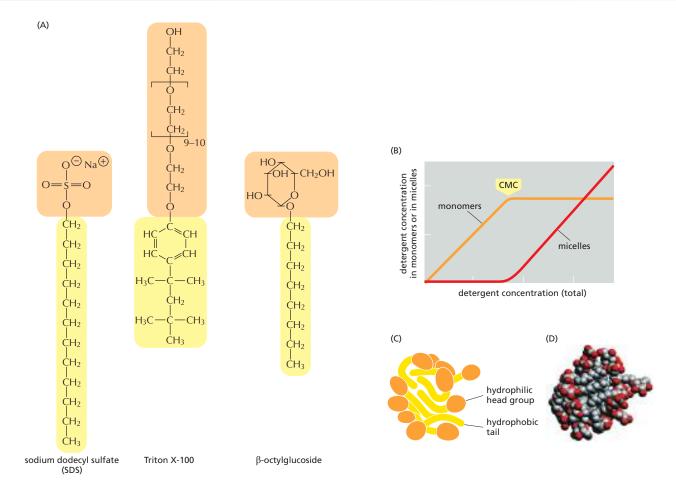

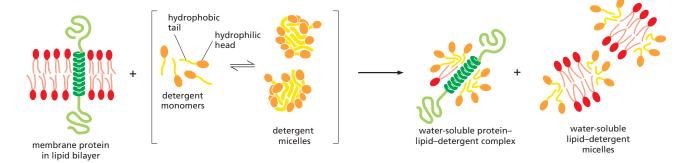

Figure 10–26 The structure and function of detergents. (A) Three commonly used detergents are sodium dodecyl sulfate (SDS), an anionic detergent, and Triton X-100 and β -octylglucoside, two nonionic detergents. Triton X-100 is a mixture of compounds in which the region in brackets is repeated between 9 and 10 times. The hydrophobic portion of each detergent is shown in *yellow*, and the hydrophilic portion is shown in *orange*. (B) At low concentration, detergent molecules are monomeric in solution. As their concentration is increased beyond the critical micelle concentration (CMC), some of the detergent molecules form micelles. Note that the concentration of detergent monomer stays constant above the CMC. (C) Because they have both polar and nonpolar ends, detergent molecules are amphiphilic; and because they are coneshaped, they form micelles rather than bilayers (see Figure 10–7). Detergent micelles are thought to have constantly changing, irregular shapes. Because of packing constraints, the hydrophobic tails are partially exposed to water. (D) The space-filling model shows a snapshot in time of a micelle composed of 20 β-octylglucoside molecules, predicted by *molecular dynamics calculations*. The head groups are shown in *red* and the hydrophobic tails in *gray*. Note that the hydrophobic regions are transiently exposed. (B, adapted with permission from G. Gunnarsson, B. Jönsson, and H. Wennerström, *J. Phys. Chem. A* 84:3114–3121, 1980. Copyright 1980 American Chemical Society; C, from S. Bogusz, R.M. Venable, and R.W. Pastor, *J. Phys. Chem. B* 104:5462–5470, 2000.)

When mixed with membranes, the hydrophobic ends of detergents bind to the hydrophobic regions of the membrane proteins, where they displace lipid molecules with a collar of detergent molecules. Because the other end of the detergent molecule is polar, this binding tends to bring the membrane proteins into solution as detergent-protein complexes (Figure 10–27). Usually, some lipid molecules also remain attached to the protein.

Strong ionic detergents, such as SDS, can solubilize even the most hydrophobic membrane proteins. This allows the proteins to be analyzed by SDS polyacrylamidegel electrophoresis (discussed in Chapter 8). Such strong detergents, however, unfold (denature) proteins by disrupting their internal hydrophobic cores, thereby rendering the proteins inactive and unusable for functional studies. Nonetheless, proteins can be readily separated and purified in their SDS-denatured form. In

MBOC7_ptr_ch10_603-636.indd 623 02/12/21 12:35 PM

some cases, removal of the SDS allows the purified protein to renature, with recovery of functional activity.

Many membrane proteins can be solubilized and then purified in an active form by the use of mild detergents. These detergents cover the hydrophobic regions on membrane-spanning segments that become exposed after lipid removal but do not unfold the protein. Especially when working with multipass membrane proteins, it is often important to maintain a thin layer of lipids upon detergent extraction to retain the protein's activity. If the detergent concentration

Figure 10–27 Solubilizing a membrane protein with a mild nonionic detergent. The detergent disrupts the lipid bilayer and brings the protein into solution as protein-lipid–detergent complexes. The phospholipids in the membrane are also solubilized by the detergent, as lipid–detergent micelles.

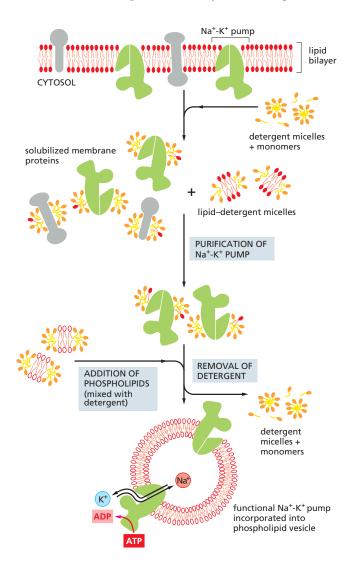

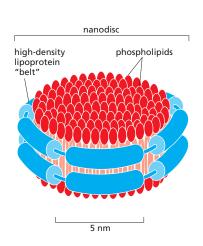

Figure 10–28 The use of mild nonionic detergents for solubilizing, purifying, and reconstituting functional membrane protein systems. In this example, functional Na⁺-K⁺ pump molecules are purified and incorporated into phospholipid vesicles. This pump is present in the plasma membrane of most animal cells, where it uses the energy of ATP hydrolysis to pump Na⁺ out of the cell and K⁺ in, as discussed in Chapter 11. The phospholipids that are newly added in the reconstitution experiments are shown with white polar head groups.

MBOC7_ptr_ch10_603-636.indd 624 02/12/21 12:35 PM

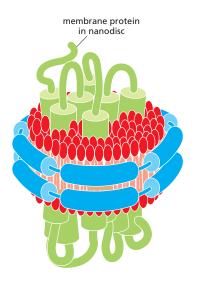

Figure 10–29 Model of a membrane protein reconstituted into a nanodisc. When detergent is removed from a solution containing a multipass membrane protein, lipids, and a protein subunit of the high-density lipoprotein (HDL), the membrane protein becomes embedded in a small patch of lipid bilayer, which is surrounded by a belt of the HDL protein. In such nanodiscs, the hydrophobic edges of the bilayer patch are shielded by the protein belt, which renders the assembly water-soluble.

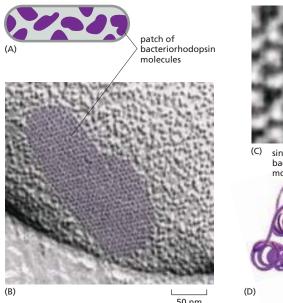

of a solution of solubilized membrane proteins is reduced (by dilution, for example), membrane proteins do not remain soluble. In the presence of an excess of phospholipid molecules in such a solution, however, membrane proteins incorporate into small liposomes that form spontaneously. In this way, functionally active membrane protein systems can be reconstituted from purified components, providing a powerful means of analyzing the activities of membrane transporters, ion channels, signaling receptors, and so on (Figure 10–28). Such functional reconstitution can determine which proteins are both necessary and sufficient for a particular cell function. For example, the approach provided proof for the hypothesis that the enzymes that make ATP (ATP synthases) use H⁺ gradients in mitochondrial, chloroplast, and bacterial membranes to produce ATP.

Membrane proteins can also be reconstituted from detergent solution into nanodiscs, which are small, uniformly sized patches of membrane that are surrounded by a belt of a specially designed protein, which covers the exposed edge of the bilayer to keep the patch in solution (Figure 10-29). The belt protein is derived from high-density lipoproteins (HDLs), whose normal function is to keep lipids soluble for transport in the blood. In nanodiscs the membrane protein of interest can be studied in its native lipid environment and is experimentally accessible from both sides of the bilayer, which is useful, for example, for ligand-binding experiments. Proteins contained in nanodiscs can also be analyzed by single-particle electron microscopy techniques to determine their structure. By this technique (discussed in Chapter 9), the structure of a membrane protein can be determined to high resolution without a requirement of the protein of interest to crystallize into a regular lattice, which is often hard to achieve for membrane proteins. These developments have led to a rapid increase in the number of three-dimensional structures of membrane proteins and protein complexes that are known, although they are still few compared to the known structures of water-soluble proteins and protein complexes.

Bacteriorhodopsin Is a Light-driven Proton (H^+) Pump That Traverses the Lipid Bilayer as Seven α Helices

In Chapter 11, we consider how multipass transmembrane proteins mediate the selective transport of small hydrophilic molecules across cell membranes. But a detailed understanding of how such a membrane transport protein works requires precise information about its three-dimensional structure in the bilayer. *Bacteriorhodopsin* was the first membrane transport protein whose structure was determined, and it emerged as the prototype of many multipass membrane proteins that have a similar structure.

MBOC7_ptr_ch10_603-636.indd 625 02/12/21 12:35 PM

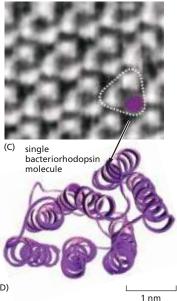

Figure 10-30 Patches of purple membrane, which contain bacteriorhodopsin in the archaeon Halobacterium salinarum. (A) These archaea live in saltwater pools, where they are exposed to sunlight. They have evolved a variety of light-activated proteins, including bacteriorhodopsin, which is a light-activated H+ pump in the plasma membrane. (B) The bacteriorhodopsin molecules in the purple membrane patches are tightly packed into two-dimensional crystalline arrays. (C) Details of the molecular surface visualized by atomic force microscopy. With this technique, individual bacteriorhodopsin molecules can be seen. (D) Outline of the approximate location of the bacteriorhodopsin monomer and the individual α helices in the image shown in C. (B-C, courtesy of Dieter Oesterhelt; D, PDB code: 2BRD.)

The "purple membrane" of the archaeon *Halobacterium salinarum* is a specialized patch in the plasma membrane that contains a single species of protein molecule, **bacteriorhodopsin** (**Figure 10–30A**). The protein functions as a light-activated H⁺ pump that transfers H⁺ out of the archaeal cell. The ability of bacteriorhodopsin molecules to tightly pack with each other into a planar two-dimensional crystal (**Figure 10–30B, C, and D**) facilitated the determination of its three-dimensional structure.

Each bacteriorhodopsin molecule is folded into seven closely packed transmembrane α helices and contains a single light-absorbing group, or chromophore (in this case, retinal), which gives the protein its purple color. Retinal is vitamin A in its aldehyde form and is identical to the chromophore found in rhodopsin of the photoreceptor cells of the vertebrate eye (discussed in Chapter 15). Retinal is covalently linked to a lysine side chain of the bacteriorhodopsin protein. When activated by a single photon of light, the excited chromophore changes its shape and causes a series of small conformational changes in the protein, resulting in the transfer of one H^+ from the inside to the outside of the cell (Figure 10–31A). In bright light, each bacteriorhodopsin molecule can pump several hundred protons per second. The light-driven proton transfer establishes an H^+ gradient across the plasma membrane, which in turn drives the production of ATP by a second protein in the cell's plasma membrane. The energy stored in the

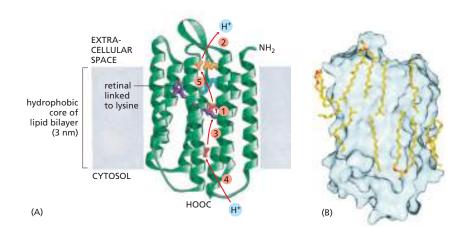

Figure 10-31 The three-dimensional structure of a bacteriorhodopsin molecule. (Movie 10.5) (A) The polypeptide chain crosses the lipid bilayer seven times as α helices. The location of the retinal chromophore (purple) and the probable pathway taken by H+ during the light-activated pumping cycle (red arrows) are shown. The first and key step is the passing of an H⁺ from the chromophore to the side chain of aspartic acid 85 (red, located next to the chromophore) that occurs upon absorption of a photon by the chromophore. Subsequently, other H⁺ transfer steps—in the numerical order indicated and utilizing the hydrophilic amino acid side chains that line a path through the membrane-complete the pumping cycle and return the enzyme to its starting state. (Movie 10.5 explains how the individual transfer steps are linked mechanistically.) Color code: glutamic acid (orange), aspartic acid (red), arginine (blue). (B) The high-resolution crystal structure of bacteriorhodopsin shows many lipid molecules (yellow with red head groups) that are tightly bound to specific places on the surface of the protein. (A, adapted from H. Luecke et al., Science 286:255-261, 1999. B, from H. Luecke et al., J. Mol. Biol. 291:899-911, 1999. With permission from Elsevier.)

MBOC7_ptr_ch10_603-636.indd 626 02/12/21 12:35 PM

 ${
m H}^+$ gradient also drives other energy-requiring processes in the cell. Thus, bacteriorhodopsin converts solar energy into an ${
m H}^+$ gradient, which provides energy to the archaeal cell.

The high-resolution crystal structure of bacteriorhodopsin reveals many lipid molecules bound in specific places on the protein surface (Figure 10-31B). Interactions with specific lipids are thought to help stabilize many membrane proteins, which work best and sometimes crystallize more readily if some of the lipids remain bound during detergent extraction or if specific lipids are added back to the proteins in detergent solutions. The specificity of these lipid-protein interactions helps explain why eukaryotic membranes contain such a variety of lipids, with head groups that differ in size, shape, and charge. This layer of lipids also helps to fill gaps between the jagged hydrophobic surface of the membrane protein and the hydrophobic core of the lipid bilayer and to maintain the permeability barrier of the membrane for ions and other solutes. These lipids are in dynamic association with the protein surface, binding and dissociating at a millisecond time scale. We can think of the membrane lipids as constituting a two-dimensional solvent for the proteins in the membrane, just as water constitutes a three-dimensional solvent for proteins in an aqueous solution: some membrane proteins can function only in the presence of specific lipid head groups, just as many enzymes in aqueous solution require a particular ion for activity.

Bacteriorhodopsin is a member of a large superfamily of membrane proteins with similar structures but different functions. For example, rhodopsin in rod cells of the vertebrate retina and many cell-surface receptor proteins that bind extracellular signal molecules are also built from seven transmembrane α helices. These proteins function as signal transducers rather than as transporters: each responds to an extracellular signal by activating a GTP-binding protein (G protein) inside the cell, and they are therefore called *G-protein-coupled receptors* (*GPCRs*), as we discuss in Chapter 15 (see Figure 15-6B). Although the structures of bacteriorhodopsins and GPCRs are strikingly similar, they show no sequence similarity and thus probably belong to two evolutionarily distant branches of an ancient protein family. A related class of membrane proteins, the channelrhodopsins that green algae use to detect light, form ion channels when they absorb a photon. When engineered so that they are expressed in animal brains, these proteins have become invaluable tools in neurobiology because they allow specific neurons to be stimulated experimentally by shining light on them, as we discuss in Chapter 11 (Figure 11-47).

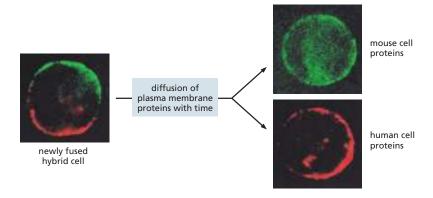

Membrane Proteins Often Function as Large Complexes

Many membrane proteins function as part of multicomponent complexes. One is a bacterial photosynthetic reaction center, which was the first membrane protein complex to be crystallized and analyzed by x-ray diffraction. In Chapter 14, we discuss how such photosynthetic complexes function to capture light energy and use it to pump H⁺ across the membrane. Many of the membrane protein complexes involved in photosynthesis, proton pumping, and electron transport are even larger than the photosynthetic reaction center. The enormous photosystem II complex from cyanobacteria, for example, contains 19 protein subunits and well over 60 transmembrane helices (see Figure 14–49). Membrane proteins are often arranged in large complexes, not only for harvesting various forms of energy but also for transducing extracellular signals into intracellular ones (discussed in Chapter 15).

Many Membrane Proteins Diffuse in the Plane of the Membrane

Like most membrane lipids, membrane proteins do not tumble (flip-flop) across the lipid bilayer. Tumbling would require large hydrophilic domains to pass through the membrane's hydrophobic core, which is energetically prohibitive. But just like membrane lipids, proteins can rotate rapidly about an axis perpendicular to the plane of the bilayer (*rotational diffusion*) and move laterally within the membrane (*lateral diffusion*). An experiment in which mouse cells were

MBOC7_ptr_ch10_603-636.indd 627 02/12/21 12:35 PM

artificially fused with human cells to produce hybrid cells (heterokaryons) provided the first direct evidence that some plasma membrane proteins are mobile in the plane of the membrane. Two differently labeled antibodies were used to distinguish selected mouse and human plasma membrane proteins. Although at first the mouse and human proteins were confined to their own halves of the newly formed heterokaryon, the two sets of proteins diffused and mixed over the entire cell surface in about half an hour (Figure 10–32). Lateral membrane protein mobility is important as it allows many cell signaling proteins to assemble and disassemble into protein complexes in response to extracellular ligands, turning their signaling functions on and off.

The lateral diffusion rates of membrane proteins and lipids can be measured by using the technique of *fluorescence recovery after photobleaching (FRAP)*. The method usually involves marking the membrane protein of interest with a specific fluorescent group. This can be done either with a fluorescent ligand such as a fluorophore-labeled antibody that binds to the protein or with recombinant DNA technology to express the protein fused to a fluorescent protein such as green fluorescent protein (GFP; discussed in Chapter 9). The fluorescent group is then bleached in a small area of membrane by a laser beam, and the time taken for adjacent membrane proteins carrying unbleached ligand or GFP to diffuse into the bleached area is measured (Figure 10–33). From FRAP measurements, we can estimate the diffusion coefficient for the marked cell-surface protein. The values of the diffusion coefficients for different membrane proteins in different cells are highly variable, because interactions with other proteins impede the diffusion of the proteins to varying degrees. Measurements of proteins that are minimally impeded in this way indicate that cell membranes have a viscosity comparable to that of olive oil.

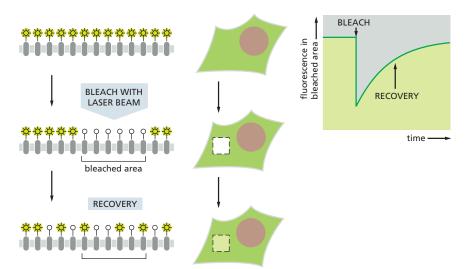

Figure 10-32 An experiment demonstrating the diffusion of proteins in the plasma membrane of mousehuman hybrid cells. In this experiment, a mouse and a human cell were fused to create a hybrid cell, which was then stained with two fluorescently labeled antibodies. One antibody (labeled with a green dye) detects mouse plasma membrane proteins, the other antibody (labeled with a red dye) detects human plasma membrane proteins. When cells are stained immediately after fusion, mouse and human plasma membrane proteins are still found in the membrane domains originating from the mouse and human cell, respectively. After a short time, however, the plasma membrane proteins diffuse over the entire cell surface and completely intermix. (From L.D. Frye and M. Edidin, J. Cell Sci. 7:319-335, 1970. With permission from the Company of Biologists.)

Figure 10-33 Measuring the rate of lateral diffusion of a membrane protein by fluorescence recovery after photobleaching. A specific protein of interest can be expressed as a fusion protein with green fluorescent protein (GFP), which is intrinsically fluorescent. The fluorescent molecules are bleached in a small area using a laser beam. The fluorescence intensity recovers as the bleached molecules diffuse away and unbleached molecules diffuse into the irradiated area (shown here in side and top views). The diffusion coefficient is calculated from a graph of the rate of recovery: the greater the diffusion coefficient of the membrane protein, the faster the recovery (see Figure 9-20 and Movie 10.6).

MBOC7_ptr_ch10_603-636.indd 628 02/12/21 12:35 PM

One drawback to the FRAP technique is that it monitors the movement of large populations of molecules in a relatively large area of membrane; one cannot follow individual protein molecules. If a protein fails to migrate into a bleached area, for example, one cannot tell whether the molecule is truly immobile or just restricted in its movement to a very small region of membrane—perhaps by cytoskeletal proteins. Single-particle tracking techniques overcome this problem by labeling individual membrane molecules with antibodies coupled to fluorescent dyes or tiny gold particles and tracking their movement by video microscopy. Using single-particle tracking, one can record the diffusion path of a single membrane protein molecule over time. Results from all of these techniques indicate that plasma membrane proteins differ widely in their diffusion characteristics, as we now discuss.

Cells Can Confine Proteins and Lipids to Specific Domains Within a Membrane

The recognition that biological membranes are two-dimensional fluids was a major advance in understanding membrane structure and function. It has become clear, however, that the picture of a membrane as a lipid sea in which all proteins float freely is greatly oversimplified. Most cells confine membrane proteins to specific regions in a continuous lipid bilayer. We have already discussed how bacteriorhodopsin molecules in the purple membrane of *Halobacterium* assemble into large two-dimensional crystals, in which individual protein molecules are relatively fixed in relationship to one another (see Figure 10–30). ATP synthase complexes in the inner mitochondrial membrane associate into long double rows, as we discuss in Chapter 14 (see Figure 14–33). Large aggregates of this kind diffuse very slowly.

In epithelial cells, such as those that line the gut or the tubules of the kidney, certain plasma membrane enzymes and transport proteins are confined to the apical surface of the cells, whereas others are confined to the basal and lateral surfaces (Figure 10–34). This asymmetric distribution of membrane proteins is often essential for the function of the epithelium, as we discuss in Chapter 11 (see Figure 11–11). The lipid compositions of these two membrane domains are also different, demonstrating that epithelial cells can prevent the diffusion of lipid as well as protein molecules between the domains. The barriers set up by a specific type of intercellular junction (called a *tight junction*, discussed in Chapter 19; see Figure 19–18) maintain the separation of both protein and lipid molecules.

A cell can also create membrane domains without using intercellular junctions. As we already discussed, regulated protein-protein interactions in membranes can create nanometer-scale raft domains that are thought to function in signaling and membrane trafficking. A more extreme example is seen in the mammalian spermatozoon, a single cell that consists of several structurally and functionally distinct parts covered by a continuous plasma membrane. When a sperm cell is examined

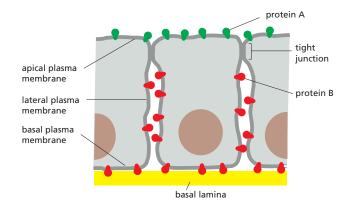

Figure 10-34 How membrane molecules can be restricted to a particular membrane domain. In this drawing of an epithelial cell, protein A (in the apical domain of the plasma membrane) and protein B (in the basal and lateral domains) can diffuse laterally in their own domains but are prevented from entering the other domain, at least partly by the specialized cell-cell junction called a tight junction Lipid molecules in the outer (extracellular) monolayer of the plasma membrane are likewise unable to diffuse between the two domains; lipids in the inner (cytosolic) monolayer, however, are able to do so (not shown). The basal lamina is a thin mat of extracellular matrix that separates epithelial sheets from other tissues (discussed in Chapter 19).

MBOC7_ptr_ch10_603-636.indd 629 02/12/21 12:35 PM

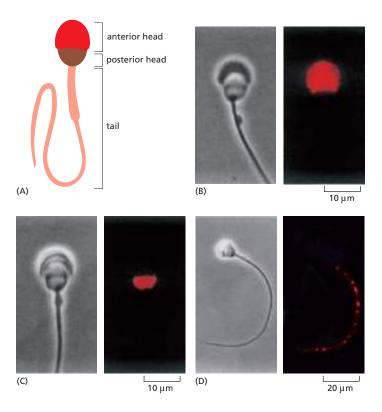

Figure 10–35 Three domains in the plasma membrane of a guinea pig sperm. (A) A drawing of a guinea pig sperm. (B–D) In the three pairs of micrographs, phase-contrast micrographs are on the *left*, and the same cell is shown with cell-surface immunofluorescence staining on the *right*. Different monoclonal antibodies selectively label cell-surface molecules on (B) the anterior head, (C) the posterior head, and (D) the tail. (From D.G. Myles, P. Primakoff, and A.R. Belvé, *Cell* 23:433–439, 1981. With permission from Elsevier.)

by immunofluorescence microscopy with a variety of antibodies, each of which reacts with a specific cell-surface molecule, the plasma membrane is found to consist of at least three distinct domains (Figure 10–35). Some of the membrane molecules can diffuse freely within the confines of their own domain. While the molecular nature of most "fences" that prevent the molecules from leaving their domain is not known, some molecular mechanisms for restricting membrane protein movements are understood. The plasma membrane of nerve cells, for example, contains a domain enclosing the cell body and dendrites, and another enclosing the axon; in this case a belt of actin filaments tightly associates with the plasma membrane at the cell-body–axon junction and forms part of the barrier.

Figure 10–36 shows four common ways of immobilizing specific membrane proteins through protein-protein interactions.

The Cortical Cytoskeleton Gives Membranes Mechanical Strength and Restricts Membrane Protein Diffusion

As shown in Figure 10–36B and C, a common way in which a cell restricts the lateral mobility of specific membrane proteins is to tether them to macromolecular assemblies on either side of the membrane. The characteristic biconcave shape of a red blood cell (Figure 10–37), for example, results from interactions of its plasma membrane proteins with an underlying *cytoskeleton*, which consists mainly of a meshwork of the filamentous protein **spectrin**. Spectrin is a long, thin, flexible rod about 100 nm in length. As the principal component of the red blood cell cytoskeleton, it maintains the structural integrity and shape of the plasma membrane, which is the cell's only membrane, as the cell has no nucleus or other organelles. The spectrin cytoskeleton is attached to the membrane through various membrane proteins. The final result is a deformable, netlike meshwork that covers the entire cytosolic surface of the cell membrane (Figure 10–38). This spectrin-based cytoskeleton enables the red blood cell to withstand the stress on its membrane as it is forced through narrow capillaries. Mice and humans with genetic abnormalities in spectrin are anemic and have red blood cells that are

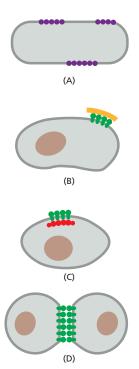

Figure 10–36 Four ways of restricting the lateral mobility of specific plasma membrane proteins. (A) The proteins can self-assemble into large aggregates (as seen for bacteriorhodopsin in the purple membrane of *Halobacterium salinarum*); they can be tethered by interactions with assemblies of macromolecules (B) outside or (C) inside the cell; or (D) they can interact with proteins on the surface of another cell.

MBOC7_ptr_ch10_603-636.indd 630 02/12/21 12:35 PM

Figure 10–37 A scanning electron micrograph of human red blood cells. The cells have a biconcave shape and lack a nucleus and other organelles (Movie 10.7). (Courtesy of Bernadette Chailley.)

spherical (instead of concave) and fragile; the severity of the anemia increases with the degree of spectrin deficiency.

An analogous but much more elaborate and highly dynamic cytoskeletal network exists beneath the plasma membrane of most other cells in our body. This network, which constitutes the **cortex** of the cell, is rich in actin filaments, which are attached to the plasma membrane in numerous ways. The dynamic

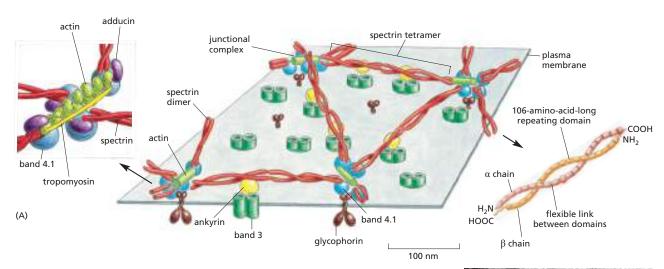

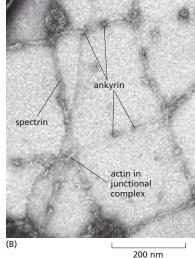

Figure 10–38 The spectrin-based cytoskeleton on the cytosolic side of the human red blood cell plasma membrane. (A) The arrangement shown in the drawing has been deduced mainly from studies on the interactions of purified proteins in vitro. Spectrin heterodimers (enlarged in the drawing on the right) are linked together into a netlike meshwork by junctional complexes (enlarged in the drawing on the left). Each spectrin heterodimer consists of two antiparallel, loosely intertwined, flexible polypeptide chains called α and β . The two spectrin chains are attached noncovalently to each other at multiple points, including at both ends. Both the α and β chains are composed largely of repeating domains. Two spectrin heterodimers join end-to-end to form tetramers.

The junctional complexes are composed of short actin filaments (containing 13 actin monomers) and the proteins *band 4.1* and *adducin*, as well as a *tropomyosin* molecule that probably determines the length of the actin filaments. The cytoskeleton is linked to the membrane through two transmembrane proteins: a multipass protein called band 3 and a single-pass protein called glycophorin. The spectrin tetramers bind to some band 3 proteins via *ankyrin* molecules, and to glycophorin and band 3 (not shown) via band 4.1 proteins.

(B) The electron micrograph shows the cytoskeleton on the cytosolic side of a red blood cell membrane after fixation and negative staining. The spectrin meshwork has been purposely stretched out to allow the details of its structure to be seen. In a normal cell, the meshwork shown would be much more crowded and occupy only about one-tenth of this area. (B, courtesy of T. Byers and D. Branton, *Proc. Natl. Acad. Sci. USA* 82:6153–6157, 1985.)

MBOC7_ptr_ch10_603-636.indd 631 02/12/21 12:35 PM

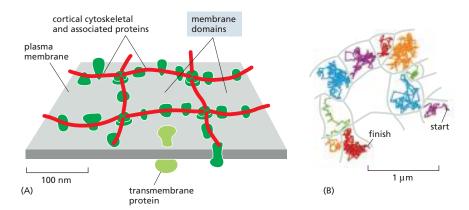

Figure 10-39 Corralling plasma membrane proteins by cortical cytoskeletal filaments. (A) The filaments are thought to provide diffusion barriers that divide the membrane into small domains, or corrals. (B) High-speed, single-particle tracking was used to follow the path of a single fluorescently labeled membrane protein of one type over time. The trace shows that an individual protein molecule diffuses within tightly delimited membrane domains and only infrequently escapes into a neighboring domain (highlighted by a switch of color). (Adapted from A. Kusumi et al., Annu. Rev. Biophys. Biomol. Struct. 34:351-378, 2005. With permission from Annual Reviews.)

remodeling of the cortical actin network provides a driving force for many essential cell functions, including cell movement, endocytosis, and the formation of transient, mobile plasma membrane structures such as filopodia and lamellipodia discussed in Chapter 16. The cortex of nucleated cells also contains proteins that are structurally homologous to spectrin and the other components of the red cell cytoskeleton. We discuss the cortical cytoskeleton in nucleated cells and its interactions with the plasma membrane in Chapter 16.

The cortical cytoskeletal network restricts diffusion of plasma membrane proteins beyond those that are directly anchored to it. Because the cytoskeletal filaments are often closely apposed to the cytosolic surface of the plasma membrane, they can form mechanical barriers that obstruct the free diffusion of proteins in the membrane. These barriers partition the membrane into small domains, or *corrals* (Figure 10–39A), which can be either permanent, as in the sperm (see Figure 10–35), or transient. The barriers can be detected when the diffusion of individual membrane proteins is followed by high-speed, single-particle tracking. The proteins diffuse rapidly but are confined within an individual corral (Figure 10–39B); occasionally, however, thermal motions cause a few cortical filaments to detach transiently from the membrane, allowing the protein to escape into an adjacent corral.

The extent to which a transmembrane protein is confined within a corral depends on its association with other proteins and the size of its cytoplasmic domain; proteins with a large cytosolic domain will have a harder time passing through cytoskeletal barriers. When a cell-surface receptor binds its extracellular signal molecules, for example, large protein complexes build up on the cytosolic domain of the receptor, making it more difficult for the receptor to escape from its corral. It is thought that corralling helps concentrate such signaling complexes, increasing the speed and efficiency of the signaling process (discussed in Chapter 15).

Membrane-bending Proteins Deform Bilayers

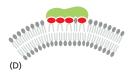

Cell membranes assume many different shapes, as illustrated by the elaborate and varied structures of cell-surface protrusions and membrane-enclosed organelles in eukaryotic cells. Flat sheets, narrow tubules, round vesicles, fenestrated sheets, and pita-bread-shaped cisternae are all part of the repertoire. Often, a variety of shapes will be present in different regions of the same continuous bilayer. Membrane shape is controlled dynamically, as many essential cell processes—including vesicle budding, cell movement, and cell division—require elaborate transient membrane deformations. In many cases, membrane shape is influenced by dynamic pushing and pulling forces exerted by cytoskeletal or extracellular structures, as we discuss in Chapters 13 and 16. A crucial part in producing these deformations is played by membrane-bending proteins, which control local membrane curvature. Often, cytoskeletal dynamics and membrane-bending-protein forces work together. Membrane-bending proteins attach to

MBOC7_ptr_ch10_603-636.indd 632 02/12/21 12:35 PM

specific membrane regions as needed and act by one or more of three principal mechanisms (Figure 10–40):

- 1. Some insert hydrophobic protein domains or attached lipid anchors into one of the leaflets of a lipid bilayer. Increasing the area of only one leaflet causes the membrane to bend (Figure 10–40B). The proteins that shape the convoluted network of narrow endoplasmic reticulum tubules work in this way (discussed in Chapter 12).
- 2. Some membrane-bending proteins form rigid scaffolds that deform the membrane or stabilize an already bent membrane (Figure 10–40C). The coat proteins that shape the budding vesicles in intracellular transport fall into this class (discussed in Chapter 13).
- 3. Asymmetric distribution of cone-shaped and inverted cone-shaped lipids in the inner or outer leaflets can cause membrane bending. Some membrane-bending proteins cause particular membrane lipids to cluster together, thereby inducing membrane curvature. The ability of a lipid to induce positive or negative membrane curvature is determined by the relative cross-sectional areas of its head group and its hydrocarbon tails. For example, the large head group of phosphoinositides make these lipid molecules wedge-shaped, and their accumulation in a domain of one leaflet of a bilayer therefore induces positive curvature (Figure 10–40D). By contrast, phospholipases that remove lipid head groups produce inversely shaped lipid molecules that induce negative curvature.

Often, different membrane-bending proteins collaborate to achieve a particular curvature, as in shaping a budding transport vesicle, as we discuss in Chapter 13.

Summary

Whereas the lipid bilayer determines the basic structure of biological membranes, proteins are responsible for most membrane functions, serving as specific receptors, enzymes, transporters, and so on. Transmembrane proteins extend across the lipid bilayer. Some of these membrane proteins are single-pass proteins, in which the polypeptide chain crosses the bilayer as a single α helix. Others are multipass proteins, in which the polypeptide chain crosses the bilayer multiple times—either as a series of α helices or as a β sheet rolled up into the shape of a barrel. All proteins responsible for the transport of ions and other small water-soluble molecules through the membrane are multipass proteins. Some membrane proteins do not span the bilayer but instead are attached to either side of the membrane: some are attached to the cytosolic side by an amphipathic α helix on the protein surface or by the covalent attachment of one or more lipid chains, others are attached to the noncytosolic side by a GPI anchor. Some membrane-associated proteins are bound by noncovalent interactions with transmembrane proteins. In the plasma membrane of all eukaryotic cells, most of the proteins exposed on the cell surface and some of the lipid molecules in the outer lipid monolayer have oligosaccharide chains covalently attached to them. Like the lipid molecules in the bilayer, many membrane proteins are able to diffuse rapidly in the plane of the membrane. However, cells have ways of immobilizing specific membrane proteins, as well as ways of confining both membrane protein and lipid molecules to particular domains in a continuous lipid bilayer. The dynamic association of membrane-bending proteins confers on membranes their characteristic three-dimensional shapes.

Figure 10-40 Three ways in which membrane-bending proteins shape membranes. Lipid bilayers are gray and proteins are green. (A) Bilayer without protein bound. (B) A hydrophobic region of the protein can insert as a wedge into one monolayer to pry lipid head groups apart. Such regions can either be amphiphilic helices as shown or hydrophobic hairpins. (C) The curved surface of the protein can bind to lipid head groups and deform the membrane or stabilize its curvature. (D) A protein can bind to and cluster lipids that have large head groups and thereby bend the membrane. (Adapted from W.A. Prinz and J.E. Hinshaw, Crit. Rev. Biochem. Mol. Biol. 44:278-291, 2009.)

MBOC7_ptr_ch10_603-636.indd 633 02/12/21 12:35 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **10–1** It is estimated that about 30% of the proteins encoded in an animal's genome are membrane proteins that are required for a cell to function and interact with its environment.
- **10–2** All of the common phospholipids—phosphatidylcholine, phosphatidylethanolamine, phosphatidylserine, and sphingomyelin—carry a positively charged moiety on their head group, but none carry a net positive charge.
- **10–3** Although phospholipid molecules are free to diffuse in the plane of the bilayer, they cannot flip-flop across the bilayer unless enzyme catalysts called phospholipid translocators are present in the membrane.
- **10–4** Whereas all the carbohydrate in the plasma membrane faces outward on the external surface of the cell, all the carbohydrate on internal membranes faces toward the cytosol.
- **10–5** Although membrane domains with different protein compositions are well known, there are at present no examples of membrane domains that differ in lipid composition.

Discuss the following problems.

10–6 When a lipid bilayer is torn, why does it not seal itself by forming a "hemi-micelle" cap at the edges, as shown in **Figure Q10–1?**

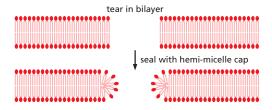

Figure Q10–1 A torn lipid bilayer sealed with a hypothetical "hemimicelle" cap (Problem 10–6).

- **10–7** Which one of the following changes is energetically favorable and occurs spontaneously in an aqueous solution?
- A. Conversion of a membrane vesicle to a flat bilayer
- B. Dispersion of one oil droplet into many small ones
- C. Formation of a bilayer from phospholipid molecules
- D. Formation of a long tear in a phospholipid bilayer
- 10–8 Hydrophobic solutes are said to "force the adjacent water molecules to reorganize into icelike cages" (Figure Q10–2). It seems paradoxical that water molecules do not interact with hydrophobic solutes, yet they seem to "know" about the presence of a hydrophobic solute and change their behavior to interact differently with one

another. Why would such an icelike cage be energetically unfavorable relative to pure water?

- A. An icelike cage gives water a higher temperature.
- B. An icelike cage is less organized than pure water.
- C. An icelike cage is unstable and easily breaks down.
- D. An icelike cage reduces the entropy of the system.

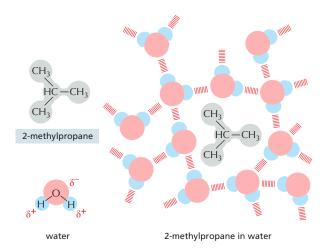

Figure Q10–2 An icelike cage of water molecules around a hydrophobic solute (Problem 10–8).

- **10–9** Margarine is made from vegetable oil by a chemical process. Do you suppose this process converts saturated fatty acids to unsaturated ones or vice versa? Explain your answer.
- **10–10** If a lipid raft is typically 70 nm in diameter and each lipid molecule has a diameter of 0.5 nm, about how many lipid molecules would there be in a lipid raft composed entirely of lipid?
- **10-11** Each of the following lipid anchors is used to attach intracellular proteins to membranes *except*:
- A. A farnesyl anchor
- B. A GPI anchor
- C. A myristoyl anchor
- D. A palmitoyl anchor
- 10–12 Monomeric single-pass transmembrane proteins span a membrane with a single α helix that has characteristic chemical properties in the region of the bilayer. Which of the three 19-amino-acid sequences listed below is the most likely candidate for such a transmembrane segment? Explain the reasons for your choice. (See back of book for one-letter amino acid code; FAMILY VW is a convenient mnemonic for hydrophobic amino acids.)
- A. ITEIYFGRMAGVIGTDLIS
- B. ITLIYFGVMAGVIGTILIS
- C. ITPIYFGPMAGVIGTPLIS

REFERENCES 635

10–13 You are studying the binding of proteins to the cytoplasmic face of cultured neuroblastoma cells and have found a method that gives a good yield of inside-out vesicles from the plasma membrane. Unfortunately, your preparations are contaminated with variable amounts of right-side-out vesicles. Nothing you have tried avoids this problem. A friend suggests that you pass your vesicles over an affinity column made of lectin coupled to solid beads. What is the point of your friend's suggestion?

10–14 Glycophorin, a protein in the plasma membrane of red blood cells, normally exists as a homodimer that is held together entirely by interactions between its transmembrane domains. As transmembrane domains are hydrophobic, how is it that they can associate with one another so specifically?

10–15 Three mechanisms by which membrane-binding proteins bend a membrane are illustrated in Figure Q10–3A, B, and C. As shown, each of these cytosolic membrane-bending proteins would induce an invagination of the plasma membrane. Could similar kinds of cytosolic proteins induce a protrusion of the plasma membrane (Figure Q10–3D)? Which ones? Explain how they might work.

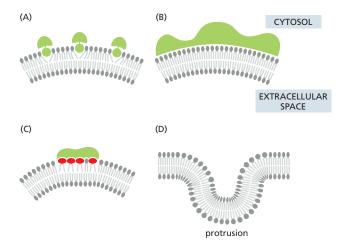

Figure Q10–3 Bending of the plasma membrane by cytosolic proteins (Problem 10–15). (A) Insertion of a protein "finger" into the cytosolic leaflet of the membrane. (B) Binding of lipids to the curved surface of a membrane-binding protein. (C) Binding of membrane proteins to membrane lipids with large head groups. (D) A segment of the plasma membrane showing a protrusion.

Small-Molecule Transport and Electrical Properties of Membranes

CHAPTER

11

Because of its hydrophobic interior, the lipid bilayer of cell membranes restricts the passage of most polar molecules. This barrier function allows the cell to maintain concentrations of solutes in its cytosol that differ from those in the extracellular fluid and in each of the intracellular membrane-enclosed compartments. To benefit from this barrier, however, cells have had to evolve ways of transferring specific water-soluble molecules and ions across their membranes in order to ingest essential nutrients, excrete metabolic waste products, and regulate intracellular ion concentrations. Cells use specialized *membrane transport proteins* to accomplish this goal. The importance of such small-molecule transport is reflected in the large number of genes in all organisms that code for the transmembrane transport proteins involved, which make up 15–30% of the membrane proteins in all cells. Some mammalian cells, such as nerve and kidney cells, devote up to two-thirds of their total metabolic energy consumption to such transport processes.

Cells can also transfer macromolecules and even large particles, such as cell debris, viruses, and bacteria, across their membranes, but the mechanisms involved in most of these cases differ from those used for transferring small molecules, and they are discussed in Chapters 12 and 13.

We begin this chapter by describing some general principles of how small water-soluble molecules traverse cell membranes. We then consider, in turn, the two main classes of membrane proteins that mediate this transmembrane traffic: transporters, which undergo sequential conformational changes to transport specific small molecules across membranes, and channels, which form narrow pores, allowing passive transmembrane movement, primarily of water and small inorganic ions. Transporters can be coupled to a source of energy to catalyze active transport, which, together with selective passive permeability, creates large differences in the composition of the cytosol compared with that of either the extracellular fluid (Table 11-1) or the fluid within membrane-enclosed organelles. By generating inorganic ion-concentration differences across the lipid bilayer, cell membranes can store potential energy in the form of electrochemical gradients, which drive various transport processes, convey electrical signals in electrically excitable cells, and (in mitochondria, chloroplasts, and bacteria) are harnessed to make most of the cell's ATP. We focus our discussion mainly on transport across the plasma membrane, but similar mechanisms operate across the other membranes of the eukaryotic cell, as discussed in later chapters.

In the last part of the chapter, we concentrate mainly on the functions of ion channels in neurons (nerve cells). In these cells, channel proteins perform at their highest level of sophistication, enabling networks of neurons to carry out all the astonishing feats your brain is capable of.

PRINCIPLES OF MEMBRANE TRANSPORT

We begin this section by describing the permeability properties of an artificial membrane—a synthetic lipid bilayer made solely from lipids without proteins present. We then introduce some of the terms used to describe the various forms of membrane transport and some strategies for characterizing the proteins and processes involved.

IN THIS CHAPTER

Principles of Membrane Transport

Transporters and Active Membrane Transport

Channels and the Electrical Properties of Membranes

MBOC7_ptr_ch11_637-682.indd 637 08/12/21 11:47 AM

TABLE 11–1 A Comparison of Inorganic Ion Concentrations Inside and Outside a Typical Mammalian Cell*					
Component	Cytoplasmic concentration (mM)	Extracellular concentration (mM)			
Cations					
Na ⁺	5–15	145			
K ⁺	140	5			
Mg ²⁺	0.5	1–2			
Ca ²⁺	10 ⁻⁴	1–2			
H ⁺	7×10^{-5} (10 ^{-7.2} M or pH 7.2)	4×10^{-5} (10 ^{-7.4} M or pH 7.4)			
Anions					
CI-	5–15	110			

*The cell must contain equal quantities of positive and negative charges (that is, it must be electrically neutral). Thus, in addition to Cl $^-$, the cell contains many other anions not listed in this table; in fact, most cell constituents are negatively charged (HCO $_3$ $^-$, PO $_4$ 3 $^-$, nucleic acids, metabolites carrying phosphate and carboxyl groups, etc.). The concentrations of Ca 2 + and Mg 2 + given are for the free ions: although there is a total of about 20 mM Mg 2 + and 1–2 mM Ca 2 + in cells, both ions are mostly bound to other substances (such as proteins, free nucleotides, RNA, etc.) and, for Ca 2 +, stored within various organelles (such as the endoplasmic reticulum and mitochondria).

Protein-free Lipid Bilayers Are Impermeable to Ions

Given enough time, virtually any molecule will diffuse down its concentration gradient across a protein-free lipid bilayer. The rate of diffusion, however, varies enormously, depending partly on the size of the molecule but mostly on its relative hydrophobicity (solubility in oil). In general, the smaller the molecule and the more hydrophobic, or nonpolar, it is, the more easily it will diffuse across a lipid bilayer. Small nonpolar molecules, such as O₂ and CO₂, readily dissolve in lipid bilayers and therefore diffuse rapidly across them. Small uncharged polar molecules, such as water or urea, also diffuse across a bilayer, albeit much more slowly (Figure 11–1 and see Movie 10.3). By contrast, lipid bilayers are essentially impermeable to charged molecules (ions), no matter how small: the charge and high degree of hydration of such molecules prevent them from entering the hydrocarbon phase of the bilayer (Figure 11–2).

There Are Two Main Classes of Membrane Transport Proteins: Transporters and Channels

Like synthetic lipid bilayers, cell membranes allow small nonpolar molecules to permeate by diffusion. Cell membranes, however, also have to allow the passage of various polar molecules, such as ions, sugars, amino acids, nucleotides, water, and many cell metabolites that cross synthetic lipid bilayers only very slowly. Special membrane transport proteins transfer such solutes across cell membranes. These proteins occur in many forms and in all types of biological membranes. Each protein often transports only a specific molecular species or sometimes a class of molecules (such as ions, sugars, or amino acids). Early studies found that bacteria with a single-gene mutation were unable to transport a particular class of sugars across their plasma membrane, thereby demonstrating the specificity of membrane transport proteins. We now know that humans with similar mutations suffer from various inherited diseases that hinder the transport of a specific solute or solute class in the kidney, intestine, or other cell type. Individuals with the inherited disease *cystinuria*, for example, cannot transport certain amino acids

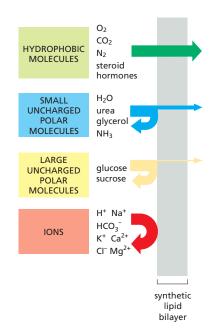

Figure 11–1 The relative permeability of a synthetic lipid bilayer to different classes of molecules. The smaller the molecule and, more important, the less strongly it associates with water, the more rapidly the molecule diffuses across the bilayer.

MBOC7_ptr_ch11_637-682.indd 638 08/12/21 11:47 AM

Figure 11–2 Permeability coefficients for the passage of various molecules through synthetic, protein-free lipid bilayers. The rate of flow of a solute across the bilayer is directly proportional to the difference in its concentration on the two sides of the membrane. Multiplying this concentration difference (in mol/cm³) by the permeability coefficient (in cm/sec), which is an experimentally determined constant characteristic of each solute, gives the flow of solute in moles per second per square centimeter of bilayer. A concentration difference of tryptophan of 10^{-4} mol/cm³ $(10^{-4}$ mol/ 10^{-3} L = 0.1 M), for example, would cause a flow of 10^{-4} mol/cm³ 10^{-7} cm/ sec = 10^{-11} mol/sec through 1 cm² of bilayer, or 10^{-4} molecules/sec through 10^{-4} mol/ $10^{$

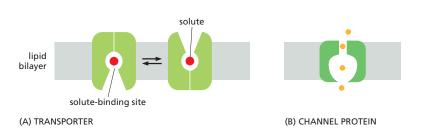

(including cystine, the disulfide-linked dimer of cysteine) from either the urine or the intestine into the blood; the resulting accumulation of cystine in the urine leads to the formation of cystine stones in the kidneys.

All membrane transport proteins that have been studied in detail are multipass transmembrane proteins; that is, their polypeptide chains traverse the lipid bilayer two or more times. By forming a protein-lined pathway across the membrane, these proteins enable specific hydrophilic solutes to cross the membrane without coming into direct contact with the hydrophobic interior of the lipid bilayer.

Transporters and channels are the two major classes of membrane transport proteins (Figure 11-3). Transporters (sometimes called *carriers* or *permeases*) bind the specific solute to be transported and undergo a series of conformational changes that alternately expose solute-binding sites on one side of the membrane and then on the other side to transfer the solute across it. Channels, by contrast, interact much more transiently with the solute to be transported. When opened by conformational changes, channels form continuous pores that extend across the lipid bilayer. The pores allow specific solutes (such as inorganic ions of appropriate size and charge, and in some cases small molecules, including water, glycerol, and ammonia) to pass through them and thereby cross the membrane. Because no stepwise conformational changes are required once a channel is opened, it is not surprising that transport through channels occurs at a much faster rate than transport mediated by transporters. Although water can slowly diffuse across synthetic lipid bilayers, cells use dedicated channel proteins (called water channels, or aquaporins) that greatly increase the permeability of their membranes to water, as we discuss later.

Active Transport Is Mediated by Transporters Coupled to an Energy Source

All channels and some transporters allow solutes to cross the membrane only passively ("downhill"), a process called **passive transport**. In the case of transport of a single uncharged molecule, the difference in the concentration on the two sides of the membrane—its *concentration gradient*—drives passive transport and determines its direction (**Figure 11–4A**). If the solute carries a net charge, however, both its concentration gradient and the electrical potential difference across the membrane, the *membrane potential*, influence its transport. The concentration gradient and the electrical gradient combine to form a net driving force, the **electrochemical gradient**, for each charged solute (**Figure 11–4B**). We discuss electrochemical gradients in more detail later and in Chapter 14. In fact, almost all plasma membranes have an electrical potential difference (that is, a voltage) across them, with the inside usually negative with respect to the outside. This

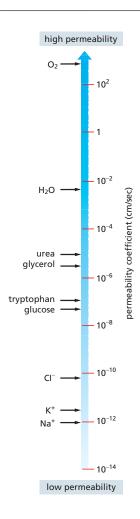

Figure 11–3 Transporters and channel proteins. (A) A transporter alternates between two conformations, so that the solute-binding site of the transporter is sequentially accessible on one side of the bilayer and then on the other. (B) In contrast, a channel protein forms a pore across the bilayer through which specific solutes can passively diffuse.

MBOC7_ptr_ch11_637-682.indd 639 08/12/21 11:47 AM

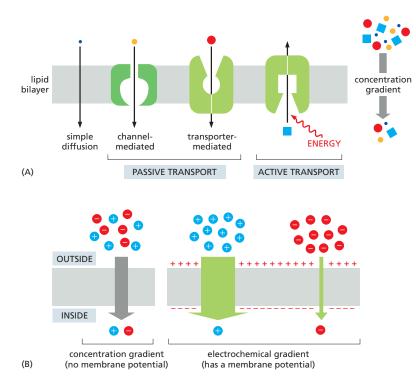

Figure 11-4 Different forms of membrane transport and the influence of the membrane. (A) Passive transport down a concentration gradient (or an electrochemical gradient—see panel B) occurs spontaneously, by diffusion, either through the lipid bilayer directly or through channels or passive transporters. By contrast, active transport involves movement of the solute against its concentration or electrochemical gradient and hence requires an input of metabolic energy. (B) The electrochemical gradient of a charged solute (an ion) affects its transport. This gradient (green) combines the membrane potential and the concentration gradient of the solute. The electrical and chemical gradients can work additively to increase the driving force on an ion across the membrane (middle) or they can work against each other (right).

potential favors the entry of positively charged ions into the cell but opposes the entry of negatively charged ions (see Figure 11–4B); it also opposes the efflux of positively charged ions.

In addition to passive transport, cells need to be able to actively pump certain solutes across the membrane "uphill," against their electrochemical gradients. Such active transport is mediated by transporters whose pumping activity is directional because it is tightly coupled to a source of metabolic energy, such as an ion gradient or ATP hydrolysis, as discussed later. Transmembrane movement of small molecules mediated by transporters can be either active or passive, whereas that mediated by channels is always passive (see Figure 11–4A).

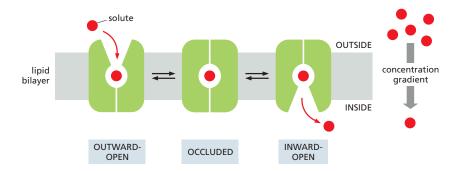

Summary

Lipid bilayers are virtually impermeable to most polar molecules. To transport small water-soluble molecules into or out of cells or intracellular membrane-enclosed compartments, cell membranes contain various membrane transport proteins, each of which is responsible for transferring a particular solute or class of solutes across the membrane. There are two types of membrane transport proteins—transporters and channels. Both form protein pathways across the lipid bilayer. Whereas transmembrane movement mediated by transporters can be either active or passive, solute flow through channel proteins is always passive. Ion transport across the membrane is influenced by the ion's concentration gradient and the membrane potential; that is, its electrochemical gradient.

TRANSPORTERS AND ACTIVE MEMBRANE TRANSPORT

The process by which a transporter transfers a solute molecule across the lipid bilayer resembles an enzyme-substrate reaction, and in many ways transporters behave like enzymes. In contrast to ordinary enzyme-substrate reactions, however, the transporter does not modify the transported solute but instead delivers it unchanged to the other side of the membrane.

MBOC7_ptr_ch11_637-682.indd 640 08/12/21 11:47 AM

Each type of transporter has one or more specific binding sites for its solute (substrate). It transfers the solute across the lipid bilayer by undergoing reversible conformational changes that alternately expose the solute-binding site first on one side of the membrane and then on the other side—but never on both sides at the same time. The transition occurs through an intermediate state in which the solute is inaccessible, or occluded, from either side of the membrane (Figure 11-5). When the transporter is saturated (that is, when all solute-binding sites are occupied), the rate of transport is maximal. This rate, referred to as $V_{\rm max}$ (V for velocity), is characteristic of the specific carrier. V_{max} is the maximal rate at which the carrier can flip between its conformational states. In addition, each transporter has a characteristic affinity for its solute, reflected in the $K_{\rm m}$ of the reaction, which is equal to the concentration of solute when the transport rate is half its maximum value (Figure 11-6). As with enzymes, the binding of solute can be blocked by either competitive inhibitors (which compete for the same binding site and may or may not be transported) or noncompetitive inhibitors (which bind elsewhere and alter the structure of the transporter).

As we discuss shortly, conceptually it requires only a relatively minor modification of the mechanism shown in Figure 11–5 to link a transporter to a source of energy in order to pump a solute uphill against its electrochemical gradient. Cells carry out such active transport in three main ways (Figure 11–7):

- 1. *Coupled transporters* harness the energy stored in concentration gradients to couple the uphill transport of one solute across the membrane to the downhill transport of another.
- 2. ATP-driven pumps couple uphill transport to the hydrolysis of ATP.
- 3. *Light- or redox-driven pumps*, which are known in bacteria, archaea, mitochondria, and chloroplasts, couple uphill transport to an input of energy from light, as with bacteriorhodopsin and photosystem II (discussed in Chapters 10 and 14, respectively), or from a redox reaction, as with cytochrome *c* oxidase (discussed in Chapter 14).

Comparisons of amino acid sequences and three-dimensional structures suggest that, in many cases, there are strong similarities in structure between transporters that mediate active transport and those that mediate passive transport. Some bacterial transporters, for example, that use the energy stored in the ${\rm H}^+$ gradient across the plasma membrane to drive the active uptake of various sugars are structurally similar to the transporters that mediate passive glucose transport into most animal cells. There is thus a clear evolutionary relationship between various transporters. Given the cell's essential need to transport small metabolites across membranes, it comes as no surprise that the superfamily of transporters is a large and ancient one.

We begin our discussion of active membrane transport by considering a class of coupled transporters that are driven by ion-concentration gradients. These proteins have a crucial role in the transport of small metabolites across membranes in all cells. We then discuss ATP-driven pumps, including the Na $^+$ -K $^+$ pump that is found in the plasma membrane of most animal cells. Examples of the third class of active transport—light- or redox-driven pumps—are discussed in Chapter 14.

Figure 11-5 A model of how a conformational change in a transporter mediates the passive movement of a solute. The transporter is shown in three conformational states: in the outwardopen state, the binding sites for solute are exposed on the outside; in the occluded state, the same sites are not accessible from either side; and in the inward-open state, the sites are exposed on the inside. The transitions between the states occur randomly. They are completely reversible and do not depend on whether the solutebinding site is occupied. Therefore, if the solute concentration is higher on the outside of the bilaver, more solute binds to the transporter in the outward-open conformation than in the inward-open conformation, and there is a net transport of solute down its concentration gradient (or, if the solute is an ion, down its electrochemical gradient).

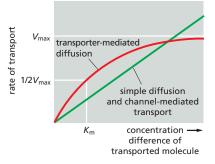

Figure 11-6 The kinetics of simple diffusion compared with transportermediated diffusion. Whereas the rate of simple diffusion and of channel-mediated transport is directly proportional to the solute concentration (within the physical limits imposed by total surface area or total channels available), the rate of transportermediated diffusion approaches a maximum $(V_{\rm max})$ as the transporter reaches saturation. The solute concentration when the transport rate is at half its maximal value is termed its K_m and is analogous to the K_m of an enzyme for its substrate. Note that, while the graph illustrates the shape of the curves, their absolute scale on the Y axis is very different. A typical channel conducts water or ions at rates of up to 108 per second, whereas a typical transporter moves solutes at rates between 10² and 10⁴ molecules per second.

MBOC7_ptr_ch11_637-682.indd 641 08/12/21 11:47 AM

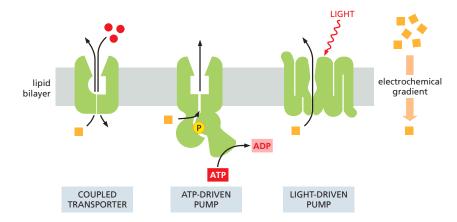

Figure 11–7 Three ways of driving active transport. The actively transported molecule is shown in *orange*, and the energy source is shown in *red*. Redoxdriven active transport is discussed in Chapter 14 (see Figures 14–18 and 14–19).

Active Transport Can Be Driven by Ion-Concentration Gradients

Some transporters simply facilitate the passive movement of a single solute from one side of the membrane to the other at a rate determined by their $V_{\rm max}$ and $K_{\rm m}$; they are called **uniporters**. Others function as *coupled transporters*, in which the transfer of one solute strictly depends on the transport of a second. Coupled transport involves either the intimately coupled transfer of a second solute in the same direction, performed by **symporters** (also called *co-transporters*), or the transfer of a second solute in the opposite direction, performed by **antiporters** (also called *exchangers*) (**Figure 11–8**).

The tight coupling between the transfer of two solutes allows the coupled transporters to harvest the energy stored in the electrochemical gradient of one solute, typically an inorganic ion, to transport the other. In this way, the free energy released during the movement of an inorganic ion or H⁺ down an electrochemical gradient is used as the driving force to pump other solutes uphill, against their electrochemical gradient. This strategy can work in either direction; some coupled transporters function as symporters, others as antiporters. In the plasma membrane of animal cells, Na⁺ is the usual co-transported ion because its electrochemical gradient provides a large driving force for the active transport of a second molecule. Such ion-driven coupled transporters are said to mediate secondary active transport. The Na⁺ that enters the cell during coupled transport is subsequently pumped out by an ATP-driven Na⁺-K⁺ pump in the plasma membrane (as we discuss later), which, by exchanging K⁺ for Na⁺, maintains the Na⁺ gradient, indirectly driving the coupled transport. Such ATP-driven pumps are therefore said to mediate primary active transport because in these the free energy of ATP hydrolysis is used to directly drive the transport of a solute against its electrochemical gradient. The energy stored in the gradient is then used to fuel the secondary active transport processes.

Intestinal and kidney epithelial cells contain a variety of symporters that are driven by the Na⁺ gradient across the plasma membrane. Each Na⁺-driven

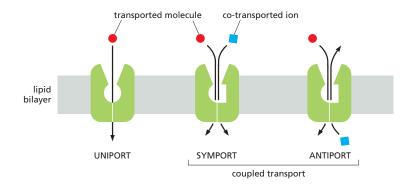

Figure 11–8 This schematic diagram shows transporters functioning as uniporters, symporters, and antiporters (Movie 11.1).

MBOC7_ptr_ch11_637-682.indd 642 08/12/21 11:47 AM

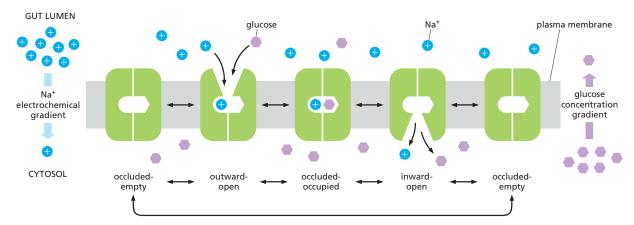

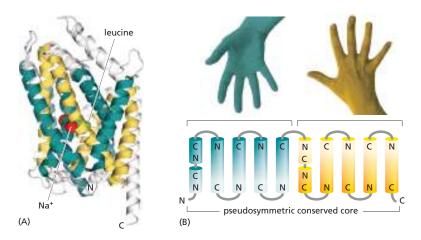

Figure 11–9 Mechanism of glucose transport fueled by an Na⁺ gradient. As in the model shown in Figure 11–5, the transporter alternates between inward-open and outward-open states via occluded intermediate states. Binding of Na⁺ and glucose is cooperative; that is, the binding of either solute increases the protein's affinity for the other. Because the Na⁺ concentration is much higher in the extracellular space than in the cytosol, glucose is more likely to bind to the transporter in the outward-facing state. The transition to the occluded state occurs only when both Na⁺ and glucose are bound; their precise interactions in the solute-binding sites slightly stabilize the occluded state and thereby make this transition energetically favorable. Stochastic fluctuations caused by thermal energy drive the transporter randomly into the inward-open or outward-open conformation. If it opens outwardly, nothing is achieved, and the process starts all over. However, whenever it opens inwardly, Na⁺ dissociates quickly in the low-Na⁺-concentration environment of the cytosol. Glucose dissociation is likewise enhanced when Na⁺ is lost, because of cooperativity in binding of the two solutes. The overall result is the net transport of both Na⁺ and glucose into the cell. Because the occluded state is not formed when only one of the solutes is bound, the transporter switches conformation only when it is fully occupied or fully empty, thereby ensuring strict coupling of the transport of Na⁺ and glucose.

symporter is specific for importing a small group of related sugars or amino acids into the cell. Because the Na⁺ tends to move into the cell down its electrochemical gradient, the sugar or amino acid is, in a sense, "dragged" into the cell with it. The greater the electrochemical gradient for Na⁺, the more solute is transported into the cell (Figure 11–9). Neurotransmitters (released by nerve cells to signal at synapses—as we discuss later) are taken up again by Na⁺ symporters after their release. This both terminates their signaling to postsynaptic cells and recycles them for reuse. These neurotransmitter transporters are important drug targets: stimulants, such as cocaine and antidepressants, inhibit them and thereby prolong signaling by the neurotransmitters because they are not cleared efficiently.

Despite their great variety, transporters share structural features that can explain how they function and how they evolved. Transporters are typically built from bundles of 10 or more α helices that span the membrane. Solute- and ion-binding sites are located midway through the membrane, where some helices are broken or distorted and amino acid side chains and polypeptide backbone atoms form ion- and solute-binding sites. In the inward-open and outward-open conformations, these binding sites are accessible by passageways from one side of the membrane but not the other. In switching between the two conformations, the transporter protein transiently adopts an occluded conformation, in which both passageways are closed; this prevents the driving ion and the transported solute from crossing the membrane unaccompanied, which would deplete the cell's energy store to no purpose. Because only transporters with both types of binding sites appropriately filled change their conformation, tight coupling between ion and solute transport is ensured.

Like enzymes, transporters can work in the reverse direction if ion and solute gradients are appropriately adjusted experimentally. This chemical symmetry is mirrored in their physical structure. Protein structural analyses have revealed that many transporters are built from *inverted repeats*: the packing of the transmembrane α helices in one half of the helix bundle is structurally similar to the packing in the other half, but the two halves are inverted in the membrane relative to each other. Transporters are therefore said to be pseudosymmetric, and the

MBOC7_ptr_ch11_637-682.indd 643 08/12/21 11:47 AM

passageways that open and close on either side of the membrane have closely similar geometries, allowing alternating access to the ion- and solute-binding sites in the center (Figure 11–10). It is thought that the two halves evolved by gene duplication of a smaller ancestor protein.

Some other types of important membrane transport proteins are also built from inverted repeats. Examples even include channel proteins such as the aquaporin water channel (discussed later) and the Sec61 channel through which nascent polypeptides move into the endoplasmic reticulum (discussed in Chapter 12). It is thought that these channels evolved from coupled transporters in which the gating functions were lost, allowing them to open toward both sides of the membrane simultaneously to provide a continuous path across the membrane.

In bacteria, yeasts, and plants, as well as in many membrane-enclosed organelles of animal cells, most ion-driven active transport systems depend on H^+ rather than Na^+ gradients, reflecting the predominance of H^+ pumps in these membranes. An electrochemical H^+ gradient across the bacterial plasma membrane, for example, drives the inward active transport of many sugars and amino acids.

Transporters in the Plasma Membrane Regulate Cytosolic pH

Most proteins operate optimally at a particular pH. Lysosomal enzymes, for example, function best at the low pH (\sim 5) found in lysosomes, whereas cytosolic enzymes function best at the close-to-neutral pH (\sim 7.2) found in the cytosol. It is therefore crucial that cells control the pH of their intracellular compartments.

Most cells have one or more types of Na⁺-driven antiporters in their plasma membrane that help to maintain the cytosolic pH at about 7.2. These transporters use the energy stored in the Na⁺ gradient to pump out excess H⁺, which either leaks in or is produced in the cell by acid-forming reactions. Two mechanisms are used: either H⁺ is directly transported out of the cell or HCO₃⁻ is brought into the cell to neutralize H⁺ in the cytosol (according to the reaction HCO₃⁻ + $\mathrm{H^+} \rightarrow \mathrm{H_2O} + \mathrm{CO_2}$). One of the antiporters that uses the first mechanism is an Na⁺-H⁺ exchanger, which couples an influx of Na⁺ to an efflux of H⁺. Another, which uses a combination of the two mechanisms, is an Na⁺-driven Cl⁻-HCO₃⁻ exchanger that couples an influx of Na⁺ and HCO₃⁻ to an efflux of Cl⁻ and H⁺ (so that NaHCO₃ comes in and HCl goes out). The Na⁺-driven Cl⁻-HCO₃⁻ exchanger is twice as effective as the Na⁺-H⁺ exchanger: it pumps out one H⁺ and neutralizes another for each Na⁺ that enters the cell. If HCO₃⁻ is available, as is usually the case, this antiporter is the most important transporter regulating the cytosolic pH. The pH inside the cell regulates both exchangers; when the pH in the cytosol falls, both exchangers sense the change and increase their activity.

An Na^+ -independent Cl^- - HCO_3^- exchanger adjusts the cytosolic pH in the reverse direction. Like the Na $^+$ -dependent transporters, pH regulates the Na $^+$ -independent Cl^- - HCO_3^- exchanger, but the exchanger's activity increases as the cytosol becomes too alkaline. The movement of HCO_3^- in this case is normally

Figure 11–10 Transporters are built from inverted repeats. (A) LeuT, a bacterial Na⁺/leucine symporter related to human neurotransmitter transporters, such as the serotonin transporter, is shown. The core of the transporter is built from two bundles, each composed of six α helices (blue and yellow). The helices shown in light gray are additions to the conserved core structure and differ among members of this transporter family. They are thought to play regulatory roles that are specific to a particular transporter. (B) Both core helix bundles are packed in a similar arrangement, but the second bundle is inverted with respect to the first (shown as two right hands, with the broken helices as the thumbs). The transporter's structural pseudosymmetry reflects its functional symmetry: the transporter can work in either direction, depending on the direction of the ion gradient. (A, PDB code: 3F3E.)

MBOC7_ptr_ch11_637-682.indd 644 08/12/21 11:47 AM

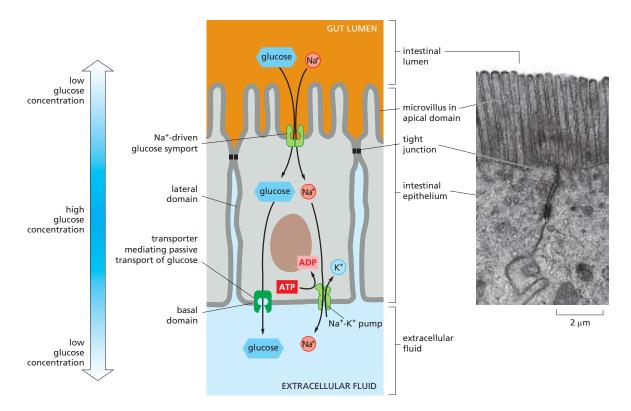

out of the cell, down its electrochemical gradient, which decreases the pH of the cytosol. An Na^+ -independent Cl^- - HCO_3^- exchanger in the membrane of red blood cells (called band 3 protein—see Figure 10–38) facilitates the quick discharge of CO_2 (as HCO_3^-) as the cells pass through capillaries in the lung.

The intracellular pH is not entirely regulated by transporters in the plasma membrane: ATP-driven H^+ pumps are used to control the pH of many intracellular compartments. As discussed in Chapter 13, H^+ pumps maintain the low pH in lysosomes, as well as in endosomes and secretory vesicles. These H^+ pumps use the energy of ATP hydrolysis to pump H^+ into these acidic organelles from the cytosol. An advantage of using electrochemical H^+ gradients to power intracellular transport events is that they can dissipate and regenerate quickly, thus affording more opportunity to switch transport reactions on and off. To create an electrochemical H^+ gradient of similar energy to that of the Na $^+$ gradient at the plasma membrane requires the movement of far fewer H^+ . This is because the H^+ concentration is many orders of magnitude smaller (0.1 μ M at pH 7) than that of Na $^+$ and K $^+$ (~ 100 mM).

An Asymmetric Distribution of Transporters in Epithelial Cells Underlies the Transcellular Transport of Solutes

In epithelial cells, such as those that absorb nutrients from the gut, transporters are distributed nonuniformly between the apical and basolateral plasma membranes and thereby contribute to the **transcellular transport** of absorbed solutes. By the actions of the transporters in these cells, solutes are moved across the epithelial-cell layer into the extracellular fluid from where they pass into the blood. As shown in **Figure 11–11**, Na⁺-linked symporters located in the apical (absorptive) domain of the plasma membrane actively transport nutrients into the cell, building up substantial concentration gradients for these solutes across the plasma membrane. Uniporters in the basal and lateral (basolateral) domain allow the nutrients to leave the cell passively down these concentration gradients to enter the bloodstream for use in the rest of the body.

Figure 11-11 Transcellular transport. The transcellular transport of glucose across an intestinal epithelial cell depends on the nonuniform distribution of transporters in the cell's plasma membrane. The process shown here results in the transport of alucose from the intestinal lumen to the extracellular fluid (from where it passes into the blood). Glucose is pumped into the cell through the apical domain of the membrane by an Na⁺-powered glucose symporter (see Figure 11-9). Glucose passes out of the cell (down its concentration gradient) by passive movement through a glucose uniporter in the basal and lateral membrane domains. The Na+ gradient driving the glucose symport is maintained by the Na+-K+ pump in the basal and lateral plasma membrane domains, which keeps the internal concentration of Na+ low (Movie 11.2). Adjacent cells are connected by impermeable tight junctions, which have a dual function in the transport process illustrated: they prevent solutes from crossing the epithelium between cells, allowing a concentration gradient of glucose to be maintained across the cell sheet (see Figure 19-19). They also serve as diffusion barriers (fences) within the plasma membrane, which help confine the various transporters to their respective membrane domains (see Figure 10-34). (Micrograph from Dennis Kunkel/Science

MBOC7_ptr_ch11_637-682.indd 645 08/12/21 11:47 AM

In many of these epithelial cells, the plasma membrane area is greatly increased by the formation of thousands of microvilli, which extend as thin, fingerlike projections from the apical surface of each cell. Such microvilli can increase the total absorptive area of a cell as much as 25-fold, thereby enhancing its transport capabilities.

As we have seen, ion gradients have a crucial role in driving many essential transport processes in cells. Ion pumps that use the energy of ATP hydrolysis establish and maintain these gradients, as we discuss next.

There Are Three Classes of ATP-driven Pumps

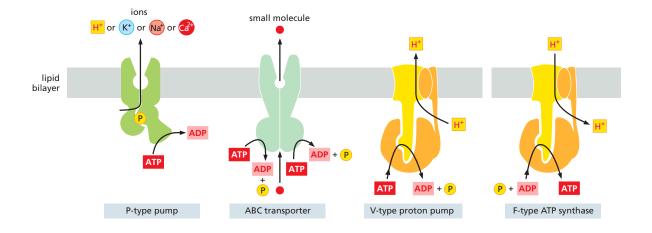

ATP-driven pumps are often called *transport ATPases* because they hydrolyze ATP to ADP and phosphate and use the energy released to pump ions or other solutes across a membrane. There are three principal classes of ATP-driven pumps (**Figure 11–12**), and representatives of each are found in all prokaryotic and eukaryotic cells.

- P-type pumps are structurally and functionally related multipass transmembrane proteins. They are called "P-type" because they phosphorylate themselves during the pumping cycle. This class includes many of the ion pumps that are responsible for setting up and maintaining gradients of Na⁺, K⁺, H⁺, and Ca²⁺ across cell membranes.
- ABC transporters (<u>A</u>TP-<u>b</u>inding <u>c</u>assette transporters) differ structurally from P-type ATPases and primarily pump small organic molecules across cell membranes.
- 3. **V-type pumps** are turbine-like protein machines constructed from multiple different subunits. The V-type proton pump transfers H⁺ into organelles, such as lysosomes, synaptic vesicles, and plant or yeast vacuoles (V = vacuolar), to acidify the interior of these organelles (see Figures 13–46 and 13–47).

Structurally related to the V-type pumps is a distinct subclass of *F-type ATPases*, more commonly called *ATP synthases* because they normally work in reverse: instead of using ATP hydrolysis to drive $\mathrm{H^+}$ transport, they use the $\mathrm{H^+}$ gradient across the membrane to drive the synthesis of ATP from ADP and phosphate (see Figure 14–31). ATP synthases are found in the plasma membrane of bacteria, the inner membrane of mitochondria, and the thylakoid membrane of chloroplasts. The $\mathrm{H^+}$ gradient is generated either during the electron-transport steps of oxidative phosphorylation (in aerobic bacteria and mitochondria), during photosynthesis (in chloroplasts), or by the light-driven $\mathrm{H^+}$ pump (bacteriorhodopsin) in *Halobacterium*. We discuss some of these proteins in detail in Chapter 14.

For the remainder of this section, we focus on P-type pumps and ABC transporters.

Figure 11–12 Three types of ATP-driven pumps. Like any enzyme, all ATP-driven pumps can work in either direction, depending on the electrochemical gradients of their solutes and the ATP/ADP ratio. When the ATP/ADP ratio is high, they hydrolyze ATP; when the ATP/ADP ratio is low, they can synthesize ATP. The F-type ATPases in mitochondria and chloroplasts normally work in this "reverse" mode to make most of the cell's ATP.

MBOC7_ptr_ch11_637-682.indd 646 08/12/21 11:47 AM

A P-type ATPase Pumps Ca²⁺ into the Sarcoplasmic Reticulum in Muscle Cells

Eukaryotic cells maintain very low concentrations of free Ca^{2+} in their cytosol ($\sim 10^{-7}$ M) in the face of a very much higher extracellular Ca^{2+} concentration ($\sim 10^{-3}$ M). Therefore, even a small influx of Ca^{2+} significantly increases the concentration of free Ca^{2+} in the cytosol, and the flow of Ca^{2+} down its steep concentration gradient in response to extracellular signals is one means of transmitting these signals rapidly across the plasma membrane (discussed in Chapter 15). It is thus important that the cell maintains a steep Ca^{2+} gradient across its plasma membrane. Ca^{2+} transporters that actively pump Ca^{2+} out of the cytosol help maintain the gradient. One of these is a P-type Ca^{2+} ATPase; the other is an antiporter (called an Na^+ – Ca^{2+} exchanger) that is driven by the Na^+ electrochemical gradient (discussed in Chapter 15).

The Ca^{2+} pump, or Ca^{2+} ATPase, in the *sarcoplasmic reticulum* (SR) membrane of skeletal muscle cells is a well-understood P-type transport ATPase. The SR is a specialized type of endoplasmic reticulum that forms a network of tubular sacs in the muscle-cell cytoplasm, and it serves as an intracellular store of Ca^{2+} . When an action potential depolarizes the muscle-cell plasma membrane, Ca^{2+} is released into the cytosol from the SR through Ca^{2+} -release channels, stimulating the muscle to contract (discussed in Chapters 15 and 16). The Ca^{2+} pump, which accounts for about 90% of the membrane protein of the SR, moves Ca^{2+} from the cytosol back into the SR. The endoplasmic reticulum of non-muscle cells also stores Ca^{2+} using a closely homologous Ca^{2+} pump and Ca^{2+} -release channels.

Enzymatic studies and analyses of the three-dimensional structures of transport intermediates of the SR Ca²⁺ pump and related pumps have revealed the molecular mechanism of P-type transport ATPases in great detail. They all have similar structures, containing 10 transmembrane α helices connected to three cytosolic domains (Figure 11-13). In the Ca²⁺ pump, amino acid side chains protruding from the transmembrane helices form two centrally positioned binding sites for Ca²⁺. As shown in Figure 11-14, in the pump's ATP-bound nonphosphorylated state, these binding sites are accessible only from the cytosolic side of the SR membrane. Ca²⁺ binding triggers a series of conformational changes that close the passageway to the cytosol and activate a phosphotransfer reaction in which the terminal phosphate of the ATP is transferred to an aspartate that is conserved among all P-type ATPases. The ADP then dissociates and is replaced with a fresh ATP, causing another conformational change that opens a passageway to the SR lumen through which the two Ca²⁺ ions exit. They are replaced by two H⁺ ions and water molecules that stabilize the empty Ca2+-binding sites and close the passageway to the SR lumen, switching the pump to the occluded conformation. Hydrolysis of the labile phosphoryl-aspartate bond opens the passageway to the cytosol. H⁺ is released as the pump opens the passageway to the cytosol,

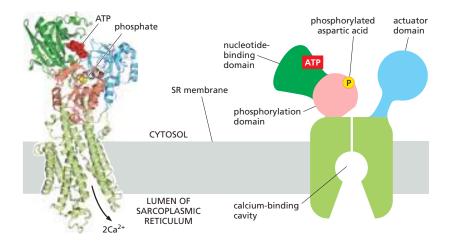

Figure 11-13 The structure of the sarcoplasmic reticulum Ca2+ pump. The ribbon model (left), derived from x-ray crystallographic analyses, shows the pump in its phosphorylated, ATP-bound state. The three globular cytosolic domains of the pump—the nucleotide-binding domain (dark green), the actuator domain (blue), and the phosphorylation domain (pink), also shown schematically on the right - change conformation dramatically during the pumping cycle. These changes in turn alter the arrangement of the transmembrane helices, which allows the Ca2+ to be released from its binding cavity into the SR lumen (Movie 11.3). (PDB code: 3B9B.)

MBOC7_ptr_ch11_637-682.indd 647 08/12/21 11:47 AM

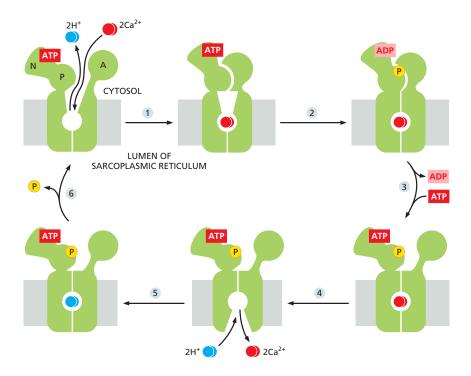

Figure 11-14 The pumping cycle of the sarcoplasmic reticulum Ca2+ pump. lon pumping proceeds by a series of stepwise conformational changes in which movements of the pump's three cytosolic domains [the nucleotide-binding domain (N), the phosphorylation domain (P), and the actuator domain (A)] are mechanically coupled to movements of the transmembrane α helices. Helix movement opens and closes passageways through which Ca2+ enters from the cytosol and binds to the two centrally located Ca2+binding sites. The two Ca2+ then exit into the SR lumen and are replaced by two H+, which are transported in the opposite direction. The ion-dependent (Ca2+ and H+ in the case of the SR Ca²⁺ pump) phosphorylation and dephosphorylation of an aspartate are universally conserved steps in the reaction cycle of all P-type pumps: they cause the conformational transitions to occur in an orderly manner, enabling the proteins to do useful work. (Adapted from C. Toyoshima et al., Nature 432:361-368, 2004; and J.V. Møller et al., Q. Rev. Biophys. 43:501-566, 2010.)

returning it to the initial conformation, and the cycle starts again. The transient self-phosphorylation of the pump during its cycle is an essential characteristic of all P-type pumps.

The Plasma Membrane Na⁺-K⁺ Pump Establishes Na⁺ and K⁺ Gradients Across the Plasma Membrane

The concentration of K^+ is typically 10–30 times higher inside cells than outside, whereas the reverse is true of Na⁺ (see Table 11–1, p. 638). An Na⁺-K⁺ pump, or Na⁺-K⁺ ATPase, found in the plasma membrane of virtually all animal cells, maintains these concentration differences. Like the Ca²⁺ pump, the Na⁺-K⁺ pump belongs to the family of P-type ATPases and operates as an ATP-driven antiporter, actively pumping Na⁺ out of the cell against its steep electrochemical gradient and pumping K⁺ in (Figure 11–15).

We mentioned earlier that the Na⁺ gradient produced by the Na⁺-K⁺ pump drives the transport of most nutrients into animal cells and also has a crucial role in regulating cytosolic pH. A typical animal cell devotes almost one-third of its energy to fueling this pump, and the pump consumes even more energy in nerve

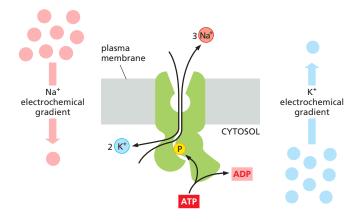

Figure 11–15 The function of the Na⁺-K⁺ pump. This P-type ATPase actively pumps Na⁺ out of and K⁺ into a cell against their electrochemical gradients. It is structurally closely related to the Ca²⁺ ATPase but differs in its selectivity for ions: for every molecule of ATP hydrolyzed by the pump, three Na⁺ are pumped out and two K⁺ are pumped in. As in the Ca²⁺ pump, an aspartate is phosphorylated and dephosphorylated during the pumping cycle (Movie 11.4).

MBOC7_ptr_ch11_637-682.indd 648 08/12/21 11:47 AM

cells and in cells that are dedicated to transport processes, such as those forming kidney tubules.

Because the Na⁺-K⁺ pump drives three positively charged ions out of the cell for every two it pumps in, it is *electrogenic*: it drives a net electric current across the membrane, tending to create an electrical potential, with the cell's inside being negative relative to the outside. This electrogenic effect of the pump, however, seldom directly contributes more than 10% to the membrane potential. The remaining 90%, as we discuss later, depends only indirectly on the Na⁺-K⁺ pump.

ABC Transporters Constitute the Largest Family of Membrane Transport Proteins

The last type of transport ATPase that we discuss here is the family of ABC transporters, so named because each member contains two highly conserved ATPase domains, or ATP-binding "cassettes," on the cytosolic side of the membrane. ATP binding brings together the two ATPase domains, and ATP hydrolysis leads to their dissociation (Figure 11–16). These movements of the cytosolic domains are transmitted to the transmembrane segments, driving cycles of conformational changes that alternately expose solute-binding sites on one side of the membrane and then on the other side, as we have seen for other transporters. In this way, ABC transporters harvest the energy released upon ATP binding and hydrolysis to drive transport of solutes across the bilayer. The transport is directional toward the inside or toward the outside, depending on the particular conformational change in the solute-binding site that is linked to ATP hydrolysis (see Figure 11–16).

ABC transporters constitute the largest family of membrane transport proteins and are of great clinical importance. The first of these proteins to be characterized was found in bacteria. We have already mentioned that the plasma membranes of all bacteria contain transporters that use the ${\rm H}^+$ gradient across the membrane to actively transport a variety of nutrients into the cell. In addition, bacteria use ABC transporters to import certain small molecules. In Gram-negative bacteria, such

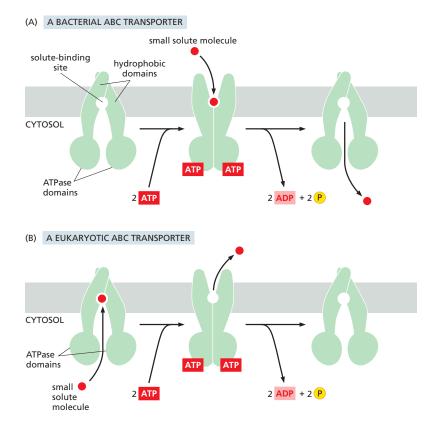

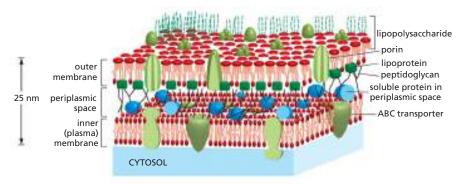

Figure 11-16 Small-molecule transport by typical ABC transporters. ABC transporters consist of multiple domains. Typically, two hydrophobic domains, each built of six membrane-spanning $\boldsymbol{\alpha}$ helices, together form the translocation pathway and provide substrate specificity. Two ATPase domains protrude into the cytosol. In some cases, the two halves of the transporter are formed by a single polypeptide, whereas in other cases they are formed by two or more separate polypeptides that assemble into a similar structure. Without ATP bound, the transporter exposes a substrate-binding site on one side of the membrane. ATP binding induces a conformational change that exposes the substrate-binding site on the opposite side; ATP hydrolysis followed by ADP dissociation returns the transporter to its original conformation. Most individual ABC transporters are unidirectional. (A) Both importing and exporting ABC transporters are found in bacteria; an ABC importer is shown in this diagram. (B) In eukaryotes, most ABC transporters export substances-either from the cytosol to the extracellular space or from the cytosol to a membrane-bound intracellular compartment such as the endoplasmic reticulum—or from the mitochondrial matrix to the intermembrane space.

MBOC7_ptr_ch11_637-682.indd 649 08/12/21 11:47 AM

as *Escherichia coli*, that have double membranes (**Figure 11–17**), the ABC transporters are located in the inner membrane, and auxiliary proteins in the periplasm typically capture the nutrients and deliver them to the transporters (**Figure 11–18**).

In *E. coli*, 78 genes (an amazing 5% of the bacterium's genes) encode ABC transporters, and animal genomes encode an even larger number. Although each transporter is thought to be specific for a particular molecule or class of molecules, the variety of substrates transported by this superfamily is great and includes inorganic ions, amino acids, monosaccharides and polysaccharides, peptides, lipids, drugs, and, in some cases, even proteins that can be larger than the transporter itself.

The first eukaryotic ABC transporters identified were discovered because they pump hydrophobic drugs out of the cytosol. One of these transporters is the **multidrug resistance (MDR) protein**, also called P-glycoprotein. It is present at elevated levels in many human cancer cells and makes the cells simultaneously resistant to a variety of chemically unrelated cytotoxic drugs that are widely used in cancer chemotherapy. Treatment with any one of these drugs can result in the selective survival and overgrowth of those cancer cells that express an especially large amount of the MDR transporter. These cells pump drugs out of the cell very efficiently and are therefore relatively resistant to the drugs' toxic effects (Movie 11.5). Selection for cancer cells with resistance to one drug can thereby lead to resistance to a wide variety of anticancer drugs. Some studies indicate that up to 40% of human cancers develop multidrug resistance, making it a major hurdle in the battle against cancer.

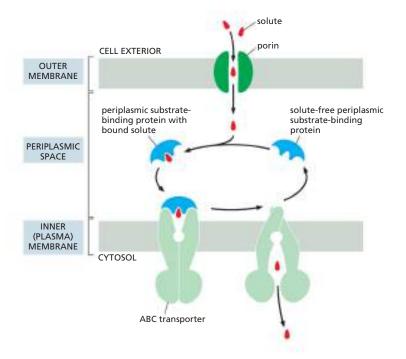

Figure 11-17 A small section of the double membrane of an E. coli bacterium. The inner membrane is the cell's plasma membrane. Between the inner and outer membranes is a highly porous, rigid peptidoglycan layer, composed of protein and polysaccharide that constitute the bacterial cell wall. It is attached to lipoprotein molecules in the outer membrane and fills the periplasmic space (only a little of the peptidoglycan laver is shown). This space also contains a variety of soluble protein molecules. The dashed threads (shown in green) at the top represent the polysaccharide chains of the special lipopolysaccharide molecules that form the external monolaver of the outer membrane; for clarity, only a few of these chains are shown. Bacteria with double membranes are called Gram negative because they do not retain the dark blue dve used in Gram staining. Bacteria with single membranes (but thicker peptidoglycan cell walls), such as staphylococci and streptococci, retain the dark blue dye and are therefore called Gram positive: their single membrane is analogous to the inner (plasma) membrane of Gram-negative bacteria.

Figure 11–18 The auxiliary transport system associated with transport ATPases in bacteria with double membranes. The solute diffuses through channel proteins (porins) in the outer membrane and binds to a periplasmic substrate-binding protein that delivers it to the ABC transporter, which pumps it across the plasma membrane. The peptidoglycan layer is omitted for simplicity; its porous structure allows the substrate-binding proteins and water-soluble solutes to move freely through it by diffusion.

A related and equally sinister phenomenon occurs in the protist *Plasmodium falciparum*, which causes malaria. More than 200 million people are infected worldwide with this parasite, which remains a major cause of human death, killing almost a million people every year. The development of resistance to the antimalarial drug *chloroquine* has hampered the control of malaria. The resistant *P. falciparum* have amplified a gene encoding an ABC transporter that pumps out the chloroquine.

In most vertebrate cells, an ABC transporter in the endoplasmic reticulum (ER) membrane (named *transporter associated with antigen processing*, or *TAP transporter*) actively pumps a wide variety of peptides from the cytosol into the ER lumen. These peptides are produced by protein degradation in proteasomes (discussed in Chapter 6). They are carried from the ER to the cell surface, where they are displayed for scrutiny by cytotoxic T lymphocytes, which kill the cell if the peptides are derived from a virus or other microorganism lurking in the cytosol of an infected cell (discussed in Chapter 24).

Yet another member of the ABC transporter family is the *cystic fibrosis transmembrane conductance regulator* (CFTR) protein, which was discovered through studies of the common genetic disease *cystic fibrosis*. This disease is caused by a mutation in the gene encoding CFTR, a Cl⁻ transport protein in the plasma membrane of epithelial cells. CFTR regulates ion concentrations in the extracellular fluid, especially in the lung. One in 27 Caucasians carries a gene encoding a mutant form of this protein; in 1 in 2900, both copies of the gene are mutated, causing the disease. In contrast to other ABC transporters, ATP binding and hydrolysis in the CFTR protein do not drive the transport process. Instead, they control the opening and closing of a continuous channel, which provides a passive conduit for Cl⁻ to move down its electrochemical gradient. Thus, some ABC proteins can function as transporters and others as gated channels. Even though we treat transporters and channels as distinct in this chapter, the border is not absolute as this example illustrates. Indeed, the structure of some other Cl⁻ channels reveals that they also resemble transporters more than they resemble most other ion channels.

Summary

Transporters bind specific solutes and transfer them across the lipid bilayer by undergoing conformational changes that alternately expose the solute-binding site on one side of the membrane and then on the other side. Some transporters move a single solute "downhill," whereas others can act as pumps to move a solute "uphill" against its electrochemical gradient, by using energy provided by ATP hydrolysis, by a downhill flow of another solute (such as Na^+ or H^+), or by light to drive the requisite series of conformational changes in an orderly manner. Transporters belong to a small number of protein families. Each family evolved from a common ancestral protein, and its members all operate by a similar mechanism. The family of P-type transport ATPases, which includes Ca^{2+} and Na^+ - K^+ pumps, is an important example; each of these ATPases sequentially phosphorylates and dephosphorylates itself during the pumping cycle. The superfamily of ABC transporters is the largest family of membrane transport proteins and is especially important clinically. It includes proteins that are responsible for drug resistance in both cancer cells and cells infected with malaria-causing parasites and for pumping pathogen-derived peptides into the ER for cytotoxic lymphocytes to reorganize on the surface of infected cells, and mutations in an ABC transporter cause cystic fibrosis.

CHANNELS AND THE ELECTRICAL PROPERTIES OF MEMBRANES

Unlike transporters, channels form pores across membranes. One class of channel proteins found in virtually all animals forms *gap junctions* between adjacent cells; each plasma membrane contributes equally to the formation of the channel, which connects the cytoplasm of the two cells. In plants, *plasmodesmata* fulfill many of the same functions. These channels are discussed in Chapter 19 and will

MBOC7_ptr_ch11_637-682.indd 651 08/12/21 11:47 AM

not be considered further here. Both gap junctions and *porins*, the channels in the outer membranes of bacteria, mitochondria, and chloroplasts (discussed in Chapter 10), have relatively large and permissive pores, and it would be disastrous if they directly connected the inside of a cell to an extracellular space. Indeed, many bacterial toxins do exactly that to kill other cells (discussed in Chapter 24).

In contrast, most channels in the plasma membrane of animal and plant cells that connect the cytosol to the cell exterior necessarily have narrow, highly selective pores that can open and close rapidly. Because these proteins are concerned specifically with inorganic ion transport, they are referred to as ion channels. For transport efficiency, ion channels have an advantage over transporters, in that they can pass up to 100 million ions through one open channel each second—a rate 10⁵ times greater than even the fastest transporter. As discussed earlier, however, channels cannot be coupled to an energy source to perform active transport, so the conductance they mediate is always passive (downhill). Thus, the function of ion channels is to allow specific inorganic ions—primarily Na⁺, K⁺, Ca²⁺, or Cl⁻—to diffuse rapidly down their electrochemical gradients across the lipid bilayer. In this section, we will see that the ability to control ion fluxes through these channels is essential for many cell functions. Nerve cells (neurons), in particular, have made a specialty of using ion channels, and we will consider how they use many different ion channels to receive, conduct, and transmit signals. Before we discuss ion channels, however, we briefly consider the aquaporin water channels that we mentioned earlier.

Aquaporins Are Permeable to Water but Impermeable to Ions

Because cells are mostly water (typically ~70% by weight), water movement across cell membranes is fundamentally important for life. Cells also contain a high concentration of solutes, including numerous negatively charged organic molecules that are confined inside the cell (the so-called *fixed anions*) and their accompanying cations that are required for charge balance. This creates an osmotic gradient, which mostly is balanced by an opposite osmotic gradient due to a high concentration of inorganic ions—chiefly Na⁺ and Cl⁻—in the extracellular fluid. The small remaining osmotic force tends to "pull" water into the cell, causing it to swell until the forces are balanced. Because all biological membranes are moderately permeable to water (see Figure 11–2), cell volume equilibrates in minutes or less in response to an osmotic gradient. For most animal cells, however, osmosis has only a minor role in regulating cell volume. This is because most of the cytoplasm is in a gel-like state and resists large changes in its volume in response to changes in osmolarity.

In addition to the direct diffusion of water across the lipid bilayer, some prokaryotic and eukaryotic cells have **water channels**, or **aquaporins**, embedded in their plasma membranes to allow water to move more rapidly. Aquaporins are particularly abundant in animal cells that must transport water at high rates, such as the epithelial cells of the kidney or exocrine cells that must transport or secrete large volumes of fluids (**Figure 11–19**). Water flow is highly regulated in these tissues. In the kidney, hormones such as antidiuretic hormone (vasopressin) regulate the concentration of aquaporin in the plasma membrane.

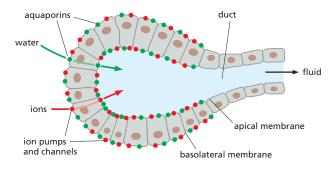

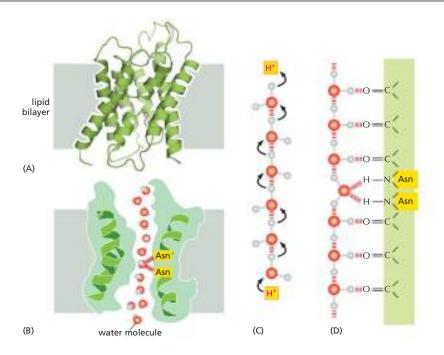

Figure 11-19 The role of aquaporins in fluid secretion. Cells lining the ducts of exocrine glands (as found, for example, in the pancreas and liver, and in mammary, sweat, and salivary glands) secrete large volumes of body fluids. These cells are organized into epithelial sheets in which their apical plasma membrane faces the lumen of the duct. Ion pumps and channels situated in the basolateral and apical plasma membranes move ions (mostly Na and Cl⁻) into the ductal lumen, creating an osmotic gradient between the surrounding tissue and the duct. Water molecules rapidly follow the osmotic gradient through aquaporins that are present in high concentrations in both the apical and basolateral plasma membranes.

MBOC7_ptr_ch11_637-682.indd 652 08/12/21 11:47 AM

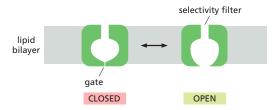

Aquaporins must solve a problem that is opposite to that facing ion channels. To avoid disrupting ion gradients across membranes, they have to allow the rapid passage of water molecules while completely blocking the passage of ions. The three-dimensional structure of an aquaporin reveals how it achieves this remarkable selectivity. The channels have a narrow pore that allows water molecules to traverse the membrane in single file, following the path of carbonyl oxygens that line one side of the pore (Figure 11-20A and B). Hydrophobic amino acids line the other side of the pore. The pore is too narrow for any hydrated ion to enter, and the energy cost of dehydrating an ion would be enormous because the hydrophobic wall of the pore cannot interact with a dehydrated ion to compensate for the loss of water. This design readily explains why the aquaporins cannot conduct K⁺, Na⁺, Ca²⁺, or Cl⁻ ions. These channels are also impermeable to H⁺, which is mainly present in cells as H₃O⁺. These hydronium ions diffuse through water extremely rapidly, using a molecular relay mechanism that requires the making and breaking of hydrogen bonds between adjacent water molecules (Figure 11-20C). Aquaporins contain two strategically placed asparagines, which bind to the oxygen atom of the central water molecule in the line of water molecules traversing the pore, imposing a bipolarity on the entire single-file column of water molecules (Figure 11-20C and D). Because both valences of this central oxygen are unavailable for hydrogen-bonding, the central water molecule cannot participate in an H⁺ relay. This makes it impossible for the "making and breaking" sequence of hydrogen bonds (shown in Figure 11-20C) to get past the central asparaginebonded water molecule, and the pore is therefore impermeable to H⁺.

We now turn to ion channels, the subject of the rest of the chapter.

Ion Channels Are Ion-selective and Fluctuate Between Open and Closed States

Two important properties distinguish ion channels from aqueous pores. First, they show *ion selectivity*, permitting some inorganic ions to pass, but not others. This suggests that their pores must be narrow enough in places to force permeating ions into intimate contact with the walls of the channel so that only ions of appropriate size and charge can pass. In some cases permeating ions have to shed most or all of their associated water molecules to pass, whereas in other cases hydrated or partially hydrated ions pass through the channel. Passage occurs in

Figure 11-20 The structure of aquaporins. (A) A ribbon diagram of an aquaporin monomer. In the membrane, aquaporins form tetramers, with each monomer containing an aqueous pore in its center (not shown). Each individual aquaporin channel passes about 109 water molecules per second. (B) A longitudinal cross section through one aquaporin monomer, in the plane of the central pore. One face of the pore is lined with hydrophilic amino acids, which provide transient hydrogen bonds to water molecules; these bonds help line up the transiting water molecules in a single row and orient them as they traverse the pore. (C and D) A model explaining why aquaporins are impermeable to H+ (C) In water, H⁺ diffuses extremely rapidly by being relayed from one water molecule to the next. (D) Carbonyl groups (C=O) lining the hydrophilic face of the pore align water molecules, and two strategically placed asparagines in the center are thought to tether a central water molecule such that both valences on its oxygen are occupied. This arrangement bipolarizes the entire column of water molecules, with each water molecule acting as a hydrogenbond acceptor from its inner neighbor (Movie 11.6). (PDB code: 3GD8.)

single file, through the narrowest part of the channel, which is called the *selectivity filter*, and limits the channel's rate of ion movement and determines which ions can pass through (Figure 11–21). Thus, as the ion concentration increases, the flux of the ion through a channel increases proportionally but then levels off (saturates) at a maximum rate.

The second important distinction between ion channels and aqueous pores is that ion channels are not continually open. Instead, they are *gated*, which allows them to open briefly and then close again. Moreover, with prolonged (chemical or electrical) stimulation, most ion channels go into a closed "desensitized," or "inactivated," state, in which they are refractory to further opening until the stimulus has been removed, as we discuss later. In most cases, the gate opens in response to a specific stimulus. As shown in Figure 11–22, the main types of stimuli that are known to cause ion channels to open are a change in the voltage across the membrane (*voltage-gated channels*), a mechanical stress (*mechanically gated channels*), or the binding of a ligand (*ligand-gated channels*). The ligand can be either an extracellular mediator—specifically, a neurotransmitter (*transmitter-gated channels*)—or an intracellular mediator such as an ion (*ion-gated channels*) or a nucleotide (*nucleotide-gated channels*). In addition, protein phosphorylation and dephosphorylation regulate the activity of many ion channels; this type of channel regulation is discussed, together with nucleotide-gated ion channels, in Chapter 15.

More than 200 types of ion channels have been identified thus far, and new ones are still being discovered, each characterized by the ions it conducts, the mechanism by which it is gated, and its abundance and localization in the cell and in specific cells. Ion channels are responsible for the electrical excitability of muscle cells, and they mediate most forms of electrical signaling in the nervous system. A single neuron typically contains 10 or more kinds of ion channels, located in different domains of its plasma membrane. But ion channels are not restricted to electrically excitable cells. They are present in all animal cells and are found in plant cells and microorganisms: they propagate the leaf-closing response of the mimosa plant, for example (Movie 11.7), and allow the single-celled motile *Paramecium* to reverse direction after a collision.

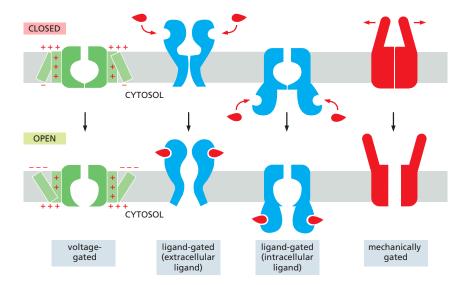

Figure 11–21 A typical ion channel, which fluctuates between closed and open conformations. The ion channel shown here in cross section forms a pore across the lipid bilayer only in the "open" conformational state. The pore narrows to atomic dimensions in one region (the selectivity filter), where the ion selectivity of the channel is largely determined. Another region of the channel forms the gate.

Figure 11–22 The gating of ion channels. This schematic drawing shows several kinds of stimuli that open ion channels. Mechanically gated channels often have cytoplasmic extensions (not shown) that link the channel to the cytoskeleton.

MBOC7_ptr_ch11_637-682.indd 654 08/12/21 11:47 AM

Ion channels that are permeable to K^+ are found in the plasma membrane of almost all cells. An important subset of K^+ channels opens even in an unstimulated or "resting" cell, and hence these are called K^+ leak channels. Although this term applies to many different K^+ channels, depending on the cell type, they serve a common purpose: by making the plasma membrane much more permeable to K^+ than to other ions, they have a crucial role in maintaining the membrane potential across all plasma membranes, as we discuss next.

The Membrane Potential in Animal Cells Depends Mainly on K⁺ Leak Channels and the K⁺ Gradient Across the Plasma Membrane

A membrane potential arises when there is a difference in the electrical charge on the two sides of a membrane because of a minute excess of positive ions over negative ones on one side and a minute deficit on the other side. Such charge differences can result both from active electrogenic pumping (see p. 648) and from passive ion diffusion in channels. As we discuss in Chapter 14, electrogenic H⁺ pumps in the mitochondrial inner membrane generate most of the membrane potential across this membrane. Electrogenic pumps also generate most of the electrical potential across the plasma membrane of plants and fungi. In typical animal cells, however, passive ion movements make the largest contribution to the electrical potential across the plasma membrane.

As explained earlier, because of the action of the $\mathrm{Na^+}$ - $\mathrm{K^+}$ pump, there is little $\mathrm{Na^+}$ inside the cell, and other intracellular inorganic cations have to be plentiful enough to balance the charge carried by the cell's fixed anions—the negatively charged organic molecules that are confined inside the cell. This balancing role is performed largely by $\mathrm{K^+}$, which is actively pumped into the cell by the $\mathrm{Na^+}$ - $\mathrm{K^+}$ pump and can also move in or out through the $\mathrm{K^+}$ leak channels in the plasma membrane. Because of the presence of these channels, $\mathrm{K^+}$ comes almost to equilibrium, where an electrical force exerted by an excess of negative charges attracting $\mathrm{K^+}$ into the cell balances the tendency of $\mathrm{K^+}$ to leak out down its concentration gradient. The membrane potential (of the plasma membrane) is the manifestation of this electrical force, and we can calculate its equilibrium value from the steepness of the $\mathrm{K^+}$ concentration gradient. The following argument may help to make this clear.

Suppose that initially there is no voltage gradient across the plasma membrane (the membrane potential is zero), but the concentration of K^+ is high inside the cell and low outside. K^+ will tend to leave the cell through the K^+ leak channels, driven solely by its concentration gradient. As K^+ begins to move out, each ion leaves behind an unbalanced negative charge, thereby creating an electrical field, or membrane potential, which will tend to oppose the further efflux of K^+ . The net efflux of K^+ halts when the membrane potential reaches a value at which this electrical driving force on K^+ exactly balances the effect of its concentration gradient; that is, when the electrochemical gradient for K^+ is zero.

The equilibrium condition, in which there is no net flow of ions across the plasma membrane, defines the **resting membrane potential** for this idealized cell. A simple but very important formula, the **Nernst equation**, quantifies the equilibrium condition and, as explained in **Panel 11–1** (p. 656), makes it possible to calculate the theoretical resting membrane potential if we know the ratio of internal and external ion concentrations. As the plasma membrane of a real cell is not exclusively permeable to K^+ , however, the actual resting membrane potential is usually not exactly equal to that predicted by the Nernst equation for K^+ .

The Resting Potential Decays Only Slowly When the Na⁺-K⁺ Pump Is Stopped

Movement of only a minute number of inorganic ions across the plasma membrane through ion channels suffices to set up the membrane potential. Thus, we can think of the membrane potential as arising from movements of charge that

MBOC7_ptr_ch11_637-682.indd 655 08/12/21 11:47 AM

THE NERNST EQUATION AND ION FLOW

The flow of any inorganic ion through a membrane channel is driven by the electrochemical gradient for that ion. This gradient represents the combination of two influences: the voltage gradient and the concentration gradient of the ion across the membrane. When these two influences just balance each other, the electrochemical gradient for the ion is zero, and there is no *net* flow of the ion through the channel. The voltage gradient (membrane potential) at which this equilibrium is reached is called the equilibrium potential for the ion. It can be calculated from an equation that will be derived below, called the Nernst equation.

The Nernst equation is

$$V = \frac{RT}{zF} \ln \frac{C_o}{C_i}$$

where

V = the equilibrium potential in volts (internal potential minus external potential)

C_o and C_i = outside and inside concentrations of the ion, respectively

R =the gas constant (8.3 J mol⁻¹ K⁻¹)

T = the absolute temperature (K)

 $F = Faraday's constant (9.6 \times 10^4 J V^{-1} mol^{-1})$

z = the valence (charge) of the ion

In = logarithm to the base e

The Nernst equation is derived as follows:

A molecule in solution (a solute) tends to move from a region of high concentration to a region of low concentration simply due to the random movement of molecules, which results in their equilibrium. Consequently, movement down a concentration gradient is accompanied by a favorable free-energy change ($\Delta G < 0$), whereas movement up a concentration gradient is accompanied by an unfavorable free-energy change ($\Delta G > 0$). (Free energy is introduced in Chapter 2 and discussed in the context of redox reactions in Panel 14–1, p. 825.)

The free-energy change per mole of solute moved across the plasma membrane (ΔG_{conc}) is equal to $-RT \ln(C_o/C_i)$.

If the solute is an ion, moving it into a cell across a membrane whose inside is at a voltage V relative to the outside will cause an additional free-energy change (per mole of solute moved) of $\Delta G_{\text{volt}} = zFV$.

At the point where the concentration and voltage gradients just balance,

$$\Delta G_{\rm conc} + \Delta G_{\rm volt} = 0$$

and the ion distribution is at equilibrium across the membrane.

Thus.

$$zFV - RT \ln \frac{C_o}{C_i} = 0$$

and, therefore,

$$V = \frac{RT}{zF} \ln \frac{C_o}{C_i}$$

or, using the constant that converts natural logarithms to base 10,

$$V = 2.3 \frac{RT}{zF} \log_{10} \frac{C_0}{C_i}$$

For a univalent cation,

$$2.3 \frac{RT}{F} = 58 \text{ mV at } 20^{\circ}\text{C}$$
 and 61.5 mV at 37°C

Thus, for such an ion at 37°C,

$$V = +61.5 \text{ mV when } C_{o}/C_{i} = 10$$

whereas

$$V = 0$$
 when $C_0/C_i = 1$

The K^+ equilibrium potential (V_K), for example, is

$$61.5 \log_{10}([K^+]_o/[K^+]_i)$$
 millivolts

(–89 mV for a typical cell, where $[K^+]_o = 5$ mM and $[K^+]_i = 140$ mM).

At $V_{\rm K}$, there is no net flow of K⁺ across the membrane.

Similarly, when the membrane potential has a value of

which is the Na $^+$ equilibrium potential ($V_{\rm Na}$), there is no net flow of Na $^+$.

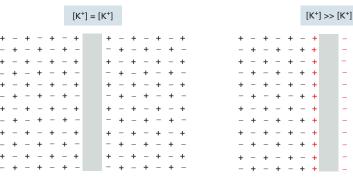

For any particular membrane potential, $V_{\rm M}$, the net force tending to drive a particular type of ion out of the cell is proportional to the difference between $V_{\rm M}$ and the equilibrium potential for the ion; hence,

for K⁺ it is
$$V_{\rm M} - V_{\rm K}$$

and for Na⁺ it is $V_{\rm M} - V_{\rm Na}$

When there is a voltage gradient across the membrane, the ions responsible for it—the excess positive ions on one side and the excess negative ions on the other—are concentrated in thin layers on either side of the membrane because of the attraction between positive and negative electric charges. The number of ions that go to form the layer of charge adjacent to the membrane is minute compared with the total number inside the cell. For example, the movement of 6000 Na+ ions across 1 μm^2 of membrane will carry sufficient charge to shift the membrane potential by about 100 mV.

Because there are about $6\times 10^6~Na^+$ ions in $1~\mu m^3$ of bulk cytoplasm, such a movement of charge will generally have a negligible effect on the ion concentration gradients across the membrane.

exact balance of charges on each side of the membrane; membrane potential = 0

a few of the positive ions (red) cross the membrane from right to left, leaving their negative counterions (red) behind; this sets up a nonzero membrane potential

leave ion *concentrations* practically unaffected and result in only a very slight discrepancy in the number of positive and negative ions on the two sides of the membrane (Figure 11–23). Moreover, these movements of charge are generally rapid, taking only a few milliseconds or less.

Consider the change in the membrane potential in a real cell after the sudden inactivation of the Na⁺-K⁺ pump. A slight drop in the membrane potential may occur immediately. This is because the pump is electrogenic and, when active, makes a small direct contribution to the membrane potential by pumping out three Na⁺ for every two K⁺ that it pumps in (see Figure 11-15). However, switching off the pump does not abolish the major component of the resting potential, which is generated by the K⁺ equilibrium mechanism just described. This component of the membrane potential persists as long as the Na⁺ concentration inside the cell stays low and the K⁺ ion concentration high—typically for many minutes. But the plasma membrane is somewhat permeable to all small ions, including Na⁺. Therefore, without the Na⁺-K⁺ pump, the ion gradients set up by the pump will eventually run down, and the membrane potential established by diffusion through the K⁺ leak channels will fall as well. As Na⁺ enters, the cell eventually comes to a new resting state where $\mathrm{Na}^+, \mathrm{K}^+,$ and Cl^- are all at equilibrium across the membrane. The membrane potential in this state is much less than it was in the normal cell with an active Na+-K+ pump.

The resting potential of an animal cell varies between -20 mV and -120 mV, depending on the organism and cell type. Although the $\rm K^+$ gradient always has a major influence on this potential, the gradients of other ions (and the disequilibrating effects of ion pumps) also have a significant effect: the more permeable the membrane for a given ion, the more strongly the membrane potential tends to be driven toward the equilibrium value for that ion. Consequently, changes in a membrane's relative permeability to different ions can cause significant changes in the membrane potential. This is one of the key principles relating the electrical excitability of cells to the activities of ion channels.

To understand how ion channels select their ions and how they open and close, we need to know their three-dimensional molecular structure. The first ion channel to be crystallized and studied by x-ray diffraction was a bacterial K^+ channel. The details of its structure revolutionized our understanding of ion channels.

The Three-dimensional Structure of a Bacterial K⁺ Channel Shows How an Ion Channel Can Work

Scientists were puzzled by the remarkable ability of ion channels to combine exquisite ion selectivity with a high conductance. K^+ leak channels, for example, conduct K^+ 10,000-fold faster than Na^+ , yet the two ions are both featureless spheres and have similar radii (0.133 nm and 0.095 nm, respectively). A single amino acid substitution in the pore of an animal cell K^+ channel can result in a loss

Figure 11-23 The ionic basis of a membrane potential. A small flow of inorganic ions through an ion channel carries sufficient charge to cause a large change in the membrane potential. The ions that give rise to the membrane potential lie in a thin (<1 nm) surface layer close to the membrane, held there by their electrical attraction to their oppositely charged counterparts (counterions) on the other side of the membrane. For a typical cell, 1 microcoulomb of charge (6 \times 10¹² monovalent ions) per square centimeter of membrane, transferred from one side of the membrane to the other side, changes the membrane potential by roughly 1 V This means, for example, that in a spherical cell of diameter 10 µm, the number of K+ ions that have to flow out to alter the membrane potential by 100 mV is only about 1/100,000 of the total number of K⁺ ions in the cytosol. This amount is so minute that the intracellular K concentration remains virtually unchanged.

MBOC7_ptr_ch11_637-682.indd 657 08/12/21 11:47 AM

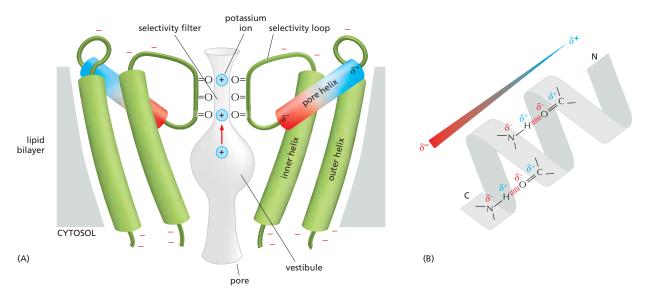

Figure 11–24 The structure of a bacterial K^+ channel. (A) The transmembrane α helices from only two of the four identical subunits are shown. From the cytosolic side, the pore (schematically shaded in *blue*) opens up into a vestibule in the middle of the membrane. The pore vestibule facilitates transport by allowing the K^+ ions to remain hydrated even though they are more than halfway across the membrane. The narrow selectivity filter of the pore links the vestibule to the outside of the cell. Carbonyl oxygens line the walls of the selectivity filter and form transient binding sites for partially dehydrated K^+ ions. Two K^+ ions occupy different sites in the selectivity filter, while a third K^+ ion is located in the center of the vestibule, where it is stabilized by electrical interactions including those contributed by the more negatively charged ends of the pore helices. The ends of the four short "pore helices" (only two of which are shown) point precisely toward the center of the vestibule, thereby guiding K^+ ions into the selectivity filter (Movie 11.8). (B) Peptide bonds have an electric dipole, with more negative charge accumulated at the oxygen of the C—O bond and at the nitrogen of the N—H bond. In an α helix, hydrogen bonds (*red*) align the dipoles. As a consequence, every α helix has an electric dipole along its axis, resulting from summation of the dipoles of the individual peptide bonds, with a more negatively charged C-terminal end (δ^-) and a more positively charged N-terminal end (δ^+). (A, adapted from D.A. Doyle et al., *Science* 280:69–77, 1998.)

of ion selectivity and cell death. We cannot explain the normal K^+ selectivity by pore size alone, because Na^+ is smaller than K^+ . Moreover, its high conductance rate is incompatible with the channel having selective, high-affinity K^+ -binding sites, as the binding of K^+ ions to such sites would greatly slow their passage.

The puzzle was solved when the structure of a *bacterial* K^+ *channel* was determined by x-ray crystallography. The channel is made from four identical transmembrane subunits, which together form a central pore through the membrane. Each subunit contributes two transmembrane α helices, which are tilted outward in the membrane and together form a cone, with its wide end facing the outside of the cell where K^+ ions exit from the channel (**Figure 11–24**). The polypeptide chain that connects the two transmembrane helices forms a short α helix (the *pore helix*) and a crucial loop that protrudes into the wide section of the cone to form the **selectivity filter**. The selectivity loops from the four subunits form a short, rigid, narrow pore, which is lined by the carbonyl oxygen atoms of their polypeptide backbones. Because the selectivity loops of all known K^+ channels have similar amino acid sequences, it is likely that they form a closely similar structure.

The structure of the selectivity filter explains the ion selectivity of the channel. A K^+ ion must lose almost all of its bound water molecules to enter the filter, where it interacts instead with the carbonyl oxygens lining the filter; the oxygens are rigidly spaced at the exact distance to accommodate a K^+ ion. An Na $^+$ ion, in contrast, cannot enter the filter because the carbonyl oxygens are too far away from the smaller Na $^+$ ion to compensate for the high energy expense associated with the loss of water molecules required for entry (Figure 11–25).

Structural studies of K^+ channels and other ion channels have also indicated some general principles of how these channels open and close. The gating involves movement of the helices in the membrane so that they either obstruct or open the path for ion movement. Depending on the particular type of channel,

MBOC7_ptr_ch11_637-682.indd 658 08/12/21 11:47 AM

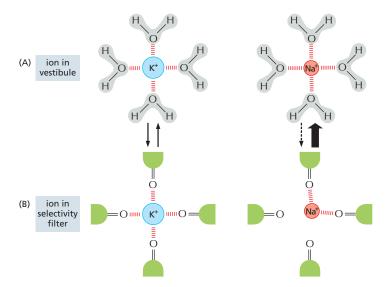

Figure 11-25 K⁺ specificity of the selectivity filter in a K+ channel. The drawings show K⁺ and Na⁺ ions (A) in the vestibule and (B) in the selectivity filter of the pore, viewed in cross section. In the vestibule, the ions are hydrated. In the selectivity filter, they have lost their water, and the carbonyl oxygens are placed to accommodate a dehydrated K⁺ ion. The dehydration of the K⁺ ion requires energy, which is precisely balanced by the energy regained by the interaction of the ion with all of the carbonyl oxygens that serve as surrogate water molecules. Because the Na⁺ ion is too small to interact with all the oxygens, it can enter the selectivity filter only at a great energetic expense. The filter therefore selects K+ ions with high specificity. (A, adapted from Y. Zhou et al., Nature 414:43-48, 2001.)

helices tilt, rotate, or bend during gating. The structure of a closed K⁺ channel shows that by tilting the inner helices, the pore constricts like a diaphragm at its cytosolic end (Figure 11–26). Bulky hydrophobic amino acid side chains block the small opening that remains, preventing the entry of ions.

Many other ion channels operate on similar principles: the channel's pore helices are allosterically coupled to sensor domains that in response, say, to ligand binding or altered membrane potential bring about conformational change in the ion-conducting pathway, either opening it or blocking it off.

Mechanosensitive Channels Allow Cells to Sense Their Physical Environment

All organisms, from single-cell bacteria to multicellular animals and plants, must sense and respond to mechanical forces both in their external environment (such as sound, touch, pressure, shear forces, and gravity) and in their internal environment (such as osmotic pressure and membrane bending). Numerous proteins are known to be capable of responding to such mechanical forces, and a large subset of those proteins has been identified as possible **mechanosensitive channels**, but very few of the candidate proteins have been shown directly to be mechanically activated ion channels. One reason for this dearth in our knowledge is that most such channels are extremely rare. Auditory hair cells in the human cochlea, for example, contain extraordinarily sensitive mechanically gated ion channels, but each of the approximately 15,000 individual hair cells is thought to have a total of only 50–100 of them (Movie 11.9 and Movie 11.10). Additional difficulties arise because the gating mechanisms of many mechanosensitive channel types require the channels to

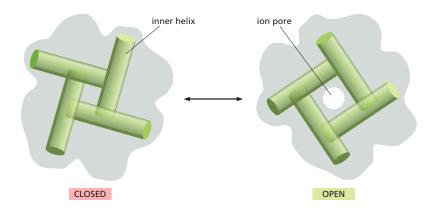

Figure 11–26 A model for the gating of a bacterial K⁺ channel. The channel is viewed in cross section. To adopt the closed conformation, the four inner transmembrane helices that line the pore on the cytosolic side of the selectivity filter (see Figure 11–24) rearrange to close the cytosolic entrance to the channel. (Adapted from E. Perozo et al., *Science* 285:73–78, 1999.)

MBOC7_ptr_ch11_637-682.indd 659 08/12/21 11:47 AM

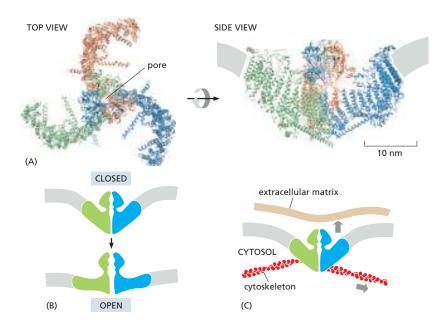

Figure 11-27 Stretch-activated Piezo channels. (A) The structure of Piezo1. Three identical subunits surround the central pore (left). The three large arm domains extend from the center and bend the membrane into a dome (right). (B) When the membrane is stretched, the dome-like protrusion flattens and the central pore opens. (C) By coupling Piezo channels to tethers on either side of the membrane (for example, to the extracellular matrix or the cytoskeleton), Piezo channels can be opened in response to extracellular or intracellular mechanical forces (arrows). (A, PDB code: 6B3R. Adapted from Y.R. Guo and R. MacKinnon, eLife 6:e33660. 2017. This article is distributed under the terms of the Creative Commons Attribution

be embedded in complex architectures that require attachment to the extracellular matrix or to the cytoskeleton, and this is difficult to reconstitute in the test tube.

To fill this gap in our knowledge, scientists used patch clamping to identify cell lines that would open an ion channel when mechanical pressure was applied to them. They then reasoned that a mechanosensitive channel would need to contain at least two membrane-spanning helices and proceeded to systematically disrupt expression of genes encoding such proteins. One such disruption caused the cells to lose their response to mechanical stimuli and identified two genes that code for related proteins. Each of these proteins contains more than 30 membrane-spanning helices, but neither shows any sequence similarity to other known ion channels. Three identical copies of either of these proteins can assemble into a mechanosensitive Piezo ion channel that lies in the plasma membranes of numerous types of animal cells (Figure 11-27). Each of the three subunits of a Piezo channel contains a large arm built from 36 transmembrane helices. The arms extend outward from a central hub that contains the channel's ion-conducting pore. The particular packing of the wing helices deforms the membrane into a dome. In this resting state, the Piezo channel is closed. When the membrane becomes stretched by mechanically pushing on the plasma membrane elsewhere, the resulting membrane tension pulls the deformation flat, which opens the channel's central pore.

Piezo channels in skin cells are required for touch sensation, and in bladder cells they detect when the bladder is full. But their importance is far greater than that. Animals that lack Piezo channels die in development because many developmental processes, such as formation of the vasculature, rely on mechanical stretching cues. Piezo channels also provide second-to-second control of blood pressure. Nerve cells in the aortic arch and carotid artery contain Piezo channels and are highly sensitive to stretch that results from increased blood pressure. In response, they signal to immediately slow the heart rate. In this way, the blood pressure falls, preventing life-threatening consequences from vessel damage or rupture. Conversely, acutely reduced blood pressure, as might occur upon getting up or bending over, stops the firing of these same nerve cells and increases the heart rate and peripheral vasoconstriction, which in turn prevents loss of consciousness by increasing blood flow to the brain.

Another well-studied class of mechanosensitive channels is found in the bacterial plasma membrane. These channels open in response to mechanical stretching of the lipid bilayer in which they are embedded. When a bacterium experiences a low-ionic-strength external environment (hypotonic conditions), such as rainwater, the cell swells as water seeps in due to the increased osmotic

MBOC7_ptr_ch11_637-682.indd 660 08/12/21 11:47 AM

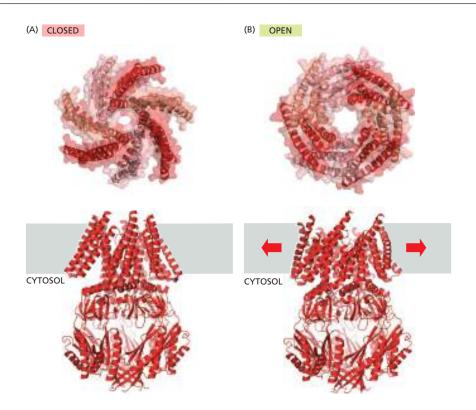

Figure 11–28 The structure of bacterial mechanosensitive channels. The crystal structures of MscS in its (A) closed and (B) open conformation are shown. The side views (lower panels) show the entire protein, including the large intracellular domain. The face views (upper panels) show the transmembrane domains only. The open structure occupies more area in the lipid bilayer and is energetically favored when a membrane is stretched. This may explain why the MscS channel opens as pressure builds up inside the cell. (PDB codes: 2OAU, 2VV5.)

pressure. If the pressure rises to dangerous levels, the cell opens mechanosensitive channels that allow small molecules to leak out. Bacteria that are experimentally placed in fresh water can rapidly lose more than 95% of their small molecules in this manner, including amino acids, sugars, and potassium ions. However, they keep their macromolecules safely inside and thus can recover quickly after environmental conditions return to normal.

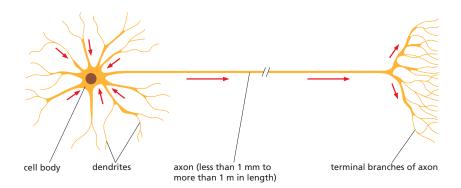

Mechanical gating has been demonstrated using biophysical techniques in which force is exerted on pure lipid bilayers containing the bacterial mechanosensitive channels; for example, by applying suction with a micropipette. Such measurements demonstrate that the cell has several different channels that open at different levels of pressure. The mechanosensitive channel of small conductance, called the MscS channel, opens at low and moderate pressures (Figure 11–28). It is composed of seven identical subunits, which in the open state form a pore about 1.3 nm in diameter—just big enough to pass ions and small molecules. Large cytoplasmic domains limit the size of molecules that can reach the pore. The mechanosensitive channel of large conductance, called the MscL channel, opens to more than 3 nm in diameter when the pressure gets so high that the cell might burst.

The Function of a Neuron Depends on Its Elongated Structure

The cells that make the most sophisticated use of channels are neurons. Before discussing how they do so, we digress briefly to describe how a typical neuron is organized.

The fundamental task of a **neuron**, or **nerve cell**, is to receive, integrate, conduct, and transmit signals. To perform these functions, neurons are often extremely elongated. In humans, for example, a single neuron extending from the spinal cord to a muscle in the foot may be as long as 1 meter. Every neuron consists of a cell body (containing the nucleus) with a number of thin processes radiating outward from it. Usually one long **axon** conducts signals away from the cell body toward distant targets, and several shorter, branching **dendrites** extend from the cell body like antennae, providing an enlarged surface area to receive

MBOC7_ptr_ch11_637-682.indd 661 08/12/21 11:47 AM

neuron. The arrows indicate the direction in which signals are conveyed. The single axon conducts signals away from the cell body, while the multiple dendrites (and the cell body) receive signals from the axons of

Figure 11-29 A typical vertebrate

body, while the multiple dendrites (and the cell body) receive signals from the axons of other neurons. The axon terminals end on the dendrites or cell body of other neurons or on other cell types, such as muscle or gland cells.

signals from the axons of other neurons (Figure 11–29), although the cell body itself also receives such signals. A typical axon divides at its far end into many branches, passing on its message to many target cells simultaneously. Likewise, the extent of branching of the dendrites can be very great—in some cases sufficient to receive as many as 100,000 inputs on a single neuron.

Despite the varied significance of the signals carried by different classes of neurons, the form of the conducted signal is always the same, consisting of changes in the electrical potential across the neuron's plasma membrane. The signal spreads because an electrical disturbance produced in one part of the membrane spreads to other parts, although the disturbance becomes weaker with increasing distance from its source, unless the neuron expends energy to amplify it as it travels. Over short distances, this attenuation is unimportant; in fact, many small neurons conduct their signals passively, without amplification. For long-distance communication, however, such passive spread is inadequate. Thus, larger neurons employ an active signaling mechanism, which is one of their most striking features. An electrical stimulus that exceeds a certain threshold strength triggers an explosion of electrical activity that propagates rapidly along the neuron's plasma membrane and is sustained by automatic amplification all along the way. This traveling wave of electrical excitation, known as an action potential, or nerve impulse, can carry a message without attenuation from one end of a neuron to the other at speeds of 100 meters per second or more. Action potentials are the direct consequence of the properties of voltage-gated cation channels, as we now discuss.

Voltage-gated Cation Channels Generate Action Potentials in Electrically Excitable Cells

The plasma membrane of all electrically excitable cells—not only neurons, but also muscle, endocrine, and egg cells—contains voltage-gated cation channels, which are responsible for generating the action potentials. An action potential is triggered by a depolarization of the plasma membrane; that is, by a shift in the membrane potential to a less negative value inside. (We shall see later how the action of some neurotransmitters causes depolarization.) In nerve and skeletal muscle cells, a stimulus that causes sufficient depolarization promptly opens the voltage-gated Na⁺ channels, allowing a small amount of Na⁺ to enter the cell down its electrochemical gradient. The influx of positive charge depolarizes the membrane further, thereby opening more Na⁺ channels, which admit more Na^+ ions, causing still further depolarization. This self-amplification process (an example of positive feedback, discussed in Chapters 8 and 15) continues until, within a fraction of a millisecond, the electrical potential in the local region of the membrane has shifted from its resting value of about -70 mV to almost as far as the Na⁺ equilibrium potential of about +50 mV (see Panel 11-1, p. 656). At this point, when the net electrochemical driving force for the flow of Na⁺ is almost zero, the cell would come to a new resting state, with all of its Na⁺ channels permanently open, if the open conformation of the channel were stable. Two mechanisms act in concert to save the cell from such a permanent electrical spasm: the Na⁺

MBOC7_ptr_ch11_637-682.indd 662 08/12/21 11:47 AM

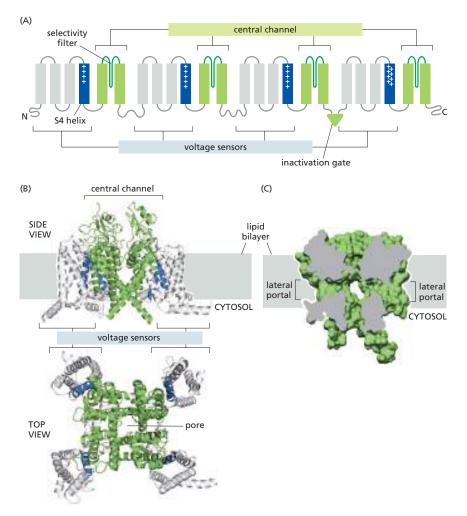

Figure 11-30 Structural models of voltage-gated Na+ channels. (A) The channel in animal cells is built from a single polypeptide chain that contains four homologous domains. Each domain contains two transmembrane α helices (green) that surround the central ionconducting pore. They are separated by sequences (dark green) that form the selectivity filter. Four additional $\boldsymbol{\alpha}$ helices (blue and gray) in each domain constitute the voltage sensor. The S4 helices (blue) are unique in that they contain an abundance of positively charged arginines. An inactivation gate that is part of a flexible loop connecting the third and fourth domains acts as a plug that obstructs the pore in the channel's inactivated state, as shown in Figure 11-32C. (B) Side and top views of a channel protein showing its arrangement within the membrane. (C) A cross section of the pore domain of the channel shown in B shows lateral portals, through which the central cavity is accessible from the hydrophobic core of the lipid bilayer. In the crystals, lipid acyl chains were found to intrude into the pore. These lateral portals are large enough to allow entry of small, hydrophobic, pore-blocking drugs that are commonly used as local anesthetics and block ion conductance. (PDB code: 6AGF.)

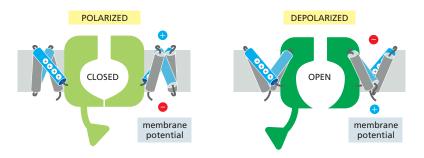

channels automatically inactivate, and **voltage-gated** K⁺ **channels** open to restore the membrane potential to its initial negative value.

The Na^+ channel is built from a single polypeptide chain that contains four structurally very similar domains. It is thought that these domains evolved by gene duplication followed by fusion into a single large gene (Figure 11–30A). In bacteria, in fact, the Na^+ channel is a tetramer of four identical polypeptide chains, supporting this evolutionary idea. The structure of the voltage-gated Na^+ channel provides insights into how the structural elements are arranged in the membrane (Figure 11–30B and C).

Each domain contributes to the central channel, which is very similar to the K^+ channel. Each domain also contains a *voltage sensor* that is characterized by an unusual transmembrane helix, S4, that contains many positively charged amino acids. When the membrane is polarized, these charges are exposed on the negatively charged cytosolic side of the membrane. Because of the charge compensation, this conformation is thermodynamically stabilized in a polarized membrane. As the membrane becomes depolarized, the S4 helices experience the electrostatic force that now stabilizes an alternative conformation in which the helices have twisted and expose the charges to the opposite, extracellular side of the membrane. The resulting conformational change opens the channel (Figure 11–31). It is estimated from energetic calculations that the exposure to the alternate side of the membrane can change the probability of the channel being in an open or closed state by many orders of magnitude.

The $\mathrm{Na^+}$ channels also have an automatic inactivating mechanism, which causes the channels to reclose rapidly even though the membrane is still depolarized (see Figure 11–32). The $\mathrm{Na^+}$ channels remain in this *inactivated* state, unable

MBOC7_ptr_ch11_637-682.indd 663 08/12/21 11:47 AM

to reopen, until after the membrane potential has returned to its initial negative value. Repolarization of the membrane requires opening of additional channels, the **delayed** K⁺ **channels**. These channels also open in response to membrane depolarization (that is, they are also voltage-gated), but because of their slower kinetics they open only during the falling phase of the action potential, when the Na⁺ channels are inactive, but with a delay of a few hundred microseconds. When these channels open, K⁺ rushes out of the cell until the cell's resting potential is restored within a millisecond or two. The time necessary for a sufficient number of Na⁺ channels to recover from inactivation to support a new action potential, termed the *refractory period*, limits the repetitive firing rate of a neuron and ensures that an action potential propagates unidirectionally. The Na⁺ channel can therefore exist in three distinct states—closed, open, and inactivated—which contribute to the rise and fall of the action potential (**Figure 11–32**). The cycle from initial stimulus to the return to the original resting state takes a few milliseconds or less.

This description of an action potential applies only to a small patch of plasma membrane. The self-amplifying depolarization of the patch, however, is sufficient

Figure 11–31 Model for the mechanism of voltage-gating. The voltage-sensing domain oscillates between two conformational states that expose positively charged arginines on one helix (corresponding to the S4 helix in Figure 11–30) to alternate sides of the membrane. Exposure to the more negatively charged side of the membrane is thermodynamically favored and hence stabilizes that state. Conformational coupling closes or opens the gate in the central pore domain of the channel. (Adapted from A.F. Kintzer et al., *Proc. Natl. Acad. Sci. USA* 115:E9095–E9104, 2018.)

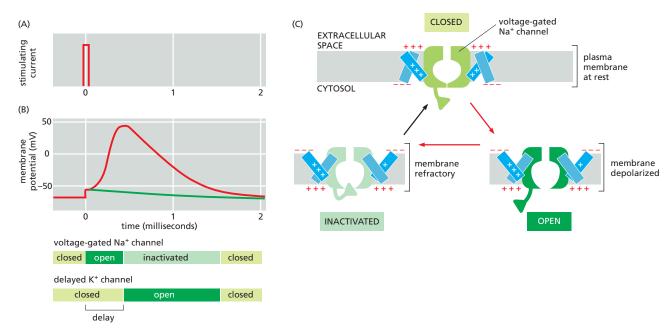

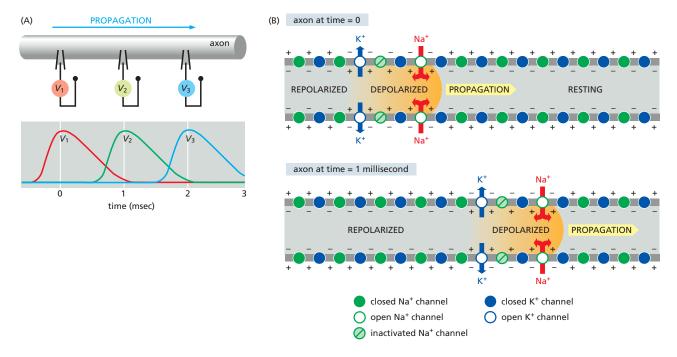

Figure 11–32 Na⁺ channels and an action potential. (A) An action potential is triggered by a brief pulse of current, which (B) partially depolarizes the membrane, as shown in the plot of membrane potential versus time. The *green curve* shows how the membrane potential would have simply relaxed back to the resting value after the initial depolarizing stimulus if there had been no voltage-gated Na⁺ channels in the membrane. The ascending part of the *red curve* shows the course of the action potential that is caused by the opening of voltage-gated Na⁺ channels. Delayed voltage-gated K⁺ channels open and Na⁺ channels become inactivated, allowing membrane repolarization (the descending part of the *red curve*). The states of the Na⁺ and K⁺ channels are indicated in the schematic in the bottom part of panel B. The membrane cannot fire a second action potential until the Na⁺ channels have returned from the inactivated to the closed conformation; until then, the membrane is refractory to stimulation. (C) The three states of the Na⁺ channel. When the membrane is at rest (highly polarized), the closed conformation of the channel has the lowest free energy and is therefore most stable; when the membrane is depolarized, the energy of the *open* conformation is lower, so the channel has a high probability of opening. But the free energy of the *inactivated* conformation is lower still; therefore, after a randomly variable period spent in the open state, the channel becomes inactivated. Thus, the open conformation corresponds to a metastable state that can exist only transiently when the membrane depolarizes (Movie 11.11).

MBOC7_ptr_ch11_637-682.indd 664 08/12/21 11:47 AM

to depolarize neighboring regions of membrane, which then go through the same cycle. In this way, the action potential sweeps like a wave from the initial site of depolarization over the entire plasma membrane, as shown in **Figure 11–33**.

Albeit small, the ion flow during an action potential is not negligible. Especially during rapid firing and in small axon branches with a high surface-to-volume ratio, the Na⁺-K⁺ pump speeds up locally to restore the electrochemical gradients. Brain positron emission tomography (for example, in a PET scan) visualizes regions of the brain whose metabolism is raised when performing a particular task. In this procedure, neurons that have a high energy consumption due to their accelerated ion pumping activity preferentially take up glucose, supplied as a radioactive tracer, to replenish the ATP expended by the Na⁺-K⁺ pump. The enrichment of the radioactive glucose is then imaged in a three-dimensional brain scan. In this way, the Na⁺-K⁺ pump serves as a sentinel in the noninvasive mapping of brain regions associated with particular brain activities (Figure 11–34).

Figure 11-33 The propagation of an action potential along an axon. (A) The voltages that would be recorded from a set of intracellular electrodes placed at intervals along the axon. (B) The changes in the Na+ channels, voltage-gated K+ channels, and current flows (red and blue arrows) that give rise to a traveling action potential. The region of the axon with a depolarized membrane is shaded in orange. Note that once an action potential has started to progress, it has to continue in the same direction, traveling only away from the site of depolarization, because Na+-channel inactivation prevents the depolarization from spreading backward.

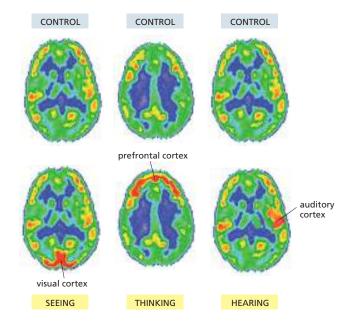

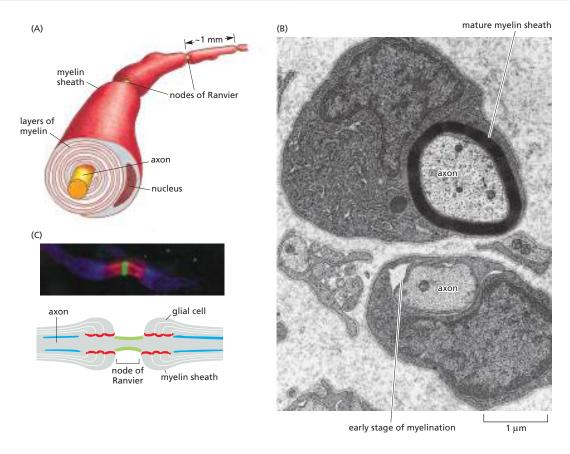

Figure 11–34 These scans noninvasively image the radiation signal derived from an injected tracer molecule. The images report on brain regions with the highest metabolic energy expenditure (red), which reflects the activity of the Na⁺-K⁺ pump consuming ATP while laboring to restore the membrane potential in axons engaged in massive electrical signaling. Myelination Increases the Speed and Efficiency of Action Potential Propagation in Nerve Cells

The axons of many vertebrate neurons are insulated by a **myelin sheath**, which greatly increases the speed at which an axon can conduct an action potential. The importance of myelination is dramatically demonstrated by the demyelinating disease *multiple sclerosis*, in which the immune system destroys myelin sheaths in some regions of the central nervous system; in the affected regions, nerve impulse propagation greatly slows or fails, often with devastating neurological consequences.

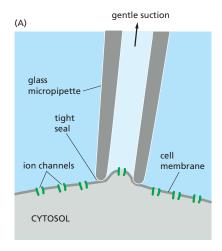

Myelin is formed by specialized non-neuronal supporting cells called **glial cells**. **Schwann cells** are the glial cells that myelinate axons in peripheral nerves, and **oligodendrocytes** do so in the central nervous system. These myelinating glial cells wrap layer upon layer of their own plasma membrane in a tight spiral around the axon (**Figure 11–35A and B**), thereby insulating the axonal membrane so that little current can leak across it. The myelin sheath is interrupted at regularly spaced *nodes of Ranvier*, where almost all the Na⁺ channels in the axon are concentrated (**Figure 11–35C**). This arrangement allows an action potential to propagate along a myelinated axon by jumping from node to node, a process called *saltatory conduction*. This type of conduction has two main advantages: action potentials travel very much faster, and metabolic energy is conserved because the active excitation is confined to the small regions of axonal plasma membrane at nodes of Ranvier.

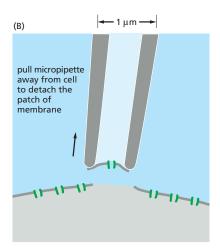

Patch-Clamp Recording Indicates That Individual Ion Channels Open in an All-or-Nothing Fashion

Neuron and skeletal muscle cell plasma membranes contain many thousands of voltage-gated Na⁺ channels, and the current crossing the membrane is the sum of the currents flowing through all of these. An intracellular microelectrode can record this aggregate current. Remarkably, however, it is also possible to record

Figure 11-35 Myelination. (A) A myelinated axon from a peripheral nerve. Each Schwann cell wraps its plasma membrane spirally around the axon to form a segment of myelin sheath about 1 mm long. For clarity, the membrane layers of the myelin are shown less compacted than they are in reality (see panel B). (B) An electron micrograph of a nerve in the leg of a young rat. Two Schwann cells can be seen: one near the bottom is just beginning to myelinate its axon; the one above it has formed an almost mature myelin sheath. (C) Fluorescence micrograph and diagram of an individual myelinated axon teased apart in a rat optic nerve, showing the confinement of the voltage-gated Na+ channels (green) to the axonal membrane at the node of Ranvier. A protein called Caspr (red) marks the junctions where the myelinating glial-cell plasma membrane tightly abuts the axon on either side of the node. Voltage-gated K⁺ channels (blue) localize to regions in the axonal plasma membrane well away from the node. [B, from C.S. Raine, in Myelin, 2nd ed. (P. Morell, ed.). New York: Plenum, 1984. MBOC7_ptr_ch11_637-682.indd 666 08/12/21 11:47 AM

current flowing through individual channels. Patch-clamp recording, developed in the 1970s and 1980s, revolutionized the study of ion channels and made it possible to examine transport through a single channel in a small patch of membrane covering the mouth of a micropipette (Figure 11–36). With this simple but powerful technique, one can study the detailed properties of ion channels in all sorts of cell types. This work led to the discovery that even cells that are not electrically excitable usually have a variety of ion channels in their plasma membrane. Many of these cells, such as yeasts, are too small to be investigated by the traditional electrophysiologist's method of impalement with an intracellular microelectrode.

Patch-clamp recording indicates that individual ion channels open in an all-or-nothing fashion. For example, a voltage-gated Na⁺ channel opens and closes stochastically with a voltage-dependent probability, but when open, the channel always has the same large conductance, allowing more than 1000 ions to pass per millisecond (Figure 11–37). Therefore, the aggregate current crossing the membrane of an entire cell does not indicate the *degree* to which a typical individual channel is open but rather the *total number* of channels in its membrane that are open at any one time.

Some simple physical principles allow us to refine our understanding of voltage-gating from the perspective of a single Na⁺ channel. The interior of the resting neuron or muscle cell is at an electrical potential about 40–100 mV more negative than the external medium. Although this potential difference seems small, it exists across a plasma membrane only about 5 nm thick, so that the resulting voltage gradient is about 100,000 V/cm. Charged proteins in the membrane such as Na⁺ channels are thus subjected to a very large electrical field that can profoundly affect their conformation. Each conformation can "flip" to another conformation if given a sufficient jolt by the random thermal movements of the surroundings, and it is the relative stability of the closed, open, and inactivated

Figure 11-37 Patch-clamp measurements for a single voltage-gated Na+ channel. A tiny patch of plasma membrane was detached from an embryonic rat muscle cell, as in Figure 11-36. (A) The membrane was depolarized by an abrupt shift of potential from -90 to about -40 mV. (B) Three current records from three experiments performed on the same patch of membrane. Each major current step in panel B represents the opening and closing of a single channel. A comparison of the three records shows that, whereas the durations of channel opening and closing vary greatly, the rate at which current flows through an open channel (its conductance) is practically constant. The minor fluctuations in the current records arise largely from electrical noise in the recording apparatus. Current flowing into the cell, measured in picoamperes (pA), is shown as a downward deflection of the curve. By convention, the electrical potential on the outside of the cell is defined as zero. (C) The sum of the currents measured in 144 repetitions of the same experiment. This aggregate current is equivalent to the usual Na+ current that would be observed flowing through a relatively large region of membrane containing 144 channels. A comparison of panels B and C reveals that the time course of the aggregate current reflects the probability that any individual channel will be in the open state; this probability decreases with time as the channels in the depolarized membrane adopt their inactivated conformation. (Data from J. Patlak and R. Horn, J. Gen. Physiol. 79:333-351, 1982.)

Figure 11-36 The technique of patch-clamp recording. Because of the extremely tight seal between the micropipette and the membrane, current can enter or leave the micropipette only by passing through the ion channels in the patch of membrane covering its tip. The term clamp is used because an electronic device is employed to maintain, or "clamp," the membrane potential at a set value while recording the ionic current through individual channels. The current through these channels can be recorded with the patch still attached to the rest of the cell, as in (A), or detached, as in (B). The advantage of the detached patch is that it is easy to alter the composition of the solution on either side of the membrane to test the effect of various solutes on channel behavior. A detached patch can also be produced with the opposite orientation. so that the cytoplasmic surface of the membrane faces the inside of the pipette.

MBOC7_ptr_ch11_637-682.indd 667 08/12/21 11:47 AM

conformations against flipping that is altered by changes in the membrane potential (see Figure 11–32C).

Voltage-gated Cation Channels Are Evolutionarily and Structurally Related

Na⁺ channels are not the only kind of voltage-gated cation channel that can generate an action potential. The action potentials in some muscle, egg, and endocrine cells, for example, depend on *voltage-gated Ca²⁺ channels* rather than on Na⁺ channels.

There is a surprising amount of structural and functional diversity within each of the different classes of voltage-gated cation channels, generated both by multiple genes and by the alternative splicing of RNA transcripts produced from the same gene. Nonetheless, the amino acid sequences and structures of the known voltage-gated Na $^+$, K $^+$, and Ca $^{2+}$ channels show striking similarities, demonstrating that they all belong to a large superfamily of evolutionarily and structurally related proteins and share many of the design principles. Whereas the single-celled yeast $Saccharomyces\ cerevisiae$ contains a single gene that codes for a voltage-gated K $^+$ channel, the genome of the worm $Caenorhabditis\ elegans$ contains 68 genes that encode different but related K $^+$ channels. This complexity indicates that even a simple nervous system made up of only 302 neurons uses a large number of different ion channels to compute its responses.

Humans carrying mutations in genes encoding ion channels can suffer from a variety of nerve, muscle, brain, kidney, or heart diseases, depending on the cells in which the mutant channel is expressed. Mutations in genes that encode voltage-gated Na⁺ channels in skeletal muscle cells, for example, can cause *myotonia*, a condition in which there is a delay in muscle relaxation after voluntary contraction, causing painful muscle spasms. In some cases, this occurs because the abnormal channels fail to inactivate normally; as a result, Na⁺ entry persists after an action potential finishes and repeatedly reinitiates membrane depolarization and muscle contraction. Similarly, mutations that affect Na⁺ or K⁺ channels in the brain can cause *epilepsy*, in which excessive synchronized firing of large groups of neurons causes epileptic seizures (convulsions, or fits).

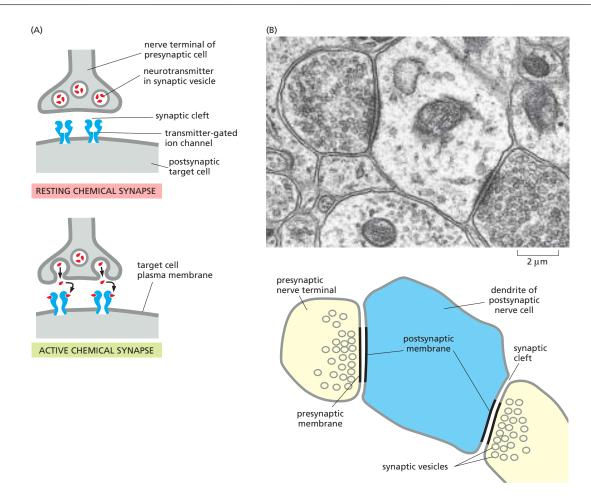

The particular combination of ion channels conducting $\mathrm{Na^+}$, $\mathrm{K^+}$, and $\mathrm{Ca^{2^+}}$ that are expressed in a neuron largely determines how the cell fires repetitive sequences of action potentials. Some neurons can repeat action potentials up to 300 times per second; other neurons fire short bursts of action potentials separated by periods of silence; while others rarely fire more than one action potential at a time. There is a remarkable diversity of neurons in the brain.

Different Neuron Types Display Characteristic Stable Firing Properties

It is estimated that the human brain contains about 10^{11} neurons and 10^{14} synaptic connections. To make matters more complex, neural circuitry is continually sculpted in response to experience, modified as we learn and store memories, and irreversibly altered by the gradual loss of neurons and their connections as we age. How can a system so complex be subject to such change and yet continue to function stably? One emerging theory suggests that individual neurons are self-tuning devices, constantly adjusting the expression of ion channels and neurotransmitter receptors in order to maintain a stable function. How might this work?

Neurons can be categorized into functionally different types, based in part on their propensity to fire action potentials and their pattern of firing. For example, some neurons can fire action potentials at high frequencies, whereas others fire rarely. The firing properties of each neuron type are determined to a large extent by the ion channels that the cell expresses. The number of ion channels in a neuron's membrane is not fixed: as conditions change, a neuron can modify the numbers of depolarizing (Na $^+$ and Ca $^{2+}$) and hyperpolarizing (K $^+$) channels and keep their proportions adjusted so as to maintain its characteristic firing behavior—a remarkable example of homeostatic control. Deciphering the molecular mechanisms involved remains an important challenge.

MBOC7_ptr_ch11_637-682.indd 668 08/12/21 11:47 AM

Transmitter-gated Ion Channels Convert Chemical Signals into Electrical Ones at Chemical Synapses

Neuronal signals are transmitted from cell to cell at specialized sites of contact known as synapses. The usual mechanism of transmission is indirect. The cells are anatomically and electrically isolated from one another, the presynaptic cell being separated from the postsynaptic cell by a narrow synaptic cleft. When an action potential arrives at the presynaptic site, the depolarization of the membrane opens voltage-gated Ca²⁺ channels that are clustered in the presynaptic membrane. Ca²⁺ influx triggers the release into the cleft of small signal molecules known as neurotransmitters that are stored in membrane-enclosed synaptic vesicles and released by exocytosis (discussed in Chapter 13). The neurotransmitter diffuses rapidly across the synaptic cleft and provokes an electrical change in the postsynaptic cell by binding to and opening transmitter-gated ion channels (Figure 11–38). After the neurotransmitter has been secreted, it is rapidly removed: it is either destroyed by specific enzymes in the synaptic cleft or, more commonly, taken up by the presynaptic nerve terminal or by surrounding glial cells. Reuptake is mediated by a variety of Na⁺-dependent neurotransmitter symporters (see Figure 11-8); in this way, neurotransmitters are recycled, allowing cells to keep up with high rates of release. Rapid removal ensures both spatial and temporal precision of signaling at a synapse. It decreases the chances that the neurotransmitter will influence neighboring cells, and it clears the synaptic cleft before the next pulse of neurotransmitter is released, so that the timing of repeated, rapid signaling events can be accurately communicated to the postsynaptic cell.

Transmitter-gated ion channels, also called **ionotropic receptors**, rapidly convert extracellular chemical signals into electrical signals at chemical synapses. The channels are concentrated in a specialized region of the postsynaptic

Figure 11-38 A chemical synapse.

(A) When an action potential reaches the nerve terminal in a presynaptic cell, it stimulates the terminal to release its neurotransmitter. The neurotransmitter molecules are contained in synaptic vesicles and are released to the cell exterior when the vesicles fuse with the plasma membrane of the nerve terminal. The released neurotransmitter binds to and opens the transmitter-gated ion channels concentrated in the plasma membrane of the postsynaptic target cell at the synapse. The resulting ion flows alter the membrane potential of the postsynaptic membrane, thereby transmitting a signal from the excited nerve (Movie 11.12). (B) A thin-section electron micrograph and an interpretive drawing of two nerve terminal synapses on a dendrite of a postsynaptic cell. (B, micrograph courtesy of Cedric Raine.)

MBOC7_ptr_ch11_637-682.indd 669 08/12/21 11:47 AM

plasma membrane at the synapse and open transiently in response to the binding of neurotransmitter molecules, thereby producing a brief permeability change in the membrane (see Figure 11–38A). Unlike the voltage-gated channels responsible for action potentials, transmitter-gated channels are relatively insensitive to the membrane potential and therefore cannot by themselves produce a self-amplifying excitation. Instead, they produce local permeability increases, and hence changes of membrane potential, that are graded according to the amount of neurotransmitter released at the synapse and how long it persists there. Only if the summation of small depolarizations at this site opens sufficient numbers of nearby voltage-gated cation channels can an action potential be triggered. This may require the opening of transmitter-gated ion channels at numerous synapses in close proximity on the target nerve cell.

Chemical Synapses Can Be Excitatory or Inhibitory

Transmitter-gated ion channels differ from one another in several important ways. First, as receptors, they have highly selective binding sites for the neurotransmitter that is released from the presynaptic nerve terminal. Second, as channels, they are selective in the type of ions that they let pass across the plasma membrane; this determines the nature of the postsynaptic response. Most excitatory neurotransmitters open nonselective cation channels, causing an influx of Na⁺, as well as Ca²⁺ and K⁺, that depolarizes the postsynaptic membrane toward the threshold potential for firing an action potential. The reason they are excitatory despite K⁺ efflux is because of the different driving forces that preferentially act on Na⁺ and Ca²⁺. **Inhibitory neurotransmitters**, by contrast, open Cl⁻ channels, and this suppresses firing by making it harder for excitatory neurotransmitters to depolarize the postsynaptic membrane. Many transmitters can be either excitatory or inhibitory, depending on where they are released, what receptors they bind to, and the ionic conditions that they encounter. Acetylcholine, for example, can either excite or inhibit, depending on the type of acetylcholine receptor it binds to. Usually, however, acetylcholine and glutamate are used as excitatory transmitters, and γ-aminobutyric acid (GABA) and glycine are used as inhibitory transmitters. Glutamate, for instance, mediates most of the excitatory signaling in the vertebrate brain.

We have already discussed how the opening of Na⁺ or Ca²⁺ channels depolarizes a membrane. The opening of K⁺ channels has the opposite effect because the K⁺ concentration gradient is in the opposite direction—high concentration inside the cell, low outside. The movement of the cell's membrane potential to a more negative value is called **hyperpolarization**. Opening K⁺ channels tends to keep the cell close to the equilibrium potential for K^{+} , which, as we discussed earlier, is normally close to the resting membrane potential because at rest K⁺ channels are the main type of channel that is open. When additional K⁺ channels open, it becomes harder to drive the cell away from the resting potential. We can understand the effect of opening Cl⁻ channels similarly. The concentration of Cl⁻ is much higher outside the cell than inside (see Table 11-1, p. 638), but the membrane potential opposes its influx. In fact, for many neurons, the equilibrium potential for Cl⁻ is close to the resting potential—or even more negative. For this reason, opening of Cl⁻ channels tends to buffer the membrane potential; as the membrane starts to depolarize, more negatively charged Cl⁻ions enter the cell and counteract the depolarization. Thus, the opening of Cl⁻ channels makes it more difficult to depolarize the membrane and hence to excite the cell. Some powerful toxins act by blocking the action of inhibitory neurotransmitters: strychnine, for example, binds to glycine receptors and prevents their inhibitory action, causing muscle spasms, convulsions, and death.

However, not all chemical signaling in the nervous system operates through these ionotropic ligand-gated ion channels. In fact, most neurotransmitter molecules that are secreted by nerve terminals, including a large variety of neuropeptides, bind to **metabotropic receptors**, which regulate ion channels only indirectly through the action of small intracellular signal molecules (discussed in Chapter 15). All neurotransmitter receptors fall into one or other of these

MBOC7_ptr_ch11_637-682.indd 670 08/12/21 11:47 AM

two major classes—ionotropic or metabotropic—on the basis of their signaling mechanisms:

- Ionotropic receptors are ion channels that appear at fast chemical synapses.
 Acetylcholine, glycine, glutamate, and GABA all act on transmitter-gated
 ion channels, mediating excitatory or inhibitory signaling that is generally
 immediate, simple, and brief.
- 2. Metabotropic receptors are *G-protein-coupled receptors* (discussed in Chapter 15) that bind to all other neurotransmitters (and, confusingly, also to acetylcholine, glutamate, and GABA). Signaling mediated by ligand-binding to metabotropic receptors tends to be far slower and more complex than that at ionotropic receptors, and longer-lasting in its consequences.

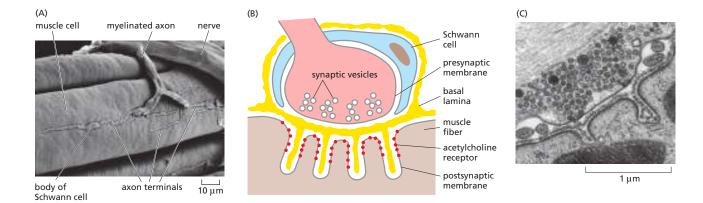

The Acetylcholine Receptors at the Neuromuscular Junction Are Excitatory Transmitter—gated Cation Channels

A well-studied example of a transmitter-gated ion channel is the acetylcholine receptor of vertebrate skeletal muscle cells. This channel is opened transiently by acetylcholine released from the nerve terminal at a neuromuscular junction—the specialized chemical synapse between a motor neuron and a skeletal muscle cell (Figure 11–39). This synapse has been intensively investigated because it is readily accessible to electrophysiological study, unlike most of the synapses in the central nervous system (that is, the brain and spinal cord in vertebrates). Moreover, the acetylcholine receptors are densely packed in the muscle-cell plasma membrane at a neuromuscular junction (about 20,000 such receptors per square micrometer), with relatively few receptors elsewhere in the same membrane.

The muscle acetylcholine receptors are composed of five transmembrane polypeptides, two of one kind and three others, encoded by four separate genes (Figure 11-40A). The four genes are strikingly similar in sequence, implying that they evolved from a single ancestral gene. The two identical polypeptides in the pentamer each contribute one acetylcholine-binding site. When two acetylcholine molecules bind to the pentameric complex, they induce a conformational change that opens the channel. With ligand bound, the channel still flickers between open and closed states, but now it has a high probability of being open. This state continues—with acetylcholine binding and unbinding—until hydrolysis of the free acetylcholine by the enzyme *acetylcholinesterase* lowers its concentration at the neuromuscular junction sufficiently. Once freed of its bound neurotransmitter, the acetylcholine receptor reverts to its initial resting state. If the presence of acetylcholine persists for a prolonged time as a result of excessive nerve stimulation, the channel inactivates. Normally, the acetylcholine is rapidly hydrolyzed and the channel closes within about 1 millisecond, well before significant desensitization occurs.

The five subunits of the acetylcholine receptor are arranged in a ring, forming a water-filled transmembrane channel that consists of a narrow pore through the

Figure 11-39 The neuromuscular junction. (A) A low-magnification scanning electron micrograph of a neuromuscular junction in a frog. The termination of a single axon on a skeletal muscle cell is shown. (B) A schematic of the specialized anatomy of the neuron-muscle synaptic cleft. Schwann (glial) cells wrap around the neuron outside the region of synaptic contact to provide myelination. (C) Transmission electron micrograph of the region of synaptic contact. [A, from J. MBOC7_ptr_ch11_637-682.indd 671 08/12/21 11:47 AM

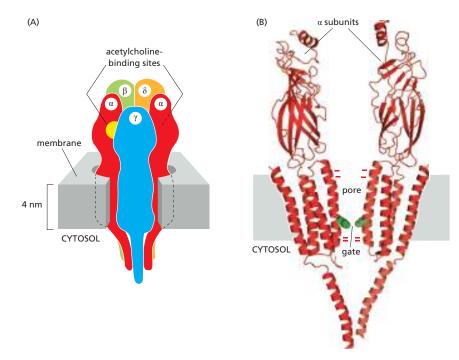

Figure 11-40 A model for the structure of the skeletal muscle acetylcholine receptor. (A) Five homologous subunits $(\alpha, \alpha, \beta, \gamma, \delta)$ combine to form a transmembrane pore. Both of the α subunits contribute an acetylcholinebinding site nestled between adjoining subunits. (B) The pore is lined by a ring of five transmembrane α helices, one contributed by each subunit (just the two α subunits are shown). In its closed conformation, the pore is occluded by the hydrophobic side chains of five leucines (green), one from each α helix, which form a gate near the middle of the lipid bilayer. When both α subunits bind acetylcholine. the channel undergoes a conformational change that opens the gate by an outward rotation of the helices containing the occluding leucines. Negatively charged side chains (indicated by the "-" signs) at either end of the pore ensure that only positively charged ions pass through the channel. (PDB code: 2BG9.)

lipid bilayer, which widens into vestibules at both ends. Acetylcholine binding opens the channel by causing the helices that line the pore to rotate outward, thus disrupting a ring of hydrophobic amino acids that blocks ion flow in the closed state. Clusters of negatively charged amino acids at either end of the pore help to exclude negative ions and encourage any positive ion of diameter less than 0.65 nm to pass through (Figure 11-40B). The normal through-traffic consists chiefly of Na⁺ and K⁺, together with some Ca²⁺. Thus, unlike voltage-gated cation channels, such as the K⁺ channel discussed earlier, there is little selectivity among cations, and the relative contributions of the different cations to the current through the channel depend chiefly on their concentrations and on the electrochemical driving forces. When the muscle-cell membrane is at its resting potential, the net driving force for K⁺ is near zero, because the voltage gradient nearly balances the K⁺ concentration gradient across the membrane (see Panel 11-1, p. 656). For Na⁺, in contrast, the voltage gradient and the concentration gradient both act in the same direction to drive the ion into the cell. (The same is true for Ca^{2+} , but the extracellular concentration of Ca^{2+} is so much lower than that of Na^+ that Ca^{2+} makes only a small contribution to the total inward current.) Therefore, the opening of the acetylcholine-receptor channels leads to a large net influx of Na⁺ (a peak rate of about 30,000 ions per channel each millisecond). This influx causes a membrane depolarization that signals the muscle to contract, as discussed later.

Neurons Contain Many Types of Transmitter-gated Channels

The ion channels that open directly in response to the neurotransmitters acetylcholine, serotonin, GABA, and glycine contain subunits that are structurally similar and probably form transmembrane pores in the same way as the ionotropic acetylcholine receptor, even though they have distinct neurotransmitter-binding specificities and ion selectivities. These channels are all built from homologous polypeptide subunits, which assemble as a pentamer. Glutamate-gated ion channels are an exception, in that they are constructed from a distinct family of subunits and form tetramers resembling the K^+ channels discussed earlier (see Figure 11–24A).

For each class of transmitter-gated ion channel, there are alternative forms of each type of subunit, which may be encoded by distinct genes or else generated by alternative RNA splicing of a single gene product. The subunits assemble in

MBOC7_ptr_ch11_637-682.indd 672 08/12/21 11:47 AM

different combinations to form an extremely diverse set of distinct channel subtypes, with different ligand affinities, different channel conductances, different rates of opening and closing, and different sensitivities to drugs and toxins. Some vertebrate neurons, for example, have acetylcholine-gated ion channels that differ from those of muscle cells in that they are formed from two subunits of one type and three of another; but there are at least nine genes coding for different versions of the first type of subunit and at least three coding for different versions of the second. Subsets of such neurons performing different functions in the brain express different combinations of the genes for these subunits. In principle, and already to some extent in practice, it is possible to design drugs targeted against these narrowly defined subsets, thereby specifically influencing particular brain functions.

Many Psychoactive Drugs Act at Synapses

Transmitter-gated ion channels have for a long time been important drug targets. A surgeon, for example, can relax muscles for the duration of an operation by blocking the acetylcholine receptors on skeletal muscle cells with *curare*, a plant-derived drug that was originally used by South American Indians to make poison arrows. Most drugs used to treat insomnia, anxiety, depression, and schizophrenia exert their effects at chemical synapses, and many of these act by binding to transmitter-gated channels. Barbiturates, tranquilizers such as Valium, and sleeping pills such as Ambien, for example, bind to GABA receptors, potentiating the inhibitory action of GABA by allowing lower concentrations of this neurotransmitter to open Cl⁻ channels. Our increasing understanding of the molecular biology of ion channels should allow us to design a new generation of psychoactive drugs that will act still more selectively to alleviate the miseries of mental illness.

In addition to ion channels, many other components of the synaptic signaling machinery are potential targets for psychoactive drugs. As mentioned earlier, after release into the synaptic cleft, many neurotransmitters are cleared by reuptake mechanisms mediated by ${\rm Na}^+$ -driven symports. Inhibiting such transporters prolongs the effect of the neurotransmitter, thereby strengthening synaptic transmission. Many antidepressant drugs, including Prozac, inhibit the reuptake of serotonin; others inhibit the reuptake of both serotonin and norepinephrine.

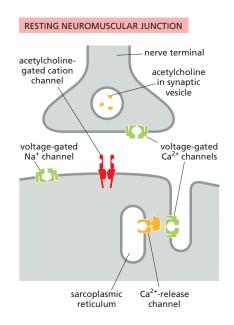

Ion channels are the basic molecular units from which neuronal devices for signaling and computation are built. To provide a glimpse of how sophisticated these devices can be, we consider several examples that demonstrate how the coordinated activities of groups of ion channels allow you to move, feel, and remember.

Neuromuscular Transmission Involves the Sequential Activation of Five Different Sets of Ion Channels

The following process, in which a nerve impulse stimulates a muscle cell to contract, illustrates the importance of ion channels to electrically excitable cells. This apparently simple response requires the sequential activation of at least five different sets of ion channels, all within a few milliseconds (Figure 11–41).

- 1. Neuromuscular transmission is initiated when a nerve impulse reaches the nerve terminal and depolarizes the plasma membrane of the terminal. The depolarization transiently opens voltage-gated Ca^{2+} channels in this presynaptic membrane. As the Ca^{2+} concentration outside cells is more than 1000 times greater than the free Ca^{2+} concentration inside, Ca^{2+} flows into the nerve terminal. The increase in Ca^{2+} concentration in the cytosol of the nerve terminal triggers the local release of acetylcholine by exocytosis into the synaptic cleft.
- 2. The released acetylcholine binds to acetylcholine receptors in the muscle-cell plasma membrane, transiently opening the cation channels associated with them. The resulting influx of Na^+ causes a local membrane depolarization in the muscle.
- 3. The local depolarization opens voltage-gated Na⁺ channels in this membrane, allowing more Na⁺ to enter, which further depolarizes the

MBOC7_ptr_ch11_637-682.indd 673 08/12/21 11:47 AM

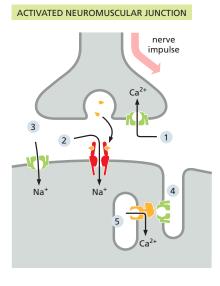

Figure 11–41 The system of ion channels at a neuromuscular junction. These gated ion channels are essential for the stimulation of muscle contraction by a nerve impulse. The various channels are numbered in the sequence in which they are activated, as described in the text.

membrane. This, in turn, opens neighboring voltage-gated Na⁺ channels and results in a self-propagating depolarization (an action potential) that spreads to involve the entire muscle plasma membrane (see Figure 11–33).

- 4. The generalized depolarization of the muscle-cell plasma membrane activates voltage-gated Ca²⁺ channels in the transverse tubules (T tubules—discussed in Chapter 16) of this membrane.
- 5. This in turn causes Ca^{2+} -release channels in an adjacent region of the sarcoplasmic reticulum (SR) membrane to open transiently and release Ca^{2+} stored in the SR into the cytosol. The T-tubule and SR membranes are closely apposed, and the two types of channel are joined together in a specialized structure, in which activation of the voltage-sensitive Ca^{2+} channel in the T-tubule plasma membrane causes a channel conformational change that is mechanically transmitted to the Ca^{2+} -release channel in the SR membrane, opening it and allowing Ca^{2+} to flow from the SR lumen into the cytoplasm (see Figure 16–30). The sudden increase in the cytosolic Ca^{2+} concentration causes the myofibrils in the muscle cell to contract.

Whereas the initiation of muscle contraction by a motor neuron is complex, an even more sophisticated interplay of ion channels is required for a neuron to integrate a large number of input signals at its synapses and compute an appropriate output, as we now discuss.

Single Neurons Are Complex Computation Devices

In the central nervous system, a single neuron can receive inputs from thousands of other neurons, and it can in turn form synapses with many thousands of other cells. Several thousand nerve terminals, for example, make synapses on an average motor neuron in the spinal cord, almost completely covering its cell body and dendrites (Figure 11–42). Some of these synapses transmit signals from the brain or spinal cord; others bring sensory information from muscles or from the skin. The motor neuron must combine the information received from all these sources and react, either by firing action potentials along its axon or by remaining quiet.

Of the many synapses on a neuron, some tend to excite it, while others inhibit it. Neurotransmitter released at an excitatory synapse causes a small depolarization in the postsynaptic membrane called an *excitatory postsynaptic potential* (*excitatory PSP*), whereas neurotransmitter released at an inhibitory synapse generally causes a small hyperpolarization called an *inhibitory PSP*. The plasma membrane of the dendrites and cell body of most neurons contains a relatively

MBOC7_ptr_ch11_637-682.indd 674 08/12/21 11:47 AM

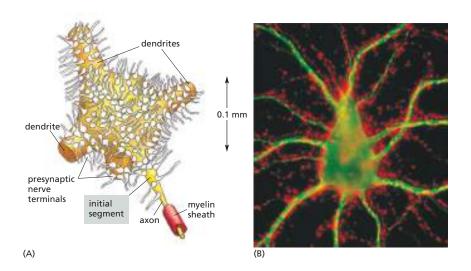

Figure 11-42 A motor neuron in the spinal cord. (A) Many thousands of nerve terminals synapse on the cell body and dendrites. These deliver signals from other parts of the organism to control the firing of action potentials along the single axon of this large cell. (B) Fluorescence micrograph showing a nerve-cell body in cell culture. Its dendrites are stained with a fluorescent antibody that recognizes a cytoskeletal protein (green) that is not present in axons. Thousands of axon terminals (red) from other nerve cells (not visible) make synapses on the cell body and dendrites; the terminals are stained with a fluorescent antibody that recognizes a protein in synaptic vesicles. (B, courtesy of Olaf Mundigl and Pietro de Camilli.)

low density of voltage-gated Na⁺ channels, and so an individual excitatory PSP is generally too small to trigger an action potential. Instead, each incoming signal initiates a local PSP, which decreases with distance from the site of the synapse. If signals arrive simultaneously at several synapses in the same region of the dendritic tree, the total PSP in that neighborhood will be roughly the sum of the individual PSPs, with inhibitory PSPs making a negative contribution to the total. The PSPs from each neighborhood spread passively and converge on the cell body. For long-distance transmission, the combined magnitude of the PSP is then translated, or *encoded*, into the *frequency* of firing of action potentials: the greater the stimulation (depolarization), the higher the frequency of action potentials.

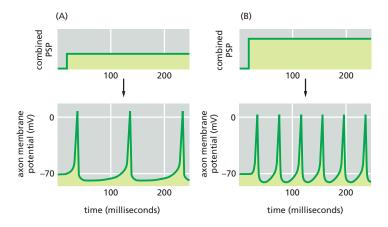

Neuronal Computation Requires a Combination of at Least Three Kinds of K⁺ Channels

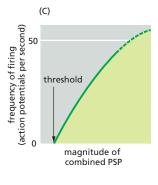

The intensity of stimulation that a neuron receives is encoded by that neuron into action potential frequency for long-distance transmission. The encoding takes place at a specialized region of the axonal membrane known as the **initial segment**, or *axon hillock*, at the junction of the axon and the cell body (see Figure 11–42). This membrane is rich in voltage-gated Na $^+$ channels, but it also contains at least four other classes of ion channels—three selective for K $^+$ and one selective for Ca $^{2+}$ —all of which contribute to the axon hillock's encoding function. The three varieties of K $^+$ channels have different properties; we shall refer to them as *delayed*, *rapidly inactivating*, and Ca^{2+} -activated K^+ channels.

To understand the need for multiple types of channels, consider first what would happen if the only voltage-gated ion channels present in the nerve cell were the Na $^+$ channels. Below a certain threshold level of synaptic stimulation, the depolarization of the initial-segment membrane would be insufficient to trigger an action potential. With gradually increasing stimulation, the threshold would be crossed, the Na $^+$ channels would open, and an action potential would fire. The action potential would be terminated by inactivation of the Na $^+$ channels. Before another action potential could fire, these channels would have to recover from their inactivation. But that would require a return of the membrane voltage to a very negative value, which would not occur as long as the strong depolarizing stimulus (from PSPs) was maintained. An additional channel type is needed, therefore, to repolarize the membrane after each action potential to prepare the cell to fire again.

The delayed K^+ channels perform this task, as discussed previously in relation to the propagation of the action potential (see Figure 11–32). Their opening permits an efflux of K^+ that drives the membrane back toward the K^+ equilibrium potential, which is so negative that the Na $^+$ channels rapidly recover from their inactivated state. Repolarization of the membrane also closes the delayed K^+ channels. The initial segment is now reset so that the depolarizing stimulus from

MBOC7_ptr_ch11_637-682.indd 675 08/12/21 11:47 AM

synaptic inputs can fire another action potential. In this way, sustained stimulation of the dendrites and cell body leads to repetitive firing of the axon.

Repetitive firing in itself, however, is not enough. The frequency of firing has to reflect the intensity of stimulation, and a simple system of $\mathrm{Na^+}$ channels and delayed $\mathrm{K^+}$ channels is inadequate for this purpose. Below a certain threshold level of steady stimulation, the cell will not fire at all; above that threshold level, it will abruptly begin to fire at a relatively rapid rate. The **rapidly inactivating K^+ channels** solve the problem. These, too, are voltage-gated and open when the membrane is depolarized, but their specific voltage sensitivity and kinetics of inactivation are such that they act to reduce the rate of firing at levels of stimulation that are only just above the threshold required for firing. Thus, they remove the discontinuity in the relationship between the firing rate and the intensity of stimulation. The result is a firing rate that is proportional to the strength of the depolarizing stimulus over a very broad range (**Figure 11–43**).

The process of encoding is usually further modulated by the two other types of ion channels in the initial segment that were mentioned earlier—voltage-gated Ca^{2+} channels and Ca^{2+} -activated K^+ channels. They act together to decrease the response of the cell to an unchanging, prolonged stimulation—a process called **adaptation**. These Ca^{2+} channels are similar to the Ca^{2+} channels that mediate the release of neurotransmitter from presynaptic axon terminals; they open when an action potential fires, transiently allowing Ca^{2+} into the axon cytosol at the initial segment.

The Ca^{2+} -activated K^+ channel opens in response to a raised concentration of Ca^{2+} at the channel's cytoplasmic face (Figure 11–44). Prolonged, strong depolarizing stimuli will trigger a long train of action potentials, each of which permits a brief influx of Ca^{2+} through the voltage-gated Ca^{2+} channels, so that local cytosolic Ca^{2+} concentration gradually builds up to a level high enough to open the Ca^{2+} -activated K^+ channels. Because the resulting increased permeability of the membrane to K^+ makes the membrane harder to depolarize, the delay between one action potential and the next is increased. In this way, a neuron that is stimulated continually for a prolonged period becomes gradually less responsive to the constant stimulus.

Such adaptation, which can also occur by other mechanisms, allows a neuron—indeed, the nervous system generally—to react sensitively to *change*, even against a high background level of steady stimulation. It is one of the computational strategies that help us, for example, to feel a light touch on the shoulder and yet ignore the constant pressure of our clothing. We discuss adaptation as a general feature in cell signaling processes in more detail in Chapter 15.

Other neurons do different computations, reacting to their synaptic inputs in myriad ways, reflecting the different assortments of ion channels in their membrane. There are several hundred genes that code for ion channels in the human genome, with more than 70 encoding voltage-gated channels alone. Further complexity is introduced by alternative splicing of RNA transcripts and assembly of channel subunits in different combinations. Moreover, ion channels are selectively

Figure 11–43 The magnitude of the combined postsynaptic potential (PSP) is reflected in the frequency of firing of action potentials. The mix of excitatory and inhibitory PSPs produces a *summed PSP* at the initial segment. A comparison of (A) and (B) shows how the firing frequency of an axon increases with an increase in the combined PSP, while (C) summarizes the general relationship.

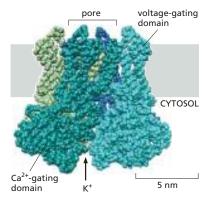

Figure 11–44 Structure of a Ca²⁺-activated K⁺ channel. The channel contains four identical subunits (which are shown in different colors for clarity). It is both voltage- and Ca²⁺-gated. The structure shown is a composite of the cytosolic and membrane portions of the channel that were separately crystallized. Note the large ligand-binding domains in the cytosol. (PDB code: 1LNQ.)

MBOC7_ptr_ch11_637-682.indd 676 08/12/21 11:47 AM

localized to different sites in the plasma membrane of a neuron. Some K^+ and Ca^{2+} channels are concentrated in the dendrites and participate in processing the input that a neuron receives. As we have seen, other ion channels are located at the axon's initial segment, where they control action potential firing; and some ligand-gated channels are distributed over the cell body and, depending on their ligand occupancy, modulate the cell's general sensitivity to synaptic inputs. The multiplicity of ion channels and their locations evidently allows each of the many types of neurons to tune their electrical behavior to the particular tasks they perform.

Voltage-gated Ca^{2+} channels are ubiquitous in neurons, and the Ca^{2+} that flows in through them is a good reflection of each nerve cell's activity. Today it is therefore quite common to express optical Ca^{2+} reporters in specific subtypes of neurons to follow their activities in transgenic animals. It is possible to image and track Ca^{2+} signals of 10,000 neurons in the brain simultaneously with a sensitive camera looking at the surface of the cortex or looking deeper into the brain with optical fibers. In this way, we begin to see neuronal circuits in living animals.

One of the crucial properties of the nervous system is its ability to learn and remember. This property depends in part on the ability of individual synapses to strengthen or weaken depending on their use—a process called **synaptic plasticity**. We will next consider a remarkable type of ion channel that has a special role in some forms of synaptic plasticity. It is located at many excitatory synapses in the central nervous system, where it is doubly gated by voltage and the excitatory neurotransmitter glutamate. It is also the site of action of the psychoactive drug phencyclidine, or angel dust.

Long-term Potentiation in the Mammalian Hippocampus Depends on Ca²⁺ Entry Through NMDA-Receptor Channels

Practically all animals can learn, but mammals seem to learn exceptionally well (or so we like to think). In a mammal's brain, the region called the *hippocampus* has a special role in learning. When it is destroyed on both sides of the brain, the ability to form new memories is largely lost, although previous long-established memories remain. Some synapses in the hippocampus show a striking form of synaptic plasticity with repeated use: whereas occasional single action potentials in the presynaptic cells leave no lasting trace, a short burst of repetitive firing causes long-term potentiation (LTP), such that subsequent single action potentials in the presynaptic cells evoke a greatly enhanced response in the postsynaptic cells. The effect lasts hours, days, or weeks, according to the number and intensity of the bursts of repetitive firing. Only the synapses that were activated exhibit LTP; synapses that have remained quiet on the same postsynaptic cell are not affected. However, while the cell is receiving a burst of repetitive stimulation via one set of synapses, if a single action potential is delivered at another synapse on its surface, that latter synapse also will undergo LTP, even though a single action potential delivered there at another time would leave no such lasting trace.

The underlying rule in such events seems to be that LTP occurs on any occasion when a presynaptic cell fires (once or more) at a time when the postsynaptic membrane is strongly depolarized (either through recent repetitive firing of the same presynaptic cell or by other means). This rule reflects the behavior of a particular class of ion channels in the postsynaptic membrane. Glutamate is the main excitatory neurotransmitter in the mammalian central nervous system, and glutamate-gated ion channels are the most common of all transmitter-gated channels in the brain. In the hippocampus, as elsewhere, most of the depolarizing current responsible for excitatory PSPs is carried by glutamate-gated ion channels called AMPA receptors, which operate in the standard way (Figure 11-45, Figure 11-46). But the current has, in addition, a second and more intriguing component, which is mediated by a separate subclass of glutamate-gated ion channels known as NMDA receptors, so named because they can be selectively activated by the artificial glutamate analog N-methyl-D-aspartate. The NMDA-receptor channels are doubly gated, opening only when two conditions are satisfied simultaneously: glutamate must be bound to the receptor, and the membrane must

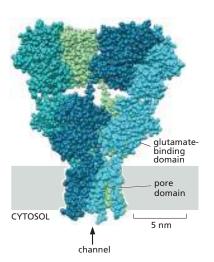

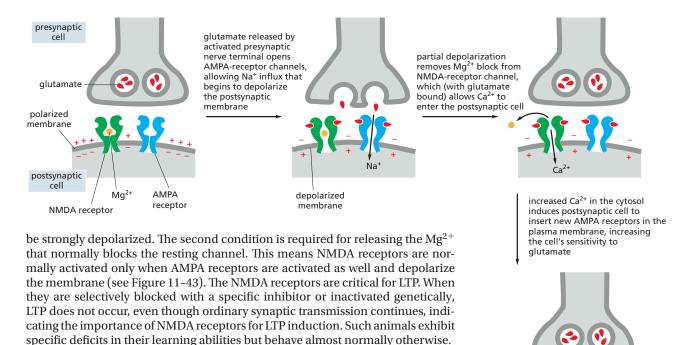

Figure 11–45 The structure of the AMPA receptor. This ionotropic glutamate receptor (named after the glutamate analog α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) is the most common mediator of fast, excitatory synaptic transmission in the central nervous system (CNS). Note the large ligand-binding domains in the extracellular space. (PDB code: 3KG2.)

MBOC7_ptr_ch11_637-682.indd 677 08/12/21 11:47 AM

How do NMDA receptors mediate LTP? The answer is that these channels, when open, are highly permeable to Ca^{2+} , which acts as an intracellular signal in the postsynaptic cell, triggering a cascade of changes that are responsible for LTP. Thus, LTP is prevented when Ca^{2+} levels are held artificially low in the postsynaptic cell by injecting the Ca^{2+} chelator EGTA into it, and LTP can be induced by artificially raising intracellular Ca^{2+} levels in the cell. Among the long-term changes that increase the sensitivity of the postsynaptic cell to glutamate is the insertion of new AMPA receptors into the plasma membrane (see Figure 11–46). In some forms of LTP, changes occur in the presynaptic cell as well, so that it releases more glutamate than normal when it is activated subsequently.

If synapses were capable only of LTP, they would quickly become saturated and thus be of limited value as an information-storage device. In fact, they also exhibit long-term depression (LTD), with the long-term effect of reducing the number of AMPA receptors in the postsynaptic membrane. This feat is accomplished by degrading AMPA receptors after their selective endocytosis. Surprisingly, LTD also requires NMDA-receptor activation and a rise in Ca^{2+} . How does Ca^{2+} trigger opposite effects at the same synapse? It turns out that this bidirectional control of synaptic strength depends on the magnitude of the rise in Ca^{2+} : high Ca^{2+} levels activate protein kinases and LTP, whereas modest Ca^{2+} levels activate protein phosphatases and LTD.

There is evidence that NMDA receptors have an important role in synaptic plasticity and learning in other parts of the brain, as well as in the hippocampus. Moreover, they have a crucial role in adjusting the anatomical pattern of synaptic connections in the light of experience during the development of the nervous system.

Thus, neurotransmitters released at synapses, besides relaying transient electrical signals, can also alter concentrations of intracellular mediators that bring about lasting changes in the efficacy of synaptic transmission. However, it is still uncertain how these changes endure for weeks, months, or a lifetime in the face of the normal turnover of cell constituents.

The Use of Channelrhodopsins Has Revolutionized the Study of Neural Circuits

Channelrhodopsins are photosensitive ion channels that open in response to light. They evolved as sensory receptors in photosynthetic green algae to allow the algae to swim toward light. The structure of channelrhodopsin closely resembles that of bacteriorhodopsin (see Figure 10–31). It contains a covalently bound

Figure 11–46 The signaling events in long-term potentiation. Although not shown, transmission-enhancing changes can also occur in the presynaptic nerve terminals in LTP, which may be induced by retrograde signals from the postsynaptic cell

MBOC7_ptr_ch11_637-682.indd 678 08/12/21 11:47 AM

retinal group that absorbs light and undergoes an isomerization reaction, which triggers a conformational change in the protein, opening an ion channel in the plasma membrane. In contrast to bacteriorhodopsin, which is a light-driven proton pump, channelrhodopsin is a light-activated cation channel.

Using genetic engineering techniques, channelrhodopsin can be expressed in virtually any cell type in vertebrates and invertebrates. Researchers first introduced the gene into cultured neurons and showed that flashing light could now activate the channelrhodopsin and induce the neurons to fire action potentials. Because the frequency of the light flashes determined the frequency of the action potentials, one can control the frequency of neuronal firing with millisecond precision.

Next, neurobiologists used the approach to activate specific neurons in the brain of experimental animals. Using a tiny fiber-optic cable implanted near the relevant brain region, they could flash light to specifically activate the channel-rhodopsin-containing neurons to fire action potentials. One group of researchers expressed channelrhodopsin in a subset of mouse neurons thought to be involved in aggression: when these cells were activated by light, the mouse immediately attacked anything in its environment—including other mice or even an inflated rubber glove (Figure 11-47); when the light was switched off, the neurons fell silent and the mouse's behavior returned to normal.

Since these pioneering studies, researchers have engineered additional light-responsive ion channels and transporters, including some that can rapidly inactivate specific neurons. It is therefore now possible to transiently activate or inhibit specific neurons in the brains of awake animals with remarkable spatial and temporal precision. In this way, the rapidly expanding new field of **optogenetics** is revolutionizing neurobiology, allowing neuroscientists to analyze the neurons and circuits underlying even the most complex behaviors in experimental animals, including nonhuman primates.

Summary

Ion channels form aqueous pores across the lipid bilayer and allow inorganic ions of appropriate size and charge to cross the membrane down their electrochemical gradients at rates about 1000 times greater than those achieved by any known transporter. The channels are "gated" and usually open transiently in response to a specific perturbation in the membrane, such as a change in membrane potential (voltage-gated channels), or the binding of a neurotransmitter to the channel (transmitter-gated channels).

 K^+ -selective leak channels have an important role in determining the resting membrane potential across the plasma membrane in most animal cells. Voltage-gated cation channels are responsible for the amplification and propagation of action potentials in electrically excitable cells, such as neurons and heart and skeletal muscle cells. Transmitter-gated ion channels convert chemical signals to electrical signals at chemical synapses. Excitatory neurotransmitters, such as acetylcholine and glutamate, open transmitter-gated cation channels and thereby depolarize the postsynaptic membrane toward the threshold level for firing an action potential. Inhibitory neurotransmitters, such as GABA and glycine, open transmitter-gated Cl^- or K^+ channels and thereby suppress firing by keeping the postsynaptic membrane polarized. A subclass of glutamate-gated ion channels, called NMDA-receptor channels, is highly permeable to Ca^{2+} , which can trigger the long-term changes in synapse efficacy (synaptic plasticity) such as LTP and LTD that are thought to be involved in some forms of learning and memory.

Figure 11-47 Optogenetic control of aggression neurons in a living mouse. A gene encoding channelrhodopsin was introduced into a subpopulation of neurons in the hypothalamus of a mouse. When the neurons were exposed to flashing blue light using a tiny, implanted fiber-optic cable, the channelrhodopsin channels opened, depolarizing and activating the cells. When the light was switched on, the mouse immediately became aggressive and attacked the inflated rubber glove: when the light was switched off, its behavior immediately returned to normal (Movie 11.13). PROBLEMS

Which statements are true? Explain why or why not.

- **11–1** Transport by transporters can be either active or passive, whereas transport by channels is always passive.
- **11–2** A symporter would function as an antiporter if its orientation in the membrane were reversed; that is, if the portion of the protein normally exposed to the cytosol faced the outside of the cell instead.
- **11–3** Excitatory synapses generally cause a small hyperpolarization of the postsynaptic membrane, whereas inhibitory synapses generally cause a small depolarization of the postsynaptic membrane.
- 11–4 Transporters approach saturation at high concentrations of the transported molecule when all their binding sites are occupied; channels, on the other hand, do not bind the ions they transport and thus the flux of ions through a channel does not saturate.
- 11–5 The membrane potential arises from movements of charge that leave ion concentrations practically unaffected, causing only a very slight discrepancy in the number of positive and negative ions on the two sides of the membrane.

Discuss the following problems.

- 11–6 Order Ca^{2+} , CO_2 , glucose, RNA, and H_2O according to their ability to diffuse through a lipid bilayer, beginning with the one that crosses the bilayer most readily. Explain the basis for your ranking.
- **11–7** How is it possible for some molecules to be at equilibrium across a biological membrane and yet not be at the same concentration on both sides?
- **11–8** Suppose a membrane contains a single passive transporter with a $K_{\rm m}$ of 0.1 mM for its solute. How effective would the transporter be at equalizing the concentrations of solute across the membrane if the starting concentrations were 0.01 mM inside and 0.05 mM outside? What if the concentrations were 100 mM inside and 500 mM outside?
- A. Effective at both low and high solute concentra-
- **B.** Effective at low solute levels but ineffective at high levels
- **C.** Ineffective at both low and high solute concentrations
- D. Ineffective at low solute levels but effective at high levels
- **11–9** Microvilli increase the surface area of intestinal cells, providing more efficient absorption of nutrients. Microvilli are shown in profile and cross section in **Figure Q11–1**. From the dimensions given in the figure, estimate the increase in surface area that microvilli provide

(for the portion of the plasma membrane in contact with the lumen of the gut) relative to the corresponding surface of a cell with a "flat" plasma membrane.

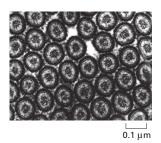

Figure Q11-1 Microvilli of intestinal epithelial cells in profile and cross section (Problem 11-9). (Left panel, from Rippel Electron Microscope Facility, Dartmouth College; right panel, from David Burgess.)

- **11–10** Ion transporters are "linked" together—not physically, but as a consequence of their actions. For example, cells can raise their intracellular pH, when it becomes too acidic, by exchanging external Na^+ for internal H^+ , using an Na^+ - H^+ antiporter. The change in internal Na^+ is then redressed using the Na^+ - K^+ pump.
- A. Can these two transporters, operating together, return both the H⁺ and the Na⁺ concentrations to their normal levels inside the cell?
- B. Does the linked action of these two pumps cause imbalances in either the K^+ concentration or the membrane potential? Why or why not?
- 11–11 According to Newton's laws of motion, an ion exposed to an electric field in a vacuum would experience a constant acceleration from the electric driving force, just as a falling body in a vacuum constantly accelerates due to gravity. In water, however, an ion moves at constant velocity in an electric field. Why do you suppose that is?
- 11–12 In a subset of voltage-gated K⁺ channels, the N-terminus of each subunit acts like a tethered ball that occludes the cytoplasmic end of the pore soon after it opens, thereby inactivating the channel. This "balland-chain" model for the rapid inactivation of voltagegated K⁺ channels has been elegantly supported for the shaker K+ channel from Drosophila melanogaster. (The $\mathit{shaker}\, \mathrm{K}^+$ channel in $\mathit{Drosophila}$ is named after a mutant form that causes excitable behavior—even anesthetized flies keep twitching.) Deletion of the N-terminal amino acids from the normal shaker channel gives rise to a channel that opens in response to membrane depolarization but stays open instead of rapidly closing as the normal channel does. A peptide (MAAVAGLYGLGEDRQHRKKQ) that corresponds to the deleted N-terminus can inactivate the open channel at 100 μ M.

Is the concentration of free peptide ($100~\mu M$) that is required to inactivate the defective K^+ channel anywhere near the local concentration of the tethered ball on a normal channel? Assume that the tethered ball can

MBOC7_ptr_ch11_637-682.indd 680 08/12/21 11:47 AM

REFERENCES 681

explore a hemisphere [volume = $(2/3)\pi r^3$] with a radius of 21.4 nm, which is the length of the polypeptide "chain" (**Figure Q11–2**). Calculate the concentration for one ball in this hemisphere. How does that value compare with the concentration of free peptide needed to inactivate the channel?

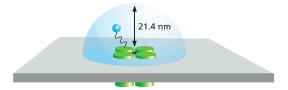

Figure Q11-2 A "ball" tethered by a "chain" to a voltage-gated K⁺ channel (Problem 11-12).

11–13 The giant axon of the squid (Figure Q11–3) occupies a unique position in the history of our understanding of cell membrane potentials and nerve action. When an electrode is stuck into an intact giant axon, the membrane potential registers –70 mV. When the axon, suspended in a bath of seawater, is stimulated to conduct a nerve impulse, the membrane potential changes transiently from –70 mV to +40 mV.

Figure Q11-3 The squid Sepioteuthis lessoniana (Problem 11-13). This squid can grow up to 30 cm in length.

For univalent ions and at 20°C (293 K), the Nernst equation reduces to

$$V = 58 \text{ mV} \times \log(C_0/C_i)$$

where C_0 and C_i are the concentrations outside and inside, respectively.

Using this equation, calculate the potential across the resting membrane (1) assuming that it is due solely to K^+ and (2) assuming that it is due solely to Na^+ . (The Na^+

and K^+ concentrations in the axon cytosol and in seawater are given in Table Q11–1.) Which calculation is closer to the measured resting potential? Which calculation is closer to the measured action potential? Explain why these assumptions approximate the measured resting and action potentials.

TABLE Q11-1 Ionic Composition of Seawater and of the Cytosol in the Squid Giant Axon (Problem 11-13)		
lon	Cytosol	Seawater
Na ⁺	65 mM	430 mM
K ⁺	344 mM	9 mM

11–14 If the resting membrane potential of a cell is –70 mV and the thickness of the lipid bilayer is 5 nm, what is the strength of the electric field across the membrane in V/cm? What do you suppose would happen if you applied this voltage to two metal electrodes separated by a 1-cm air gap?

11–15 Acetylcholine-gated cation channels at the neuromuscular junction open in response to acetylcholine released by the nerve terminal and allow Na⁺ ions to enter the muscle cell, which causes membrane depolarization and ultimately leads to muscle contraction.

A. Patch-clamp measurements show that young rat muscles have cation channels that respond to acetylcholine (Figure Q11-4). How many kinds of channel are there? How can you tell?

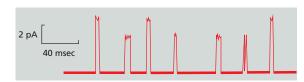

Figure Q11–4 Patch-clamp measurements of acetylcholine-gated cation channels in young rat muscle (Problem 11–15).

B. For each kind of channel, calculate the number of ions that enter in 1 millisecond. (One ampere is a current of 1 coulomb per second; 1 pA equals 10^{-12} ampere. An ion with a single charge such as Na⁺ carries a charge of 1.6×10^{-19} coulomb.)

Intracellular Organization and Protein Sorting

CHAPTER

12

The many thousands of macromolecules and their associated biochemical activities inside a cell are spatially segregated to different regions. Intracellular organization is a particularly prominent feature of eukaryotic cells, which unlike bacteria are elaborately subdivided into functionally distinct, membrane-enclosed compartments. Many of these compartments define the cell's major **organelles** such as the endoplasmic reticulum, Golgi apparatus, lysosome, plastid, and mitochondrion, the last two of which are still further subcompartmentalized by internal membranes. Other subsets of the cell's macromolecules can organize into dynamic and reversible assemblies, called **biomolecular condensates**, that can serve as specialized biochemical factories or temporary storage depots. To understand the eukaryotic cell, it is essential to know how the cell creates and maintains its complex intracellular organization.

An animal cell contains about 10 billion (10¹⁰) protein molecules of perhaps 10,000 kinds, and the synthesis of almost all of them begins in the **cytosol**, the space of the cytoplasm outside the membrane-enclosed organelles. Each newly synthesized protein is then delivered specifically to the organelle that requires it. The unique protein and lipid composition on the surface of each organelle is used as a cue to direct new deliveries of proteins and lipids to sustain that organelle's identity. The characteristic set of proteins and other specialized molecules define each organelle's structural and functional properties. They catalyze the reactions that occur there and selectively transport molecules into and out of the organelle. The intracellular transport of proteins is the central theme of both this chapter and the next. By tracing the protein traffic from one part of the cell to another, one can begin to make sense of the otherwise bewildering maze of intracellular membranes and other subcellular structures.

THE COMPARTMENTALIZATION OF CELLS

In this brief overview of the compartments of the cell and the relationships between them, we organize the cell's organelles conceptually into a small number of discrete families, discuss how proteins are directed to specific organelles, and explain how proteins cross organelle membranes.

All Eukaryotic Cells Have the Same Basic Set of Membrane-enclosed Organelles

Many vital biochemical processes take place in membranes or on their surfaces. Membrane-bound enzymes, for example, catalyze lipid metabolism, and oxidative phosphorylation and photosynthesis both require a membrane to couple the transport of \mathbf{H}^+ to the synthesis of ATP. In addition to providing increased membrane area to host biochemical reactions, intracellular membrane systems form enclosed compartments that are separate from the cytosolic compartment, thus creating functionally specialized aqueous spaces within the cell. In these spaces, subsets of molecules (proteins, reactants, ions) are concentrated to optimize the biochemical reactions in which they participate. By having multiple types of compartments inside the same cell, biochemical reactions that require very different conditions, or would compete with each other, can nevertheless occur simultaneously. Because the lipid bilayer of cell membranes is impermeable to most

MBOC7_ptr_ch12_683-748.indd 683 02/12/21 12:32 PM

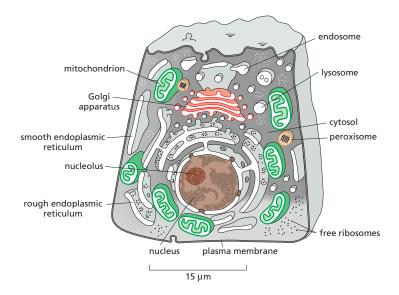

Figure 12–1 The major intracellular compartments of an animal cell.

The cytosol (gray), rough endoplasmic reticulum, smooth endoplasmic reticulum, Golgi apparatus, nucleus, mitochondrion, endosome, lysosome, and peroxisome are distinct compartments isolated from the rest of the cell by at least one selectively permeable membrane (see Movie 9.2). By contrast, the nucleolus is not enclosed by a membrane and represents one example of a biomolecular condensate.

hydrophilic molecules, the membrane of an organelle must contain membrane transport proteins to import and export specific metabolites. Each organellar membrane must also have a mechanism for importing, and incorporating into the organelle, the specific proteins that make the organelle unique.

Figure 12–1 illustrates the major intracellular compartments common to eukaryotic cells. The *nucleus* contains the genome (aside from mitochondrial and chloroplast DNA), and it is the principal site of DNA and RNA synthesis. The surrounding **cytoplasm** consists of the cytosol and the cytoplasmic organelles suspended in it. The cytosol constitutes a little more than half the total volume of the cell, and it is the main site of protein synthesis and degradation. It also performs most of the cell's intermediary metabolism; that is, the many reactions that degrade some small molecules and synthesize others to provide the building blocks for macromolecules (discussed in Chapter 2).

About half the total area of membrane in a eukaryotic cell encloses the labyrinthine spaces of the *endoplasmic reticulum* (ER). Most soluble and integral membrane proteins destined for the cell exterior or for other organelles are initially assembled at the ER. These proteins are transported into the ER as they are synthesized by ribosomes. The distinctive appearance in electron micrographs of ribosomes studding the surface of these regions of the ER is the reason they are termed the *rough ER*. The ER also produces most of the lipid and sterols for the rest of the cell and functions as a store for Ca^{2+} ions. These regions of the ER typically lack bound ribosomes and are called *smooth ER*.

The ER sends many of its proteins and lipids to the *Golgi apparatus*, which often consists of organized stacks of disc-like compartments called *Golgi cisternae*. The Golgi apparatus receives lipids and proteins from the ER and dispatches them to various destinations, usually covalently modifying them *en route*. *Lysosomes* contain digestive enzymes that degrade defunct intracellular organelles, as well as macromolecules and particles taken in from outside the cell by endocytosis. On the way to lysosomes, endocytosed material must first pass through a series of organelles called *endosomes*. As we will see, the ER, Golgi apparatus, lysosomes, endosomes, and plasma membrane are linked by the cell's major pathways of membrane traffic.

Mitochondria and chloroplasts generate most of the ATP that cells use to drive reactions requiring an input of free energy; chloroplasts are a specialized version of plastids (present in plants, algae, and some protozoa), which can also have other functions, such as the storage of food or pigment molecules. Finally, peroxisomes are small vesicular compartments that contain enzymes used in various oxidative reactions.

On average, the membrane-enclosed compartments together occupy nearly half the volume of a cell (Table 12-1), and a large amount of intracellular

Endosome membrane	0.4	Not determined	

^{*}These two cells are of very different sizes: the average hepatocyte has a volume of about 5000 μm^3 compared with 1000 μm^3 for the pancreatic exocrine cell. Total cell membrane areas are estimated at about 110,000 μm^2 and 13,000 μm^2 , respectively.

**The outer nuclear membrane is included in the measurement of the rough ER and is roughly

membrane is required to make them. In liver and pancreatic cells, for example, the endoplasmic reticulum has a total membrane surface area that is, respectively, 25 times and 12 times that of the plasma membrane (Table 12-2). The membraneenclosed organelles are packed tightly in the cytoplasm, and, in terms of area and mass, the plasma membrane is only a minor membrane in most eukaryotic cells (Figure 12-2).

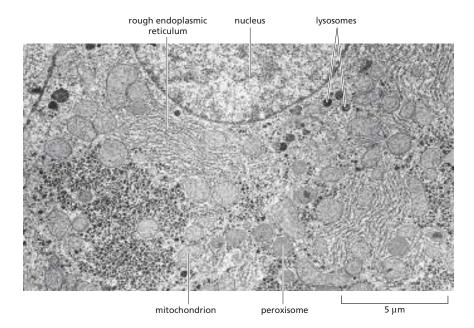

Figure 12–2 An electron micrograph of part of a liver cell seen in cross section. Examples of most of the major intracellular organelles are indicated. (Reused by permission of E.L. Bearer and Daniel S. Friend.)

MBOC7_ptr_ch12_683-748.indd 685 02/12/21 12:32 PM

equal to the inner membrane.

In general, each membrane-enclosed organelle performs the same set of basic functions in all cell types. But to serve the specialized functions of cells, these organelles vary in abundance and can have additional properties that differ from cell type to cell type. This is particularly apparent in cells that are highly specialized and therefore disproportionately rely on specific organelles. Plasma cells, for example, which daily secrete their own weight in antibody molecules into the bloodstream, contain vastly amplified amounts of rough ER, which is found in large, flat sheets. Cardiac muscle cells instead expand and specialize their smooth ER for Ca²⁺ storage and proliferate their mitochondria for energy production. Moreover, membrane-enclosed organelles are often found in characteristic positions in the cytoplasm. In most cells, for example, the Golgi apparatus is located close to the nucleus, whereas the network of ER tubules extends from the nucleus throughout the entire cytosol. These characteristic distributions depend on interactions of the organelles with the cytoskeleton (discussed in Chapter 16).

Evolutionary Origins Explain the Topological Relationships of Organelles

To understand the relationships between the compartments of the cell, it is helpful to consider how they might have originated. The precursors of the first eukaryotic cells are thought to have been relatively simple cells that—like most bacterial and archaeal cells—had a plasma membrane but no internal membranes. The plasma membrane in such cells provided all membrane-dependent functions, including the pumping of ions, ATP synthesis, protein secretion, and lipid synthesis. These ancestral precursors, like their modern-day prokaryotic counterparts,probably had a 1000- to 10,000-fold smaller volume than present-day eukaryotic cells. To increase in volume, the ancestral cells would have needed to maintain their surface area to volume ratio to sustain the many vital functions that membranes perform.

On the basis of the appearance of modern-day archaeal cells (see Figure 1–26), the membrane surface area might have initially increased by plasma membrane protrusions. The increased capacity to exchange metabolites with the surrounding environment via these protrusions would have facilitated symbiotic relationships with other organisms. Increased resource availability due to a combination of symbioses and membrane expansion may have allowed the evolution of progressively larger cells (Figure 12–3). Ultimately, the network of spaces between the numerous expanded protrusions would have become sealed off from the surrounding environment because of membrane fusion between protrusions. The consequences of this fusion are threefold and help to explain the major distinguishing features of eukaryotic cells.

First, the cell now has a set of internal membranes that are derived from an ancestral prokaryotic plasma membrane. These internal membranes enclose interior spaces that are said to be *topologically equivalent* to each other and to the exterior of the cell (Figure 12-4), because they can communicate with one another, in the sense that molecules can get from one to the other without having to cross a membrane. We shall see that this topological relationship holds for all of the organelles involved in the secretory and endocytic pathways, including the ER, Golgi apparatus, endosomes, lysosomes, and peroxisomes. As we discuss in detail in the next chapter, their interiors communicate extensively with one another and with the outside of the cell via *transport vesicles*, which bud off from one organelle and fuse with another. In this way, proteins that enter the **lumen** of the ER can be secreted outside the cell.

Second, the ancestral plasma membrane that surrounded the genome is now an internal membrane that becomes the *inner nuclear membrane*. Because of how it originated, the inner nuclear membrane is continuous with other plasma membrane-derived internal membranes, including the *outer nuclear membrane*. Specialized structures, the *nuclear pore complexes*, are located at points where the inner and outer nuclear membranes connect and provide a conduit for communication between the nucleus and cytosol. Segregation of an

MBOC7_ptr_ch12_683-748.indd 686 02/12/21 12:32 PM

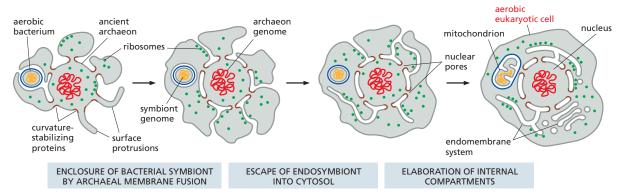

Figure 12-3 Evolutionary origins of the major internal membrane systems of a eukaryotic cell. As discussed in Chapter 1, there is evidence that the first eukaryotic cells arose when an ancient anaerobic archaeon joined forces with an aerobic bacterium roughly 1.6 billion years ago. An early step in this process was expansion of the archaeon's plasma membrane, probably through protrusions and blebs. The highly curved membrane at the necks of these protrusions might have been stabilized by proteins that eventually became part of the nuclear pore. The added surface area of these protrusions facilitated metabolite exchange with the environment and with neighboring cells. A fruitful symbiotic relationship with an aerobic bacterium might have allowed the archaeon to increase in volume. These protrusions eventually fused with each other to pinch off internal membrane-enclosed compartments, some of which contained the symbiotic bacteria. This intermediate now begins to resemble modern-day eukaryotes, with a primordial nucleus and nuclear pores, internal compartments, and an endosymbiont destined to become the mitochondrion. The lumen of the internal compartments is topologically equivalent to the extracellular space (see Figure 12-4). The membrane-enclosed endosymbiont subsequently escaped the enclosing membrane into the cytosol where it evolved into modern-day mitochondria. The internal compartments expanded and became progressively specialized to form the major intracellular compartments of a eukaryotic cell. Their common origin from a primordial intracellular compartment explains why all of these compartments can exchange material with each other through vesicular transport. The nucleus was formerly the cytosol in the ancient archaeon, explaining why the cytosol and nucleus are topologically equivalent compartments that can intermix during mitosis. (Adapted from J. Martijn and T.J.G. Ettema, Biochem. Soc. Trans. 41:451-457, 2013; D. Baum and B. Baum, BMC Biol. 12:76, 2014.)

organism's genetic material into a nucleus separate from the plasma membrane probably afforded greater protection from the environment. Furthermore, an expanded cytosol segregated from the nucleus would have facilitated the spatial separation of transcription from translation, thereby allowing greater regulation of gene expression by several mechanisms distinctive to eukaryotic cells.

Third, symbionts that were originally outside the cell were trapped inside the cell and became endosymbionts. At some point, endosymbionts escaped from their membrane enclosure into the cytosol where they eventually became mitochondria and plastids that contain their own genomes. The nature of these genomes and the close resemblance of the proteins in these organelles to those in some present-day bacteria provide strong evidence for their endosymbiont origins (see Figure 14–55). Like the bacteria from which they were derived,

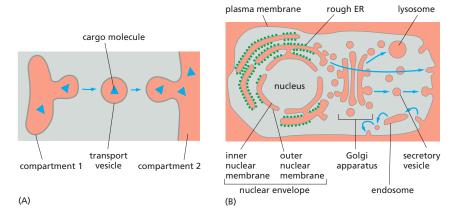

Figure 12-4 Topologically equivalent compartments in the secretory and endocytic pathways in a eukaryotic cell. Topologically equivalent spaces are shown in red. (A) Molecules can be carried from one compartment to another topologically equivalent compartment by transport vesicles that bud from one and fuse with the other. (B) In principle, cycles of membrane budding and fusion permit the lumen of any of the organelles shown to communicate with any other and with the cell exterior by means of transport vesicles. Blue arrows indicate the extensive outbound and inbound vesicular traffic (discussed in Chapter 13). Some organelles, most notably mitochondria and (in plant cells) plastids, do not take part in this communication and are isolated from the vesicular traffic between organelles shown here.

MBOC7_ptr_ch12_683-748.indd 687 02/12/21 12:32 PM

both mitochondria and plastids are enclosed by a double membrane, and they remain isolated from the extensive vesicular traffic that connects the interiors of most of the other membrane-enclosed organelles to each other and to the outside of the cell.

The evolutionary schemes we have outlined for the origins of eukaryotic organelles are most strongly supported by the striking similarities of the protein transport machinery of modern-day prokaryotes and eukaryotic organelles. The ability to transport proteins across and into membranes is a fundamental and essential feature of all living organisms. Thus, machinery that carries out these processes would have arisen in the earliest life-forms and been retained throughout evolution. The presence and orientation of these transport components therefore allow us to trace the origins and topology of the membranes within which they now reside. Consistent with the model for evolution of the endomembrane system of eukaryotic cells, the components that mediate protein import into the ER are homologous to the proteins that mediate export across the archaeal plasma membrane. Similarly, membrane protein insertion machinery in the outer and inner membranes of mitochondria and plastids contains homologous components found in the outer and inner membranes of various modern-day bacteria.

The major intracellular compartments in eukaryotic cells can therefore be categorized into three distinct families: (1) the nucleus and the cytosol, which are topologically equivalent (although functionally distinct) and connected by nuclear pore complexes; (2) all organelles that function in the secretory and endocytic pathways—including the ER, Golgi apparatus, endosomes, lysosomes, and the transport vesicles that move between them—and peroxisomes; (3) the endosymbiont-derived organelles: mitochondria and the plastids (in plants only).

Macromolecules Can Be Segregated Without a Surrounding Membrane

A membrane barrier is not the only way subsets of macromolecules can selectively segregate within cells. As we discussed in Chapter 3, one or more interacting proteins or nucleic acids can serve as *scaffolds* in *biomolecular condensates* (see Figure 3–77). These scaffold macromolecules create the condensate through multiple weak, fluctuating binding interactions among themselves; in addition, they recruit specific proteins and nucleic acids into the condensate as *client macromolecules* (Figure 12–5). Once recruited, the clients typically remain within the condensate because the local concentration of its binding sites on the interacting scaffold molecule is very high. Thus, when the client dissociates from a scaffold molecule, it is more likely to re-bind to another site on the scaffold molecule or to a neighboring one within the condensate than to diffuse away altogether. In this way, a specific set of proteins and nucleic acids can be concentrated into a cellular structure that excludes other surrounding macromolecules.

The largest and most conspicuous condensate in eukaryotic cells is the *nucleolus*, the structure within the nucleus where ribosomes are assembled (Movie 12.1). The central scaffolding component of the nucleolus is nascent pre-rRNA that is actively transcribed from arrays of rRNA genes. Nascent pre-rRNA recruits numerous proteins and small nucleolar RNAs (snoRNAs) required for pre-rRNA processing. These macromolecules further recruit other scaffold proteins—plus clients that include ribosomal proteins, assembly chaperones, and modification enzymes. In total, more than 400 proteins and RNAs contribute to the formation of this enormous condensate.

Biomolecular condensates can be found in all organisms (Figure 12–6), and eukaryotic cells contain a dozen or more different types (Table 12–3). The sizes of the known condensates range from \sim 50 nm in diameter (slightly bigger than ribosomes) to a micrometer or more in the case of nucleoli. These structures include many different types of ribonucleoprotein condensates (some in the nucleus and

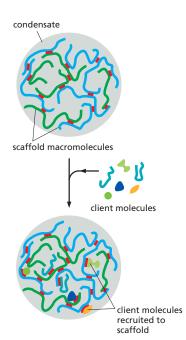

Figure 12-5 Biomolecular condensates formed by scaffold macromolecules recruit clients. As described in Chapter 3 (see Figure 3-77), a set of macromolecules that participate in weak, dynamic, and multivalent interactions (shown in red) with each other can form a biomolecular condensate (Movie 12.1). The macromolecules that directly participate in formation of the condensate are termed "scaffolds." The scaffold proteins and RNA can recruit other macromolecules, termed "clients," via specific interactions. Condensate formation does not depend on these clients, but they are part of the condensate because of their specific scaffold interactions.

MBOC7_ptr_ch12_683-748.indd 688 02/12/21 12:32 PM

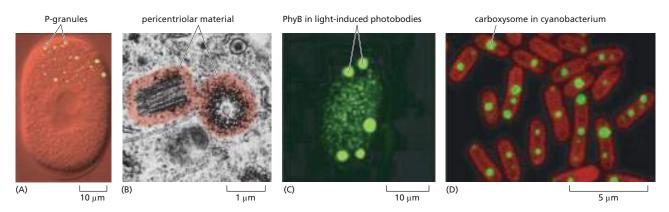

Figure 12–6 Examples of biomolecular condensates in different organisms. P-granules contain certain mRNAs and other macromolecules. (B) The pericentriolar material in the centrosome that nucleates the assembly of microtubules in an animal cell as seen by electron microscopy. (C) Green fluorescent protein (GFP)-labeled PhyB concentrates in condensates known as photobodies in the plant nucleus when the cells are exposed to bright light. Photobodies might be sites of light-mediated signaling and gene regulation. (D) Rubisco and carbonic anhydrase are concentrated in carboxysomes (green) in photosynthetic bacteria (cyanobacteria). Chlorophyll is shown in red. Carboxysomes are analogous to the pyrenoids of algae and facilitate carbon fixation. (A, from P. Brangwynne et al., Science 324:1729–1732, 2009. B, from M. McGill et al., J. Ultrastruct. Res. 57:43–53, 1976. C, from E.K. Van Buskirk et al., Plant Physiol. 158:52–60, 2012. D, from Y. Fang et al., Front. Plant Sci. 9:article 739, 2018. Courtesy of Liu Luning.)

others in the cytoplasm), a variety of different signaling protein clusters that can form tethered to the plasma membrane, and the "biochemical factories" that form as needed to catalyze DNA repair, DNA replication, and DNA transcription in the nucleus.

As illustrated by the nucleolus, each type of condensate is enriched for a characteristic complement of proteins (and in many cases, nucleic acids) that interact with each other to maintain the condensate's identity and integrity. The specificity of at least a subset of macromolecular interactions within the condensate ensures that it remains distinct in its composition and function. Thus, biomolecular condensates and membrane-enclosed compartments represent two different mechanisms that are used by eukaryotic cells to segregate subsets of macromolecules that execute specialized biochemistry (see Table 3–3). Because of this conceptual similarity, condensates are sometimes referred to as membraneless

TABLE 12-3 Examples of Eukaryotic Biomolecular Condensates		
Biomolecular condensate	Location	Proposed associated function(s)
Nucleolus	Nucleus	rRNA transcription and ribosome assembly
Pyrenoid	Chloroplast	Carbon fixation from CO ₂ in algae
Stress granules	Cytosol	Temporary storage, particularly of translation-related components

organelles. Historically, organelles were intracellular structures that could be directly visualized in the light or electron microscope. This is why the nucleolus and centrosome are called organelles. Most condensates are not organelles by this historical definition; nevertheless, they are cellular structures that segregate and concentrate specific macromolecules.

Multivalent Interactions Mediate Formation of Biomolecular Condensates

The formation of a biomolecular condensate requires that at least one of its constituent macromolecules engage in a set of weak, multivalent interactions with either itself or other constituents (see Figure 3–77A). The sites of these interactions are often separated by flexible and unstructured regions of the macromolecule. For example, nascent pre-rRNA in the nucleolus is a flexible molecule that binds a variety of clients and other scaffold molecules at numerous points along its length. Similarly, the scaffolding proteins that generate condensates of signaling proteins under the plasma membrane typically contain multiple protein–protein interaction domains separated by flexible *intrinsically disordered regions* that lack secondary structure. Experiments with artificial multivalent proteins have shown that this is the minimal element needed to drive condensate formation in a test tube and in cells.

Each individual interaction within a condensate is often very weak, allowing the macromolecules to rapidly exchange their relative positions. These dynamic and frequent rearrangements, together with the structural flexibility of many condensate constituents, means that the molecules within the condensate are highly mobile and do not have fixed positions relative to each other. This property causes the condensate to behave as a liquid. As discussed in Chapter 3 (pp. 171–173), despite this liquidlike property, the condensate does not dissolve into its surroundings because the interaction energy within the condensate offsets the entropy that would be gained if the molecules were dispersed. This is how the condensate can remain a liquid that stably resides within another liquid (the cytosol), a phenomenon termed "liquid-liquid phase separation."

Different noncovalent chemical bonds can form the weak interactions between macromolecules that drive condensate formation. Cation–pi interactions, pi–pi interactions, charge–charge interactions, short regions of crossed β sheets, and short stretches of nucleic acid base-pairing can all contribute to condensate formation. The key requirement is that the interactions have sufficient binding energy to offset the loss of entropy caused by association, while being sufficiently dynamic to give the condensate a liquid character. When these requirements are met, condensates have a spherical shape, deform and flow under shear force, and can undergo fusion and fission.

If the interactions in a condensate become less dynamic as incrementally more stable interactions form over time, its properties can change to that of a gel and eventually a solid where the binding interactions remain fixed. There is a continuum across the spectrum of physical properties that characterize different condensates. Cells can exploit such differences by forming a condensate within a condensate. This can occur if a subset of macromolecules within a condensate has slightly higher affinity among its macromolecules than for other macromolecules of the condensate. This subset then forms a new condensate with distinct physical properties (Figure 12–7). This is how the nucleolus is thought to be segregated into morphologically different concentric shells, each of which is enriched for subsets of nucleolar proteins dedicated to different aspects of ribosome assembly.

Biomolecular Condensates Create Biochemical Factories

The fluctuating network of interactions among the macromolecules inside of a condensate excludes other macromolecules from the surrounding environment. By contrast, nucleotides, metabolites, cofactors, and other small

MBOC7_ptr_ch12_683-748.indd 690 02/12/21 12:32 PM

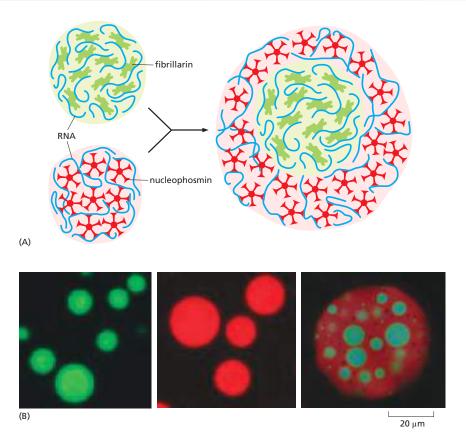

Figure 12–7 Condensates with different properties can coexist as part of a larger structure. The nucleolus is a condensate that is composed of three morphologically and functionally distinct regions, one inside the other, each formed by a different set of scaffold macromolecules. (A) In the experiment shown, the scaffolds from two nucleolar substructures have been purified—fibrillarin from the nucleolus's fibrillar component and nucleophosmin from its granular component. Both of these scaffold proteins contain binding sites for RNA, and when mixed with RNA in a test tube, each purified scaffold will assemble into an RNA–protein condensate, as illustrated at *left*. However, as illustrated at *right*, when mixed together they instead form a multilayered structure that has one type of condensate encased inside the other type of condensate. (B) The condensates, formed either separately or together, viewed by fluorescence microscopy; fibrillarin is *green* and nucleophosmin is *red*. (Adapted from M. Feric et al., *Cell* 165:1686–1697, 2016.)

molecules can rapidly diffuse into the condensate where they can engage with the enzymes that reside there. The product of these enzymes within the condensate can be used by other enzymes that are coresident in the condensate before the product diffuses away. In this way, multistep reactions can be accelerated to rates beyond that possible without co-segregation of the enzymes inside a condensate.

Consider for example, the *pyrenoid*, a complex structure found in many algae that contains a condensate enriched in the enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase (Rubisco) and a pyrenoid-specific scaffolding protein. The Rubisco-containing condensate is interwoven with membrane tubules. Carbonic anhydrase inside the membrane tubule converts bicarbonate (HCO₃⁻) into CO₂, which Rubisco uses to carboxylate ribulose 1,5-bisphosphate (**Figure 12–8**). This carboxylation reaction is a critical early step in carbon fixation during photosynthesis (discussed in Chapter 14). If Rubisco were not in a condensate in close proximity to carbonic anhydrase, the low free CO₂ concentration combined with a competition by oxygen for Rubisco's active site would favor reaction with oxygen (termed "photorespiration"; see Chapter 14, p. 847) over carbon fixation. Land plants do not need a pyrenoid to fix carbon because

MBOC7_ptr_ch12_683-748.indd 691 02/12/21 12:32 PM

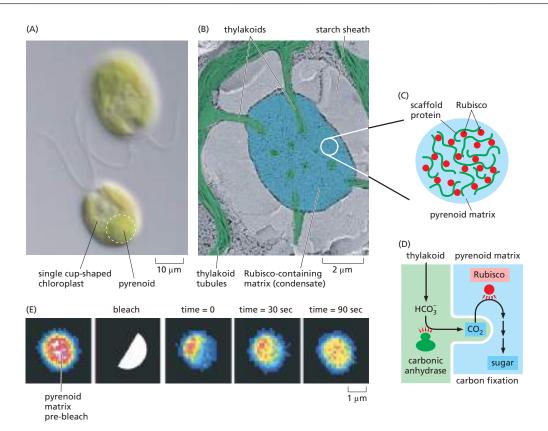

Figure 12–8 The pyrenoid contains a condensate of Rubisco that exploits locally generated CO_2 . (A) The pyrenoid as seen by light microscopy of the single-celled alga *Chlamydomonas reinhardtii*. (B) Scanning electron micrograph of the *C. reinhardtii* pyrenoid showing how the Rubisco-containing condensate is penetrated by tubules from the surrounding thylakoid. (C) Simplified depiction of the condensate containing the enzyme Rubisco and the multivalent scaffold protein EPYC1. (D) The tubules of thylakoid membranes in the pyrenoid contain the enzyme carbonic anhydrase. HCO_3^- is used by carbonic anhydrase to generate CO_2 , which is used by the surrounding Rubisco in the pyrenoid matrix. The use of locally generated CO_2 is thought to favor the carboxylation reaction performed by Rubisco rather than the competing oxygenation reaction that would be favored when O_2 is used by Rubisco instead of CO_2 . (E) Experiment demonstrating that the contents inside the pyrenoid matrix are highly dynamic. Shown is a pseudocolored fluorescence image of a pyrenoid containing a Rubisco subunit tagged with a fluorescent protein. *Red* and *white* indicate the areas of brightest fluorescence, and *blue* indicates areas of dim fluorescence. The right half of the pyrenoid was photobleached, after which fluorescence was monitored over time. Fluorescent molecules from the non-bleached half intermix with the bleached molecules within 90 seconds. (A, from Carnegie Institution for Science. B, courtesy of Ursula Goodenough. E, adapted from E.S. Freeman Rosenzweig et al., *Cell* 171:148–162, 2017.)

 ${\rm CO_2}$ in the air is more plentiful than the very low concentration of dissolved ${\rm CO_2}$ available as ${\rm HCO_3}^-$ to algae living in aquatic environments. The pyrenoid illustrates how the segregation of sequential biochemical reactions into a condensate can both speed reactions and minimize alternate off-pathway outcomes. In the same way, carrying out the highly complex and ordered process of ribosome assembly within the nucleolus prevents unwanted side reactions while promoting the desired ones.

Scientists can produce artificial condensates that contain a desired set of macromolecules by engineering them with multivalent interaction domains. This approach can be used to experimentally enhance the efficiency of an otherwise unfavorable reaction. In one experiment, all of the factors required to misread a UAG stop codon as a sense codon were engineered with artificial multivalent interaction modules to generate a condensate inside the cell. The UAG codon of the mRNA within this condensate was efficiently interpreted as a sense codon, while other mRNAs in the surrounding cytosol terminated at UAG codons. This experiment illustrates the minimal features needed to produce a

MBOC7_ptr_ch12_683-748.indd 692 02/12/21 12:32 PM

condensate-based biochemical factory within a cell and that such features can be rationally designed and engineered.

Biomolecular Condensates Form and Disassemble in Response to Need

As we have seen, the formation and stability of a biomolecular condensate rely on weak interactions among its constituents overcoming the entropy of a well-mixed system. This means that even small changes in the strength of interactions can influence the formation and physical properties of the condensate. The formation and dissolution of a condensate can therefore be readily controlled by changing the strength of the multivalent interactions that mediate its assembly. This is often accomplished by post-translational modifications, such as phosphorylation, and this mechanism is commonly used to rapidly form and disassemble large signaling clusters at the plasma membrane (Figure 12–9). Condensate formation and disassembly can also be induced by a change in a cellular condition such as temperature, pH, or osmolarity. The reversibility of condensate formation is used by cells to regulate condensates in response to need, and it affords the cell flexibility and speed in adapting to changing needs.

For example, the condensates called *stress granules* only form during certain types of cellular stress, and they dissolve when the stress is alleviated. These condensates are enriched in translationally inactive mRNAs, various translation factors, ribosomal subunits, and various RNA-binding proteins. They

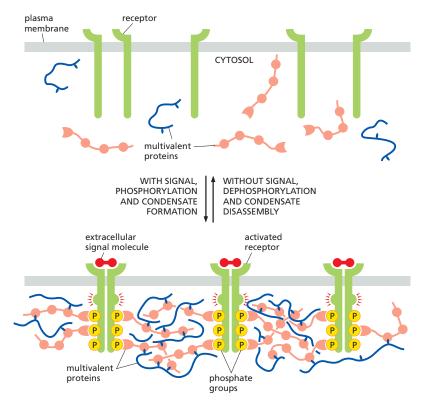

Figure 12–9 Phosphorylation regulates the formation and dissolution of condensates during signaling. When a receptor at the plasma membrane is engaged by its ligand, its cytosolic tail and associated proteins become phosphorylated. This modification, along with surrounding amino acids, forms a specific binding site for various cytosolic and membrane proteins, many of which are multivalent. The multivalent proteins interact with each other to drive the formation of a condensate that has distinctive signaling properties. When the key sites become dephosphorylated, the condensate disassembles and signaling stops. Examples of signaling clusters that form and disassemble in response to ligand are discussed in Chapter 15.

MBOC7_ptr_ch12_683-748.indd 693 02/12/21 12:32 PM

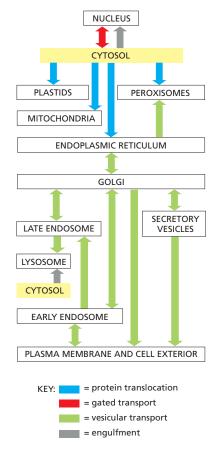

form when a block in translation initiation exposes mRNA regions that would normally be covered by translating ribosomes. When these mRNAs become exposed, they can interact with each other and with RNA-binding proteins to nucleate a condensate. It is thought that the resulting condensates serve as a storage depot for these mRNAs and factors when they are not being actively used. By temporarily sequestering these macromolecules during stress rather than degrading them, the cell can avoid the need to produce them *de novo* once the stress has been resolved.

Proteins Can Move Between Compartments in Different Ways

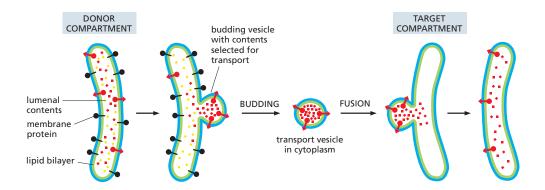

Nearly all proteins, except a few inside mitochondria and plastids, begin their synthesis on ribosomes in the cytosol. The final location of each protein depends on its amino acid sequence, which can contain one or more **sorting signals** that direct its delivery to different parts of the cell. The sorting signals in the transported protein are recognized by complementary **sorting receptors** that mediate movement between compartments. By contrast, proteins that do not have any sorting signals remain in the cytosol as permanent residents. There are four fundamentally different ways a protein is moved from one compartment to another. These four mechanisms are described below, and the transport steps at which they operate are outlined in **Figure 12–10**. We discuss protein translocation and gated transport in this chapter, vesicular transport in Chapter 13, and engulfment in both this chapter and the next.

- 1. In **protein translocation**, transmembrane *protein translocators* directly transport specific proteins from the cytosol into a space that is topologically distinct: either the other side of a membrane or within the lipid bilayer in the case of integral membrane proteins. The transported protein molecule usually must unfold to snake through the translocator. The initial transport of selected proteins from the cytosol into the ER lumen, the ER membrane, or mitochondria occurs in this way.
- 2. In gated transport, proteins and RNA molecules move between the cytosol and the nucleus through nuclear pore complexes in the nuclear envelope. The nuclear pore complexes function as selective gates that support the active transport of specific macromolecules and macromolecular assemblies between the two topologically equivalent spaces.
- 3. In vesicular transport, membrane-enclosed transport intermediates—which may be small, spherical transport vesicles, elongated tubules, or larger, irregularly shaped fragments of organelles—ferry proteins from one topologically equivalent compartment to another. The transport intermediate becomes loaded with a cargo of molecules derived from the lumen and membrane of the originating compartment as it buds and pinches off. At the destination compartment, the transport intermediate fuses with the compartment's enclosing membrane to discharge its cargo

Figure 12-10 A simplified "road map" of protein traffic within a eukaryotic cell. Proteins can move from one compartment to another by protein translocation (blue), gated transport (red), vesicular transport (green), or engulfment (gray). The sorting signals that direct a given protein's movement through the system, and thereby determine its eventual location in the cell, are contained in each protein's amino acid sequence. The journey begins with the synthesis of a protein on a ribosome in the cytosol and, for many proteins, terminates when the protein reaches its final destination. Other proteins shuttle back and forth between the nucleus and cytosol. At each intermediate station (boxes), a decision is made as to whether the protein is to be retained in that compartment or transported further. A sorting signal may direct either retention in or exit from a compartment. A special transport process termed "engulfment" is used to move proteins from the cytosol into the lysosome in autophagy or used to enclose chromosomes inside the nucleus during nuclear envelope re-formation after mitosis. The movement of macromolecules into and out of a condensate is not shown here. This process does not involve crossing a membrane barrier and is mediated by direct physical interactions among the macromolecules that form the condensate. We shall refer to this figure often as a guide in this chapter and the next, highlighting in color the particular pathway being discussed.

MBOC7_ptr_ch12_683-748.indd 694 02/12/21 12:32 PM

(Figure 12-11). The transfer of soluble and membrane-embedded proteins from the ER to the Golgi apparatus, for example, occurs in this way. The proteins transported by vesicular transport never cross a membrane during the process, and therefore retain their topological relationships within the cell.

4. In engulfment, such as autophagy (discussed in Chapter 13), double-membrane sheets wrap around portions of the cytoplasm often including fragments of organelles or even entire organelles (Figure 12-12). This membrane structure then seals by membrane fusion to enclose a separate compartment, the autophagosome. The re-formation of the nuclear envelope after mitosis (discussed later in this chapter) follows a conceptually similar process. ER tubes and sheets wrap around decondensing chromosomes and then fuse laterally with one another to form a sealed double-membrane envelope only traversed by the nuclear pores.

In addition to these mechanisms for protein movement into and between membrane-enclosed compartments, a simpler mechanism based on direct physical binding is used by macromolecules to enter biomolecular condensates. In this mechanism, the macromolecule specifically binds to another protein or RNA that is already part of the condensate to which it is specifically recruited. Once recruited, the macromolecule remains within the condensate because of persistent and repeated interactions with its partner. The interaction between a macromolecule and its binding partner in the condensate is analogous to the interaction between a sorting signal and its cognate sorting receptor; in both cases, the interaction specifies the macromolecule's destination.

Sorting Signals and Sorting Receptors Direct Proteins to the Correct Cell Address

Sorting signals are usually composed of amino acid side chains in a protein and come in two general varieties: a linear sequence of amino acids (called a signal sequence) or a specific three-dimensional arrangement of amino acids (called a signal patch). Sorting signals for protein translocation into organelles are linear signal sequences, while examples of linear signals and signal patches are known for nuclear and vesicular transport. The linear signal sequences for protein translocation are often found at the N-terminus of the polypeptide chain. These N-terminal signal sequences are usually removed from the finished protein by specialized signal peptidases once the sorting process is complete. Other types of signal sequences are not removed and remain part of the final mature protein.

Each signal sequence specifies a particular destination in the cell. The signal sequence for initial transfer to the ER usually includes a linear sequence of about 5–10 predominantly hydrophobic amino acids. Many of these proteins will in turn pass from the ER to the Golgi apparatus, but those with a specific signal sequence

Figure 12–11 Vesicle budding and fusion during vesicular transport. Transport vesicles bud from one compartment (donor) and fuse with another topologically equivalent (target) compartment. In the process, a subset of soluble components (red dots) are transferred from lumen to lumen. Note that membrane is also transferred and that the original orientation of both proteins and lipids in the donor compartment membrane is preserved in the target compartment membrane. Thus, membrane proteins retain their asymmetrical orientation, with the same domains always facing the cytosol.

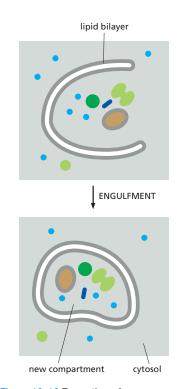

Figure 12–12 Formation of a new compartment by engulfment of contents inside of a membrane.

MBOC7_ptr_ch12_683-748.indd 695 02/12/21 12:32 PM

of four amino acids at their C-terminus are recognized as ER residents and are returned to the ER. Proteins destined for mitochondria have signal sequences of yet another type, in which positively charged amino acids alternate with hydrophobic ones. The signal for protein import into the nucleus is composed primarily of positively charged amino acids. Finally, many proteins destined for peroxisomes have a signal sequence of three characteristic amino acids at their C-terminus. A sorting signal for any particular destination needs to be sufficiently distinctive from all other sequences to permit its selective recognition by the appropriate sorting receptor.

Figure 12-13 presents some specific signal sequences. Experiments in which the peptide is transferred from one protein to another by genetic engineering techniques have demonstrated the importance of each of these signal sequences for protein targeting. Placing the N-terminal ER signal sequence at the beginning of a cytosolic protein, for example, redirects the protein to the ER; removing or mutating the signal sequence of an ER protein causes its retention in the cytosol. Signal sequences are therefore both necessary and sufficient for protein targeting. Even though their amino acid sequences can vary greatly, the signal sequences of proteins having the same destination are often functionally interchangeable; in these instances, physical properties, such as hydrophobicity, are more important in the signal-recognition process than the exact amino acid sequence.

Sorting signals are recognized by complementary sorting receptors that guide proteins to their appropriate destination, where the receptors unload their cargo. The receptors function catalytically: after completing one round of targeting, they return to their point of origin to be reused. Most sorting receptors recognize classes of proteins rather than an individual protein species. They can therefore be viewed as public transportation systems, dedicated to delivering numerous different components to their correct locations in the cell.

Construction of Most Organelles Requires Information in the Organelle Itself

When a cell reproduces by division, it has to duplicate its chromosomes, its enclosing plasma membrane, and its organelles. In general, cells do this by expanding the plasma membrane and organelles with new proteins and lipids before division and segregation to the two daughter cells. The delivery of new proteins for growth of the ER, mitochondria, and plastids requires preexisting organelle-specific protein translocators. Because the incorporation of new protein translocators requires a preexisting protein translocator, a cell must already have at least some functional ER to make more ER; the same applies to mitochondria and plastids. Thus, two types of information are required to construct these organelles: the DNA that specifies an organelle's proteins and preexisting protein translocator(s) in the organellar membrane for incorporating new deliveries of protein. Both types of information are passed from parent cell to daughter cells to maintain the cell's compartmental organization.

Some organelles, such as lysosomes, acquire all of their proteins and membrane by vesicular transport from other organelles (see Chapter 13). Because it is possible, in principle, to construct such organelles *de novo*, they do not necessarily have to be inherited at cell division. Similarly, biomolecular condensates can be constructed *de novo* by self-assembly of the constituent proteins and nucleic acids. Thus, during cell division, a condensate can be disassembled, its constituents distributed stochastically among the two daughter cells, then reassembled into a condensate. This is how the nucleolus is acquired by daughter cells.

Summary

Eukaryotic cells contain intracellular membrane-enclosed organelles that make up nearly half the cell's total volume. The main ones present in all eukaryotic cells are the endoplasmic reticulum, Golgi apparatus, nucleus, mitochondria, lysosomes, endosomes, and peroxisomes; plant cells also contain plastids such as chloroplasts. All organelles contain distinct sets of proteins, which mediate each organelle's unique function.

Cells can also segregate subsets of their macromolecules into biomolecular condensates such as the nucleolus. The components inside these condensates can work together to carry out specialized biochemical reactions. The cell contains a dozen or more condensates that vary widely in size and can assemble and disassemble in response to need.

Each newly synthesized organellar protein must find its way from a ribosome in the cytosol, where the protein is made, to the organelle where it functions. It does so by using sorting signals in its amino acid sequence that are recognized by complementary sorting receptors, which deliver the protein to the appropriate target organelle. Proteins that function in the cytosol do not contain sorting signals and therefore remain there after they are synthesized.

During cell division, organelles such as the ER and mitochondria are distributed to each daughter cell. These organelles contain information that is required for their construction, and so they cannot be made de novo. Biomolecular condensates can be constructed de novo because they self-assemble from components that are encoded genetically.

B, courtesy of Petra Boevink and Chris Hawes.)

THE ENDOPLASMIC RETICULUM

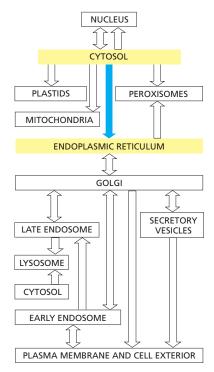

The membrane of the **endoplasmic reticulum (ER)** typically constitutes more than half of the total membrane of an average animal cell (see Table 12–2). The ER is organized into a netlike labyrinth of branching tubules and flattened sacs that extends throughout the cytosol (**Figure 12–14** and **Movie 12.2**). The tubules and sacs interconnect, and their membrane is continuous with the outer nuclear membrane. This membrane system encloses a single internal space, called the **ER lumen**, which is continuous with the space between the inner and outer nuclear membranes. The ER often occupies more than 10% of the total cell volume (see Table 12–1).

The ER has a central role in the biosynthesis of both lipids and proteins, and the ER lumen stores intracellular Ca²⁺ that is mobilized in many cell signaling responses (discussed in Chapter 15). The ER membrane is the site of production of many of the transmembrane proteins and lipids of the cell's organelles, including the ER itself, the Golgi apparatus, lysosomes, endosomes, secretory vesicles, peroxisomes, and the plasma membrane. The ER membrane is also the site at which most of the lipids for mitochondrial and plastid membranes are made. In addition, almost all of the proteins that will be secreted to the cell exterior—plus those destined for the lumen of the ER, Golgi apparatus, or lysosomes—are initially delivered to the ER lumen.

The ER Is Structurally and Functionally Diverse

While the various functions of the ER are essential to every cell, their relative importance varies greatly between individual cell types. To meet different functional demands, distinct regions of the ER become highly specialized. Functional specialization entails dramatic changes in the proportional abundance of different parts of the ER. These changes are observed as characteristically different types of ER membrane in different types of cells. The most visually remarkable specializations are the **rough ER** and **smooth ER** (**Figure 12–15**). The rough appearance is due to the abundance of ribosomes engaged in protein synthesis bound to the surface of this part of the ER. By contrast, regions of smooth ER lack ribosomes and are dedicated to other ER functions such as the biosynthesis and metabolism of lipids. All cells have both rough and smooth ER, but their relative abundance can vary enormously in specialized cells.

Most secreted proteins are synthesized by the ribosomes that stud the surface of the rough ER. Thus, cells specialized to secrete vast amounts of protein are packed with an abundance of rough ER. For example, exocrine cells of the pancreas secrete their own weight in digestive enzymes every day, explaining why the rough ER makes up 60% of these cells' membranes (see Table 12–2). Similarly, antibody-secreting plasma cells and insulin-secreting β cells also contain a markedly expanded rough ER. This correlation between highly secretory cells and an

MBOC7_ptr_ch12_683-748.indd 698 02/12/21 12:32 PM

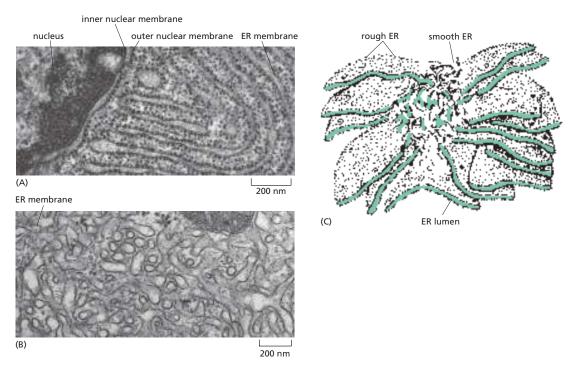

Figure 12–15 The rough and smooth ER. (A) An electron micrograph of the rough ER in a pancreatic exocrine cell that makes and secretes large amounts of digestive enzymes every day. The cytosol is filled with closely packed sheets of ER membrane that are studded with ribosomes. At the *top left* is a portion of the nucleus and its nuclear envelope; note that the outer nuclear membrane, which is continuous with the ER, is also studded with ribosomes. (B) Abundant smooth ER in a cell that secretes steroid hormone. This electron micrograph is of a testosterone-secreting Leydig cell in the human testis. (C) A three-dimensional reconstruction of a region of smooth ER and rough ER in a liver cell. The rough ER forms oriented stacks of flattened cisternae, each having a lumenal space 20–30 nm wide. The smooth ER membrane is connected to these cisternae and forms a fine network of tubules 30–60 nm in diameter. The ER lumen is colored *green*. (A, courtesy of Lelio Orci. B, courtesy of Daniel S. Friend, by permission of E.L. Bearer. C, after R.V. Kristić, Ultrastructure of the Mammalian Cell. New York: Springer-Verlag, 1979. With permission from Springer Nature.)

abundance of rough ER provided biologists the first clue that the ER is responsible for the synthesis and assembly of secreted proteins.

In contrast to rough ER, functions for the smooth ER are more diverse and can become highly specialized. A type of smooth ER found in all cells is called *transitional ER*, from which transport vesicles carrying newly synthesized proteins and lipids bud off for transport to the Golgi apparatus. In certain specialized cells, the smooth ER has additional functions that warrant its expansion. For example, cells that synthesize steroid hormones contain prominent smooth ER to accommodate the enzymes that make cholesterol and modify it to form a variety of steroid hormones (see Figure 12–15B).

The main cell type in the liver, the *hepatocyte*, also has expanded amounts of smooth ER (see Table 12–2) serving two separate purposes. The hepatocyte is the principal site of production of *lipoprotein particles*, which carry lipids via the bloodstream to other parts of the body. The enzymes that synthesize the lipid components of the particles are enriched in the membrane of the smooth ER. In addition, these membranes contain enzymes that catalyze a series of reactions to detoxify drugs and various harmful compounds produced by metabolism. The most extensively studied of these *detoxification reactions* are carried out by the *cytochrome P450* family of enzymes. They catalyze a series of reactions in which water-insoluble drugs or metabolites that would otherwise accumulate to toxic levels in cell membranes are rendered sufficiently water soluble to leave the cell and be excreted in the urine or bile.

Another crucially important function of the ER in most eukaryotic cells is to sequester Ca^{2+} from the cytosol. The release of Ca^{2+} into the cytosol from the

MBOC7_ptr_ch12_683-748.indd 699 02/12/21 12:32 PM

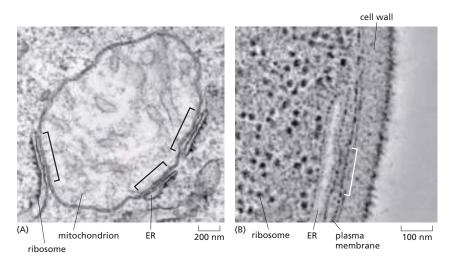

Figure 12–16 The ER makes close contacts with the mitochondria and plasma membrane. Electron micrographs of organelle contact sites between the ER and other membranes. (A) Region of a mouse embryonic fibroblast showing a mitochondrion that is closely apposed by sections of ER (black brackets). (B) Yeast cell showing a section of the ER that is closely juxtaposed with the plasma membrane (white bracket). [A, from P. Cosson et al., PLOS ONE 7(9):e46293, 2012. Courtesy of Pierre Cosson. B, courtesy of Wanda Kukulski.]

ER, and its subsequent reuptake, occur in many rapid responses to extracellular signals, as discussed in Chapter 15. A $\rm Ca^{2+}$ pump transports $\rm Ca^{2+}$ from the cytosol into the ER lumen. A high concentration of $\rm Ca^{2+}$ -binding proteins in the ER facilitates $\rm Ca^{2+}$ storage. In some cell types, specific regions of the ER are specialized for $\rm Ca^{2+}$ storage. Muscle cells have an abundant, modified smooth ER called the *sarcoplasmic reticulum*. The release and reuptake of $\rm Ca^{2+}$ by the sarcoplasmic reticulum trigger myofibril contraction and relaxation, respectively, during each round of muscle contraction (discussed in Chapter 16).

Finally, the smooth ER can be specialized in regions that make intimate contacts with other organelles, most notably the mitochondria, plastids, endosomes, and the plasma membrane (Figure 12–16). These organelle contact sites are enriched for proteins involved in communication or transport of key metabolites between the juxtaposed membranes. For example, the transport of lipids from their site of synthesis in the ER to the mitochondrion is thought to occur at ERmitochondria contact sites. Contact of ER with the plasma membrane modulates levels of plasma membrane phosphoinositides, which are lipids that participate in numerous signaling pathways (discussed in Chapters 13 and 15). Contacts between other combinations of organelles have also been observed, and it is likely that these are also involved in the selective transfer of lipids and other metabolites.

To study the functions and biochemistry of the ER, it is necessary to isolate it. This may seem to be a hopeless task because the ER is intricately interleaved with other components of the cytoplasm. Fortunately, when tissues or cells are disrupted by homogenization, the ER breaks into fragments, which reseal to form small (~100-200 nm in diameter) closed vesicles called **microsomes** (Figure 12-17). To the biochemist, microsomes represent small authentic versions of the ER, still capable of protein translocation, protein glycosylation (discussed later), Ca²⁺ uptake and release, and lipid synthesis. *Rough microsomes*, derived from rough ER, contain ribosomes on their outside surface and enclose a small part of the ER lumen. *Smooth microsomes*, which lack ribosomes, are derived from vesiculated fragments of the smooth ER, plasma membrane, Golgi apparatus, endosomes, and mitochondria. The ribosomes attached to rough microsomes make them denser than smooth microsomes. As a result, scientists use equilibrium density centrifugation to separate the rough and smooth microsomes (Figure 12-17). Smooth microsomes derived from different organelles can

MBOC7_ptr_ch12_683-748.indd 700 02/12/21 12:32 PM

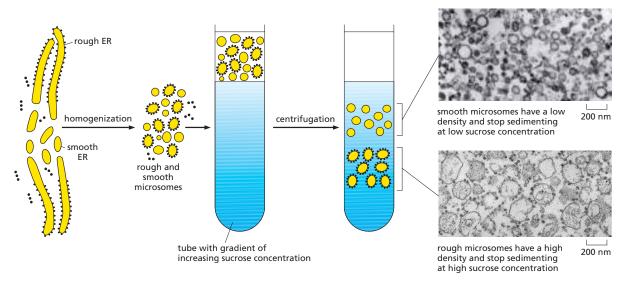

Figure 12–17 The isolation of purified rough and smooth microsomes from the ER. When an intact cell or tissue is homogenized, many of its membrane-enclosed compartments form small sealed vesicles called microsomes. When this mixture of vesicles is sedimented to equilibrium through a gradient of sucrose, the two types of microsomes separate from each other on the basis of their different densities. Note that the smooth fraction contains non-ER-derived material. Thin section electron micrographs of the purified smooth and rough microsome fractions show an abundance of ribosome-studded vesicles in the rough microsome fraction that originated from the rough ER. These are not seen in the smooth microsome fraction, which primarily contains ribosome-free vesicles originating from the smooth ER, Golgi cisternae, and other organelles. (Electron micrographs courtesy of George Palade.)

be further separated on the basis of differences in their protein content. Microsomes have been invaluable in elucidating the molecular aspects of ER function, as we discuss next.

Signal Sequences Were First Discovered in Proteins Imported into the Rough ER

The ER captures selected proteins from the cytosol as they are being synthesized. These proteins are of two types: *transmembrane proteins*, which become embedded in the ER membrane, and *water-soluble proteins*, which are fully translocated across the ER membrane into the ER lumen. Some of these proteins function in the ER, but many are destined to reside in another organelle, to reside in the plasma membrane, or to be secreted outside the cell. All of these proteins, regardless of their subsequent fate, are initially directed to the ER membrane by an **ER signal sequence**.

Signal sequences (and the signal sequence strategy of protein sorting) were discovered in secreted water-soluble proteins that are first translocated across the ER membrane. In the key experiment, the mRNA encoding a secreted protein was added to cytosol extracted from cells. In this cell-free reaction, ribosomes in the cytosol translated the mRNA into a protein that was slightly larger than the normal secreted protein (Figure 12-18). When the reaction was repeated in the presence of microsomes derived from the rough ER, a protein of the correct size was produced and located inside the microsomes (Figure 12-18). By contrast, mRNA encoding a cytosolic protein produced the correctly sized product regardless of the presence or absence of rough microsomes. The signal hypothesis was formulated to explain these observations. According to this model, the mRNA for the secretory protein codes for a protein that is bigger than the protein that is eventually secreted. It was proposed that the extra polypeptide is a signal sequence that directs the secreted protein to the ER membrane. After the signal sequence has served its function, it is cleaved off by a signal peptidase in the ER membrane before the polypeptide chain has been completed.

MBOC7_ptr_ch12_683-748.indd 701 02/12/21 12:32 PM

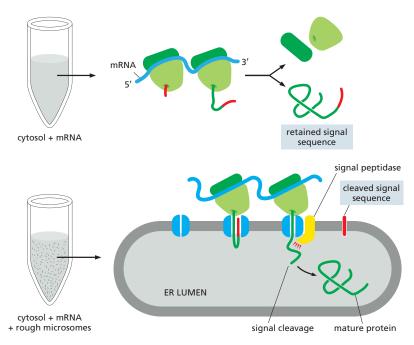

Figure 12-18 Experimental basis for the signal hypothesis. In a test tube, cytosol is mixed with mRNA that codes for a secreted protein. Two versions of this reaction are performed: one lacking and the other containing rough microsomes derived from the ER (see Figure 12-17). In both reactions, ribosomes in the cytosol translate the mRNA to produce a protein. The protein produced in the reaction lacking microsomes was observed to be slightly larger than the protein produced in the reaction containing microsomes. This difference in size was shown to be due to a small segment of protein at the N-terminus that was selectively removed only in the reaction containing microsomes. Additional analysis showed that the protein produced in the presence of microsomes was located in the microsome lumen. This collection of results was used to formulate the signal hypothesis. This sequence at the N-terminus was postulated to represent a signal sequence. When the ER signal sequence emerges from the ribosome, it directs the ribosome to a translocator on the ER membrane that forms a pore in the membrane through which the polypeptide is translocated. A signal peptidase is closely associated with the translocator and clips off the signal sequence during translation, and the mature protein is released into the lumen of the ER immediately after its synthesis is completed. The translocator is closed until the ribosome has bound, so that the permeability barrier of the ER membrane is maintained at all times.

These experiments highlight how a complex cellular process such as ER import can be reconstituted in a cell-free system by mixing together requisite cellular components such as mRNA, cytosol, and microsomes. By combining the constituent parts in different ways, the existence of signal sequences on secreted proteins was deduced long before it became possible to directly sequence their mRNAs. The ease with which this cell-free system could be manipulated proved indispensable for identifying, purifying, and studying the various components of the molecular machinery responsible for ER import. Similar systems were later established to dissect protein transport into and out of the nucleus, protein import into mitochondria and chloroplasts, and vesicular transport.

A Signal-Recognition Particle (SRP) Directs the ER Signal Sequence to a Specific Receptor at the ER

The ER signal sequence is guided to the ER membrane by at least two components: a **signal-recognition particle (SRP)**, which binds to the signal sequence, and an **SRP receptor** in the ER membrane. SRP is a large complex; in animal cells, it consists of six different polypeptide chains bound to a single RNA molecule (**Figure 12–19A**). While SRP and SRP receptor have fewer subunits in bacteria, homologs of both components are present in all living organisms.

MBOC7_ptr_ch12_683-748.indd 702 02/12/21 12:32 PM

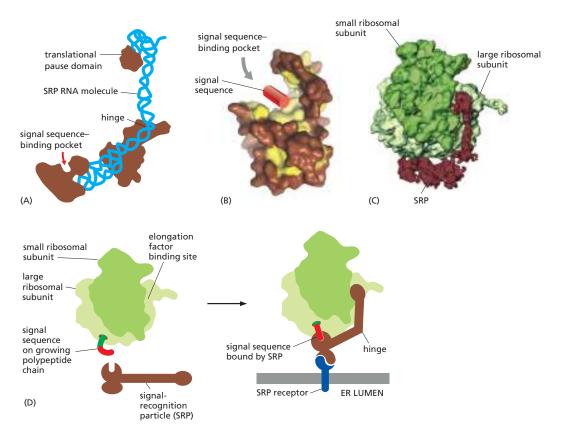

Figure 12–19 The signal-recognition particle (SRP). (A) A mammalian SRP is a rodlike ribonucleoprotein complex containing six protein subunits (brown) and one RNA molecule (blue). The SRP RNA forms a backbone that links the protein domain containing the signal sequence—binding pocket to the domain responsible for slowing translation. (B) Structure of the signal sequence—binding domain of SRP bound to the hydrophobic region of a signal sequence (red cylinder). The surfaces of SRP that are hydrophobic are depicted in yellow. (C) The three-dimensional outline of the SRP bound to a ribosome was determined by cryo-electron microscopy. SRP binds to the large ribosomal subunit so that its signal sequence—binding pocket is positioned near the growing polypeptide chain exit site. Its translational pause domain is positioned at the interface between the ribosomal subunits, where it interferes with elongation factor binding. (D) As a signal sequence emerges from the ribosome and binds to the SRP, a conformational change in the SRP exposes a binding site for the SRP receptor. (C, adapted from M. Halic et al., Nature 427:808–814, 2004.)

This protein-targeting mechanism therefore arose early in evolution and has been conserved.

ER signal sequences vary greatly in amino acid sequence, but each has eight or more nonpolar amino acids at its center (see Figure 12–13). How can SRP bind specifically to so many different sequences? The answer has come from structures of one of the SRP proteins, which shows that the signal sequence-binding site is a large hydrophobic pocket enriched in methionines (Figure 12–19B). Because methionines have unbranched, flexible side chains, the pocket is sufficiently plastic to accommodate different hydrophobic signal sequences of various sizes and shapes.

In eukaryotic cells, SRP is a hinged rodlike structure that can wrap along the large ribosomal subunit (Figure 12–19C). The end of SRP that contains the signal sequence-binding pocket is positioned near the ribosomal tunnel through which newly made polypeptides emerge. This allows SRP to engage a signal sequence as it emerges from the ribosome. Once SRP engages a signal sequence, the other end of SRP can bind at the interface between the large and small ribosomal subunits (Figure 12–19D). This is the same site where translation elongation factors bind, so a ribosome engaged by SRP will translate proteins more slowly than normal. Slower translation presumably gives the ribosome enough time to bind to the ER membrane before completion of the polypeptide

MBOC7_ptr_ch12_683-748.indd 703 02/12/21 12:32 PM

chain, thereby ensuring that the protein is not released into the cytosol. This safety device may be especially important for secreted and lysosomal hydrolases, which could wreak havoc in the cytosol; cells that secrete large amounts of hydrolases, however, take the added precaution of having high concentrations of hydrolase inhibitors in their cytosol.

When a signal sequence binds, SRP exposes a binding site for an SRP receptor (see Figure 12–19D), which is a transmembrane protein complex in the rough ER membrane. The binding of SRP to its receptor brings the SRP-ribosome complex to an unoccupied **protein translocator** in the ER membrane. The part of SRP bound near the ribosomal tunnel moves to a different site, allowing the translocator to occupy this position. SRP and SRP receptor are then released, and protein synthesis resumes at full speed. The translocator, which is now tightly bound to the translating ribosome, transfers the growing polypeptide chain across the membrane (Figure 12–20).

This **co-translational** transfer process creates two spatially separate populations of ribosomes. **Membrane-bound ribosomes**, attached to the cytosolic side of the ER membrane, are engaged in the synthesis of proteins that are being concurrently translocated across the ER membrane. **Free ribosomes**, unattached to any membrane, synthesize all other proteins encoded by the nuclear genome. Membrane-bound and free ribosomes are structurally and functionally identical. They differ only in the proteins they are making at any given time.

Because many ribosomes can engage with a single mRNA molecule, a **polyribosome** is usually formed. If the mRNA encodes a protein with an ER signal sequence, the polyribosome becomes attached to the ER membrane, directed there by the signal sequences on multiple growing polypeptide chains. The individual ribosomes associated with such an mRNA molecule can return to the cytosol when they finish translation and intermix with the pool of free ribosomes. The mRNA itself, however, remains attached to the ER membrane by a

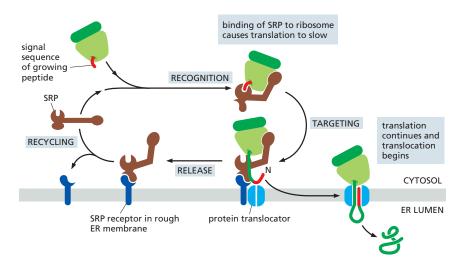

Figure 12–20 How ER signal sequences and SRP direct ribosomes to the ER membrane. The SRP and its receptor act in concert. The SRP binds to both the exposed ER signal sequence and the ribosome, thereby causing translation to slow. The SRP receptor in the ER membrane, which in animal cells is composed of two different polypeptide chains, binds the SRP-ribosome complex and directs it to the translocator. The SRP (in complex with SRP receptor) then moves away from its binding site on the ribosome, which is then occupied by the translocator in the ER membrane. SRP then releases the signal sequence, which inserts into the translocator to initiate polypeptide chain transfer across the lipid bilayer. The SRP and SRP receptor dissociate from each other and are recycled for the next round of protein targeting. Although not shown in the figure, one of the SRP proteins and both chains of the SRP receptor contain GTP-binding domains. Conformational changes that occur during cycles of GTP binding and hydrolysis (discussed in Chapter 15) ensure that SRP preferentially binds a signal sequence in the cytosol and releases it only after SRP successfully engages the SRP receptor at the ER membrane. The energy of GTP hydrolysis is therefore used to impart directionality to the cycle of SRP-mediated protein targeting.

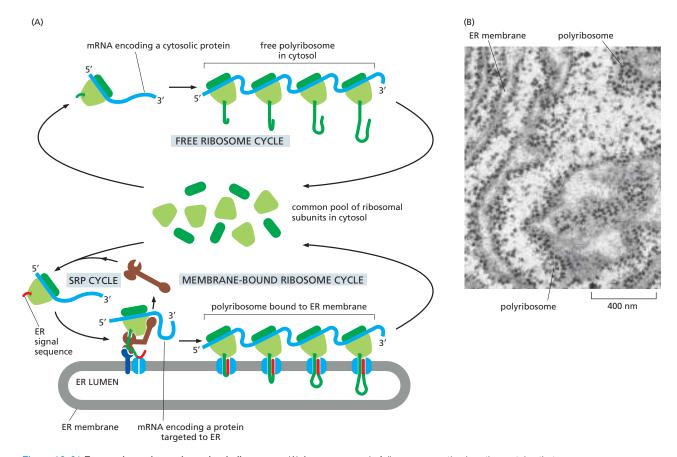

Figure 12–21 Free and membrane-bound polyribosomes. (A) A common pool of ribosomes synthesizes the proteins that stay in the cytosol and those that are transported into the ER. The ER signal sequence on a newly formed polypeptide chain binds to SRP, which directs the translating ribosome to the ER membrane. The mRNA molecule remains bound to the ER as part of a polyribosome, while the ribosomes that move along it are recycled; at the end of each round of protein synthesis, the ribosomal subunits are released and rejoin the common pool in the cytosol. (B) A thin section electron micrograph of polyribosomes attached to the ER membrane. The plane of the section in some places cuts through the ER roughly parallel to the membrane, giving a face-on view of the circular or spiral pattern of the polyribosomes. changing population of ribosomes, each transiently held at the membrane by the translocator (Figure 12-21).

The Polypeptide Chain Passes Through a Signal Sequence–gated Aqueous Channel in the Translocator

It had long been debated whether polypeptide chains are transferred across the ER membrane in direct contact with the lipid bilayer or through a channel in a protein translocator. The debate ended with the identification of the translocator, which was shown to form a water-filled channel across the membrane through which the polypeptide chain passes. The core of the translocator, called the **Sec61 complex**, is built from three subunits that are highly conserved from bacteria to eukaryotic cells. The structure of the Sec61 translocator revealed that $10~\alpha$ helices surround a central channel (**Figure 12–22**). The channel is plugged by a short α helix that keeps the translocator closed when it is idle. It is important to keep the channel closed to prevent ions, such as Ca^{2+} , from leaking out of the ER. During translocation, the plug moves out of the way so the polypeptide can pass through the channel.

The Sec61 translocator only opens for proteins containing a signal sequence. The ability of the Sec61 translocator to recognize signal sequences provides a proofreading step to ensure that only proteins truly intended for the ER are

MBOC7_ptr_ch12_683-748.indd 705 02/12/21 12:32 PM

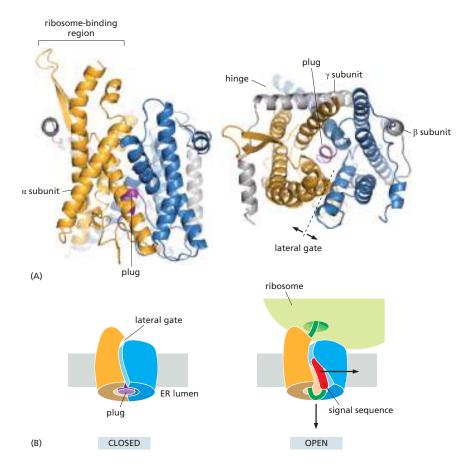

Figure 12-22 Structure of the Sec61 translocator. (A) A side view (left, seen from the membrane) and a top view (right, seen from the cytosol) of the structure of the Sec61 translocator of the archaeon Methanococcus jannaschii (where it is called the SecY translocator). The Sec61 α subunit has an inverted repeat structure (see Figure 11-10) and is shown in blue and orange to indicate this pseudosymmetry: the two smaller B and ν subunits are shown in grav. Some regions of the Sec61 α subunit that protrude into the cytosol bind to the ribosome during protein translocation. The purple short helix forms a plug that seals the pore when the translocator is closed. When the translocator is open, the plug helix moves out of the way. The Sec61/ SecY translocator can also open sideways toward the membrane at a lateral gate. (B) Models of the closed and functionally active states of the Sec61/SecY translocator. In the active state, a protein chain can either translocate across the membrane through the central channel in the translocator or move sideways into the lipid bilayer through the lateral gate. (A, PDB code: 1RH5.)

allowed to enter. **Cryo-electron microscopy** structures of the Sec61 translocator before and after signal sequence recognition show that the signal sequence wedges into a lateral gate, or seam, in Sec61 with its N-terminus facing the cytosol (**Figure 12–23A**). Insertion of the signal sequence at this lateral gate widens the central channel and releases the plug. The open translocator then readily accommodates the segment of polypeptide following the signal sequence inside the channel. The signal sequence, which is hydrophobic, laterally exits the gate into the membrane where it is cleaved off by signal peptidase and then rapidly degraded to amino acids by other proteases in the ER membrane and cytosol. As this mechanism illustrates, the lateral gate in the Sec61 translocator provides the access route from Sec61's central channel into the hydrophobic core of the membrane. In addition to its role in recognition of signal sequences, the lateral gate guides the integration of transmembrane proteins into the ER, as we discuss later.

Once the signal sequence has opened the Sec61 translocator and threaded the ensuing polypeptide into the channel, translocation occurs concurrently with continued translation. During translocation, the polypeptide tunnel inside the ribosomal large subunit is aligned with the channel within the Sec61 translocator (Figure 12–23B). This configuration provides a continuous path for the polypeptide from the peptidyl-transferase center in the ribosome, where new amino acids are added to the growing protein chain, to the ER lumen 15 nm away. In this way, the energy used for polypeptide elongation is indirectly harnessed to also drive translocation across the ER membrane.

When translation terminates, the C-terminus of the polypeptide is released from the ribosome and slips through the Sec61 translocator, whose plug returns to close the channel. Thus, the entire process of ER import, from signal sequence recognition by SRP to translocation through the Sec61 translocator, occurs co-translationally before the polypeptide has a chance to fold. This pathway provides one solution

MBOC7_ptr_ch12_683-748.indd 706 02/12/21 12:32 PM

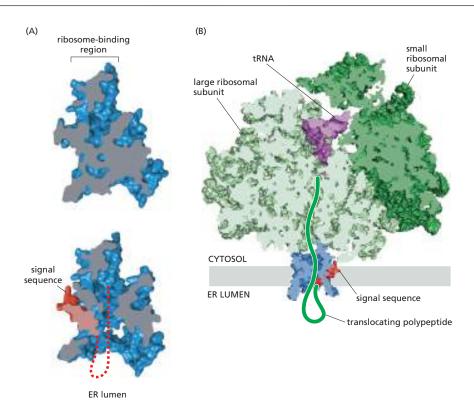

Figure 12–23 A signal sequence opens the Sec61 translocator. (A) Cross section through the Sec61 translocator before and after a signal sequence has inserted into the lateral gate. Insertion of the signal sequence causes the central channel in the translocator to widen and the plug to move out of this channel; hence, a continuous path across the membrane is now apparent (dashed line). (B) Cross section through the structure of a translating ribosome (green) bound to a Sec61 translocator (blue) that has been opened by a signal sequence (red). A translocating polypeptide is shown passing through the tunnel within the large ribosomal subunit and the Sec61 translocator. (A, PDB codes: 3J7Q and 3JC2; B, PDB code: 3JC2.)

to the problem of how to move a large protein across a membrane barrier without leakage of much smaller ions and metabolites during the process.

Translocation Across the ER Membrane Does Not Always Require Ongoing Polypeptide Chain Elongation

Some proteins are completely synthesized in the cytosol as precursors before they are imported into the ER, demonstrating that translocation does not always require ongoing translation (Figure 12–24). This is termed post-translational translocation. Post-translational protein translocation is more common across the yeast ER membrane and the evolutionarily related bacterial plasma membrane. In both cases, the Sec61 translocator (called SecY in bacteria) is used as the

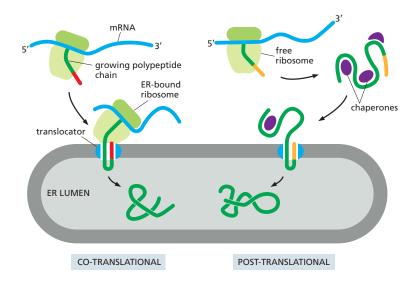

Figure 12–24 Co-translational and post-translational protein translocation. Ribosomes bind to the ER membrane during co-translational translocation. By contrast, cytosolic ribosomes complete the synthesis of a protein and release it prior to post-translational translocation. The released protein is kept unfolded in the cytosol by chaperones that dissociate before the protein is translocated across the membrane. In both cases, the protein is directed to the ER by an ER signal sequence (red and orange). See Movie 12.3.

MBOC7_ptr_ch12_683-748.indd 707 02/12/21 12:32 PM

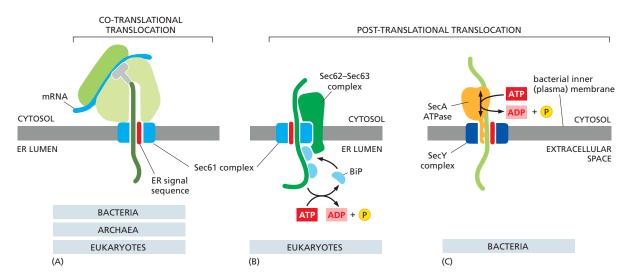

Figure 12–25 Three ways in which protein translocation can be driven through structurally similar translocators.

(A) Co-translational translocation. The ribosome is brought to the membrane by the SRP and SRP receptor and then engages with the Sec61 translocator. The growing polypeptide chain is threaded across the membrane as it is made. No additional energy is needed, as the only path available to the growing chain is to cross the membrane. (B) Post-translational translocation in eukaryotic cells requires an additional complex composed of Sec62 and Sec63 proteins. This complex is attached to the Sec61 translocator and positions BiP molecules where they can bind to the translocating chain as it emerges from the translocator in the lumen of the ER. ATP-driven cycles of BiP binding and release pull the protein into the lumen.

(C) Post-translational translocation in bacteria. The completed polypeptide chain is fed from the cytosolic side into the bacterial homolog of the Sec61 translocator (called SecY) in the plasma membrane by the SecA ATPase. ATP hydrolysis—driven conformational changes drive a pistonlike motion in SecA. The piston not only pushes several amino acids of the protein chain through the pore of the translocator but also prevents backsliding of the chain into the cytosol. Whereas the Sec61 translocator, SRP, and SRP receptor are found in all organisms, SecA is found exclusively in bacteria, and the Sec62–Sec63 complex is found exclusively in eukaryotic cells. (Adapted from P. Walter and A.E. Johnson, *Annu. Rev. Cell Biol.* 10:87–119, 1994.)

translocator; its narrow channel means that precursors can only be translocated as unfolded polypeptides. Thus, precursor proteins do not fold after their initial synthesis in the cytosol. Instead, they interact with other cytosolic proteins that prevent precursor folding or aggregation before they engage the Sec61 translocator. These interacting proteins typically are general chaperone proteins, such as those of the hsp70 family (discussed in Chapter 6), and must dissociate as the unfolded polypeptide is threaded through the translocator.

Just as in co-translational translocation discussed earlier, the signal peptide of a precursor directly engages the Sec61 translocator to open the channel. However, the next step of translocation across the membrane occurs differently and relies on accessory proteins that use cellular energy to either pull the polypeptide across the channel from the lumenal side or feed it into the channel from the cytosol (Figure 12-25). To pull proteins into the ER lumen, eukaryotic cells use accessory proteins called Sec62 and Sec63 that associate with the Sec61 translocator and position an hsp70-like chaperone protein (called BiP, for binding protein) adjacent to the lumenal opening of the translocation channel. Like its cytosolic cousin, BiP has a high affinity for unfolded polypeptide chains, and it binds tightly to an imported protein chain as soon as it emerges from the Sec61 translocator in the ER lumen. Tight binding by BiP prevents the protein chain from sliding backwards, favoring more of the chain to emerge into the lumen where it can bind another molecule of BiP. ATP hydrolysis by BiP causes it to release the polypeptide, making it available to bind again to any newly emerged segments of the translocating polypeptide. This energy-driven cycle of binding and release serves as a molecular ratchet that provides the driving force for protein import after a precursor has initially inserted into the Sec61 translocator.

Because bacteria transport proteins directly to the extracellular space, where energy is not available, they use a cytosolic accessory protein called the SecA

MBOC7_ptr_ch12_683-748.indd 708 02/12/21 12:32 PM

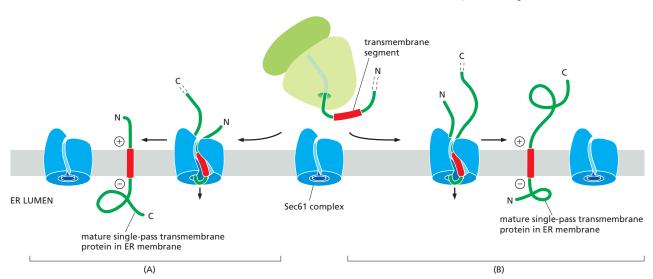

ATPase. SecA binds to the precursor polypeptide and attaches to the cytosolic side of the translocator, where it undergoes cyclic conformational changes fueled by ATP hydrolysis. Each time an ATP is hydrolyzed, a portion of the SecA protein inserts into the pore of the translocator, pushing a short segment of the precursor protein with it. As a result of this pistonlike ratchet mechanism, the SecA ATPase progressively pushes the polypeptide chain of the transported protein across the membrane.

Transmembrane Proteins Contain Hydrophobic Segments That Are Recognized Like Signal Sequences

All of the transmembrane proteins that populate the ER, Golgi apparatus, lysosomes, endosomes, secretory vesicles, and plasma membrane are inserted into the ER membrane before moving to their final destination. Transmembrane proteins made at the ER span the lipid bilayer via one or more α -helical hydrophobic **transmembrane segments** (see Figure 10–17). Thus, the biosynthesis of membrane proteins requires some parts of the polypeptide chain to be translocated across the lipid bilayer, other parts to remain in the cytosol, and the transmembrane segments to be integrated into the membrane. Despite this additional complexity, the same factors (SRP, SRP receptor, and the Sec61 translocator) just described for transferring a soluble protein into the ER lumen also mediate transmembrane protein integration into the ER membrane. The same factors can be used because the transmembrane segments that define a transmembrane protein resemble the hydrophobic ER signal sequences that direct soluble protein translocation.

In the simplest case, a transmembrane protein contains a single transmembrane segment that will ultimately be embedded in the lipid bilayer as a membrane-spanning α helix. When this transmembrane segment emerges from the ribosome during synthesis, SRP recognizes its hydrophobic α -helical features as a signal sequence and brings this ribosome to the Sec61 translocator at the ER membrane. The transmembrane segment then inserts into the lateral gate of the Sec61 translocator, which is the same site where signal sequences bind. The orientation in which the transmembrane segment inserts into the lateral gate determines whether the protein segment preceding or the one following the transmembrane segment is moved across the membrane into the ER lumen (Figure 12-26). If the N-terminus is short and unfolded, orientation of the transmembrane segment depends on features of the polypeptide chain such as the distribution of nearby charged amino acids and the length of the transmembrane segment. If the preceding N-terminal segment is long and stably folded, it does not cross the membrane through the narrow Sec61 channel. In this case, the C-terminal segment that is still being synthesized, and therefore unfolded, is translocated across the membrane.

Figure 12-26 A transmembrane segment directs membrane protein insertion into the ER membrane. Many single-pass membrane proteins use their transmembrane segment to direct insertion into the ER membrane (Movie 12.3). The transmembrane segment is recognized by SRP (not shown) and delivered via the SRP receptor (not shown) to the Sec61 translocator at the ER membrane. The transmembrane segment then inserts into the lateral gate of the Sec61 translocator in one of two orientations. (A) Some transmembrane segments insert into the lateral gate such that the N-terminal domain is retained on the cytosolic side of Sec61. This orientation is favored for proteins whose N-terminal domains are very long or folded, and for transmembrane segments whose flanking amino acids have a net positive charge on the N-terminal side. (B) Some transmembrane segments insert into the lateral gate such that the C-terminal flanking region is retained on the cytosolic side of Sec61. In this case, the N-terminal flanking region is thought to translocate across the membrane through the Sec61 channel. This orientation is favored for transmembrane segments whose flanking amino acids have a net positive charge on the C-terminal side.

MBOC7_ptr_ch12_683-748.indd 709 02/12/21 12:32 PM

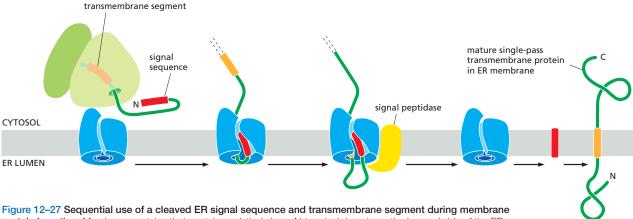

Figure 12–27 Sequential use of a cleaved ER signal sequence and transmembrane segment during membrane protein insertion. Membrane proteins that contain a relatively large N-terminal domain on the lumenal side of the ER utilize both a cleaved ER signal sequence and a transmembrane segment. Targeting to the ER membrane, initiation of translocation through Sec61, and cleavage of the signal sequence all occur exactly as for a secretory protein (see Figure 12–20). However, when the transmembrane segment enters the Sec61 translocation, translocation stops and the transmembrane segment moves through the lateral gate into the lipid bilayer. The remainder of the protein continues to be synthesized on the cytosolic side of the membrane until translation terminates.

Many transmembrane proteins contain large N-terminal lumenal domains. In this case, an N-terminal signal sequence is used to initiate translocation, just as for a soluble protein. In this way, the N-terminus of the mature polypeptide is committed to the ER lumen by the signal sequence, and the remainder of the polypeptide begins translocation through the Sec61 translocator. When a hydrophobic segment in the polypeptide emerges from the ribosome, it inserts into the lateral gate to gain access to the lipid bilayer. Because the hydrophobic segment is more stable in the membrane than in the aqueous channel, it exits the channel laterally, translocation stops, and the rest of the protein is synthesized on the cytosolic side of the ER membrane (Figure 12–27).

Hydrophobic Segments of Multipass Transmembrane Proteins Are Interpreted Contextually to Determine Their Orientation

In multipass transmembrane proteins, the polypeptide chain passes back and forth repeatedly across the lipid bilayer as hydrophobic α helices (see Figure 10–17). Synthesis of multipass transmembrane proteins up to the first transmembrane segment occurs as we have just described for single-pass transmembrane proteins. Hence, SRP will deliver the protein to the translocator, where the first transmembrane segment will insert into the lateral gate of the Sec61 translocator in an orientation dictated by features of the preceding N-terminal domain and nearby charged amino acids. In this way, insertion of the first transmembrane segment into the membrane effectively locks in the topology for the rest of the protein to come. From this point onward, each successive hydrophobic segment is interpreted by the Sec61 translocator on the basis of the topology and properties of the preceding parts of the protein.

Because of the tight coupling between the ribosome and Sec61 translocator, each hydrophobic segment emerges very close to the lateral gate that provides access to the lipid bilayer. In the simplest cases, the newly emerged hydrophobic segment engages the lateral gate in an orientation opposite to the most recently inserted transmembrane segment and inserts into the lipid bilayer (Figure 12–28). Some transmembrane segments of multipass proteins are only partially hydrophobic and would not be stable in the lipid bilayer on their own. These can nevertheless insert into the membrane if they are able to interact with one of the preceding transmembrane segments that is near the lateral gate of Sec61. This cooperation makes it possible to produce multipass transmembrane proteins that contain hydrophilic parts within the lipid bilayer, which is crucial

MBOC7_ptr_ch12_683-748.indd 710 02/12/21 12:32 PM

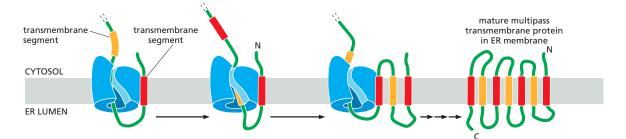

Figure 12–28 The insertion of a multipass transmembrane protein into the ER membrane. The events up to the insertion of the first transmembrane segment follow the steps for single-pass membrane proteins (see Figures 12–26 and 12–27). The orientation of this first transmembrane segment depends on the characteristics of the transmembrane segment and flanking regions just as for single-pass membrane proteins. When the next transmembrane segment emerges from the ribosome, it inserts into the lateral gate of Sec61 in an orientation opposite to that of the first transmembrane segment, then moves into the lipid bilayer. Each successive transmembrane segment is similarly inserted into the membrane via the lateral gate in an orientation opposite to that of the transmembrane segment that immediately preceded it. This proceeds until all transmembrane segments have been inserted into the membrane.

for many important proteins such as transporters and channels (discussed in Chapter 11). The hydrophilic sequences between the transmembrane segments are either synthesized into the cytosol or threaded through the Sec61 translocator, depending on the orientation of the preceding transmembrane segment. In this way, a multipass protein is woven into the membrane with successive hydrophobic segments achieving opposite orientations until all of them have been inserted into the membrane as transmembrane α helices.

Because membrane proteins are always inserted from the cytosolic side of the ER in this programmed manner, all copies of the same polypeptide chain will have the same orientation in the lipid bilayer. This generates an asymmetrical ER membrane in which the protein domains exposed on one side are different from those exposed on the other side. This asymmetry is maintained during the many membrane budding and fusion events that transport the proteins made in the ER to other cell membranes (discussed in Chapter 13). Thus, the way in which a newly synthesized protein is inserted into the ER membrane determines the orientation of the protein in all of the other membranes as well.

Some Proteins Are Integrated into the ER Membrane by a Post-translational Mechanism

Many important cytosol-facing membrane proteins are anchored in the membrane by a single transmembrane α helix very close to the C-terminus. These tail-anchored proteins include a large number of SNARE protein subunits that guide vesicular traffic (discussed in Chapter 13). When a tail-anchored protein is translated, the ribosome reaches the termination codon while the polypeptide sequence destined to become a transmembrane α helix is still inside the ribosome exit tunnel. Recognition by SRP is therefore not possible, and the protein is released from the ribosome into the cytosol. The hydrophobic segment is recognized by a specialized chaperone complex that transfers it to a targeting factor called Get3 (Figure 12-29). Although unrelated to SRP, Get3 also contains a hydrophobic pocket lined by many methionine side chains to help it recognize diverse hydrophobic segments independent of their exact sequence. Two proteins at the ER membrane called Get1 and Get2 serve not only as the receptor for Get3 but also as the translocator that inserts the hydrophobic segment of the tail-anchored protein into the lipid bilayer. This post-translational targeting mechanism is therefore conceptually similar to SRP-dependent protein targeting (see Figure 12-20). Some tail-anchored proteins are targeted to mitochondria or peroxisomes instead of the ER, but the mechanism of their targeting is not known.

MBOC7_ptr_ch12_683-748.indd 711 02/12/21 12:32 PM

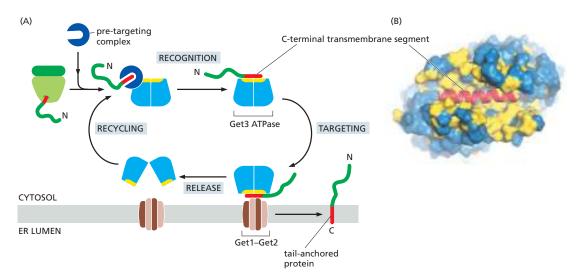

Figure 12–29 The insertion mechanism for tail-anchored proteins. (A) In this post-translational pathway for the insertion of tail-anchored membrane proteins into the ER, a soluble pre-targeting complex captures the hydrophobic C-terminal transmembrane segment (red) after it emerges from the ribosomal exit tunnel and loads it onto the Get3 targeting factor. The resulting complex is targeted to the ER membrane by interaction with the Get1–Get2 receptor complex, which functions as a membrane protein insertion machine. After the tail-anchored protein is released from Get3 and inserted into the ER membrane, Get3 is recycled back to the cytosol. This targeting cycle is conceptually similar to protein targeting by SRP (see Figure 12–20). Although not shown in the figures, both Get3 and SRP bind and hydrolyze nucleoside triphosphates to provide directionality to the targeting cycle. ATP is used by Get3, and GTP is used by SRP. (B) Crystal structure of the Get3 targeting factor bound to a transmembrane segment (red helix). The hydrophobic transmembrane segment binds to a deep groove in Get3 lined by hydrophobic amino acids (yellow), including many flexible methionines. (PDB code: 4XTR.)

Some Membrane Proteins Acquire a Covalently Attached Glycosylphosphatidylinositol (GPI) Anchor

Another way that proteins are attached to the membrane is by a glycosylphosphatidylinositol (GPI) anchor that is covalently linked to the C-terminus of some proteins destined for the plasma membrane. GPI-anchored proteins are initially made with an N-terminal signal sequence to direct them to the ER and a hydrophobic segment very close to the C-terminus. This hydrophobic segment is selectively recognized by a transamidase enzyme in the ER membrane that simultaneously cleaves off the hydrophobic segment and attaches a preformed GPI anchor to the rest of the protein (Figure 12-30). Many plasma membrane proteins are modified in this way. Because they are attached to the exterior of the plasma membrane only by their GPI anchors, they can be released from cells in soluble form in response to signals that activate a specific phospholipase in the plasma membrane. Trypanosome parasites, for example, use this mechanism to shed their coat of GPI-anchored surface proteins when attacked by the immune system. GPI anchors also participate in directing some plasma membrane proteins into specialized domains, such as lipid rafts, thus laterally segregating them from other membrane proteins (see Figure 10-13).

Translocated Polypeptide Chains Fold and Assemble in the Lumen of the Rough ER

Proteins enter the ER lumen as unfolded polypeptides. They must therefore fold and assemble into their correct three-dimensional structures just as newly made proteins in the cytosol must fold (discussed in Chapter 3). To meet this demand, the lumen of the ER contains a high concentration of resident chaperones and other protein-folding catalysts. These ER resident proteins contain an ER retention signal of four amino acids at their C-terminus that is responsible for retaining the protein in the ER (see Figure 12–13; discussed in Chapter 13, p. 768).

MBOC7_ptr_ch12_683-748.indd 712 02/12/21 12:32 PM

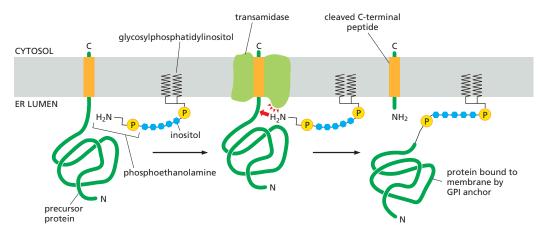

Figure 12–30 The attachment of a GPI anchor to a protein in the ER. GPI-anchored proteins are targeted to the ER membrane by an N-terminal signal sequence (not shown), integrated into the membrane, and processed by signal peptidase similarly to a single-pass transmembrane protein (see Figure 12–27). Immediately after the completion of protein synthesis, the precursor protein remains anchored in the ER membrane by a hydrophobic C-terminal sequence of 15–20 amino acids; the rest of the protein is in the ER lumen. Within less than a minute, a transamidase enzyme in the ER cleaves the protein from its membrane-bound C-terminus and simultaneously attaches the new C-terminus to an amino group on a preassembled GPI intermediate. The sugar chain contains an inositol attached to the lipid from which the GPI anchor derives its name. It is followed by a glucosamine and three mannoses. The terminal mannose links to a phosphoethanolamine that provides the amino group to attach the protein through an amide bond. The signal that specifies this modification is contained within the hydrophobic C-terminal sequence and a few amino acids adjacent to it on the lumenal side of the ER membrane; if this signal is added to other proteins, they too become modified in this way. Because of the covalently linked lipid anchor, the protein remains membrane-bound, with all of its amino acids exposed initially on the lumenal side of the ER and eventually on the exterior of the plasma membrane.

The protein **BiP**, a member of the hsp70 family of chaperone proteins, is a major component of the ER folding machinery. We have already discussed how BiP pulls proteins post-translationally into the ER through the Sec61 ER translocator. Like other chaperones (discussed in Chapter 6), BiP recognizes incorrectly folded proteins, as well as protein subunits that have not yet assembled into their final oligomeric complexes. It does so by binding to exposed hydrophobic amino acid sequences that would normally be buried in the interior of correctly folded or assembled polypeptide chains. The bound BiP both prevents the protein from aggregating and helps keep it in the ER (and thus out of the Golgi apparatus and later parts of the secretory pathway). BiP hydrolyzes ATP to shuttle between high-and low-affinity polypeptide-binding states. In this way, BiP periodically lets go of its substrate proteins to allow them an opportunity to fold, and then re-binds them if folding is not yet achieved.

The ER resident protein *protein disulfide isomerase* (*PDI*) catalyzes the oxidation of free sulfhydryl (SH) groups on cysteines to form disulfide (S—S) bonds (**Figure 12–31**). Almost all cysteines in protein domains exposed to either the

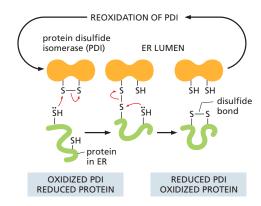

Figure 12-31 The formation of disulfide bonds in the ER. Proteins that contain free sulfhydryl (SH) groups on cysteines are oxidized during protein folding to incorporate disulfide (S-S) bonds. Protein disulfide isomerase (PDI) contains an intramolecular disulfide bond that accepts electrons from a free sulfhydryl group in the substrate protein to be oxidized. This leads to the formation of an intermolecular mixed disulfide bond between PDI and its substrate. A second free sulfhydryl group in the substrate then donates its electrons to the mixed disulfide bond, resulting in an oxidized substrate and reduced PDI. Reoxidation of PDI is carried out by other ER enzymes (not shown).

MBOC7_ptr_ch12_683-748.indd 713 02/12/21 12:32 PM

extracellular space or the lumen of organelles in the secretory and endocytic pathways are disulfide bonded. Disulfide bonds stabilize the folded state of a protein, enabling it to better withstand a harsh, variable, and chaperone-free extracellular environment. Because proteins often contain multiple cysteines, they sometimes pair incorrectly. PDI resolves this problem by rearranging the disulfide bonds in a protein until it is correctly folded. This is possible because PDI enzymes are capable of operating in reverse to reduce incorrectly paired disulfides of immature proteins. The ER lumen contains multiple members of the PDI family, some of which are specialized for reducing disulfide bonds to fully unfold misfolded proteins that need to be translocated back to the cytosol for degradation (discussed later). All PDI enzymes are therefore oxidoreductases that can catalyze either the formation or breakage of disulfide bonds in their client proteins. The formation of disulfide bonds relies on maintaining an oxidizing environment in the ER lumen. Disulfide bonds form only very rarely in domains exposed to the cytosol because of the reducing environment there.

Most Proteins Synthesized in the Rough ER Are Glycosylated by the Addition of a Common *N*-Linked Oligosaccharide

The covalent addition of oligosaccharides to proteins is one of the major biosynthetic functions of the ER. About half of the soluble and membrane-bound proteins that are processed in the ER—including those destined for transport to the Golgi apparatus, lysosomes, plasma membrane, or extracellular space—are **glycoproteins** that are modified in this way. Some proteins in the cytosol and nucleus are also glycosylated, but not with large oligosaccharides: they instead carry a much simpler sugar modification, in which a single *N*-acetylglucosamine group is added to a serine or threonine of the protein.

During the most common form of **protein glycosylation** in the ER, a preformed *precursor oligosaccharide* (containing 14 sugars composed of 2 *N*-acetylglucosamines, 9 mannoses, and 3 glucoses) is transferred as a complete unit to proteins. Because this oligosaccharide is transferred to the side-chain NH₂ group of an asparagine in the protein, it is said to be *N-linked*, or *asparagine-linked* (**Figure 12–32A**). A special lipid molecule called **dolichol** (see Panel 2–5, pp. 102–103) anchors the precursor oligosaccharide in the ER membrane. The precursor oligosaccharide is transferred to the target asparagine in a single enzymatic step by an **oligosaccharyl transferase**. This membrane-bound enzyme associates with the Sec61 translocator and has its active site exposed on the lumenal side

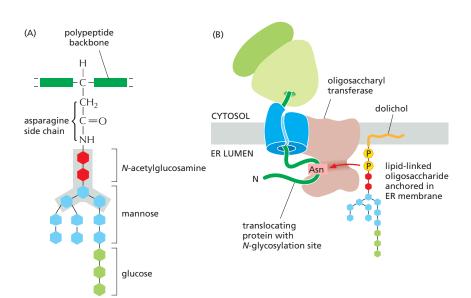

Figure 12–32 *N*-linked protein glycosylation in the rough ER.

(A) Almost as soon as a polypeptide chain enters the ER lumen, it is glycosylated on target asparagine amino acids. The precursor oligosaccharide (shown in color) is attached only to asparagine side chains in the sequences Asn-X-Ser and Asn-X-Thr (where X is any amino acid except proline). These sequences occur much less frequently in glycoproteins than in nonglycosylated cytosolic proteins. Evidently there has been selective pressure against these sequences during protein evolution, presumably because glycosylation at inappropriate sites would interfere with protein folding. The five sugars in the gray box form the core region of this oligosaccharide. For many glycoproteins, only the core sugars survive the extensive oligosaccharide trimming that takes place in the Golgi apparatus (Movie 13.4). (B) The precursor oligosaccharide is transferred from a dolichol lipid anchor to the asparagine as an intact unit in a reaction catalyzed by a transmembrane oligosaccharyl transferase enzyme complex. One copy of this enzyme is associated with each protein translocator in the ER membrane. Oligosaccharyl transferase contains 13 transmembrane α helices and a large ER lumenal domain that contains binding sites for the nascent protein and dolichol-oligosaccharide. The asparagine binds a tunnel that penetrates the enzyme interior. There, the amino group of the asparagine is twisted out of the plane that stabilizes the otherwise poorly reactive amide bond, activating it for reaction with the dolichol-oligosaccharide.

MBOC7_ptr_ch12_683-748.indd 714 02/12/21 12:32 PM

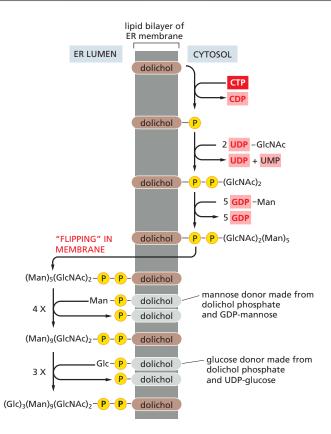

Figure 12-33 Synthesis of the lipidlinked precursor oligosaccharide in the rough ER membrane. The oligosaccharide is assembled sugar by sugar onto the carrier lipid dolichol (a polyisoprenoid; see Panel 2-5, pp. 102-103). Dolichol is long and very hydrophobic: its 22 fivecarbon units can span the thickness of a lipid bilayer more than three times, so that the attached oligosaccharide is firmly anchored in the membrane. The first sugar is linked to dolichol by a pyrophosphate bridge. This high-energy bond activates the oligosaccharide for its eventual transfer from the lipid to an asparagine side chain of a growing polypeptide on the lumenal side of the rough ER. As indicated, the synthesis of the oligosaccharide starts on the cytosolic side of the ER membrane and continues on the lumenal face after the (Man)₅(GlcNAc)₂ lipid intermediate is flipped across the bilayer by a transporter (which is not shown). All the subsequent glycosyl transfer reactions on the lumenal side of the ER involve transfers from dolichol-P-glucose and dolichol-Pmannose: these activated, lipid-linked monosaccharides are synthesized from dolichol phosphate and UDP-glucose or GDP-mannose (as appropriate) on the cytosolic side of the ER and are then flipped across the ER membrane. GlcNAc = N-acetylglucosamine: Man = mannose; Glc = glucose.

of the ER membrane. This allows the oligosaccharyl transferase to modify newly made proteins immediately after the target asparagine enters the ER lumen during protein translocation (Figure 12–32B).

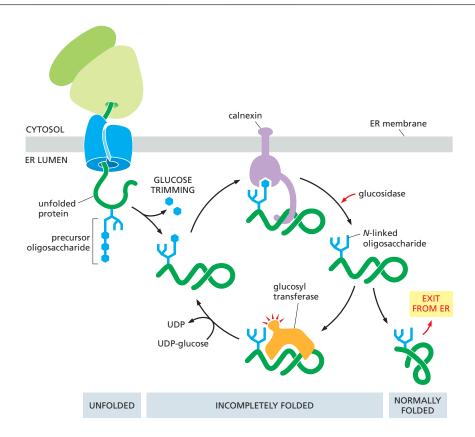

The precursor oligosaccharide is built up sugar by sugar on the membrane-bound dolichol lipid. The sugars are first activated in the cytosol by the formation of *nucleotide (UDP or GDP)-sugar intermediates*, which then donate their sugar first to the dolichol lipid and then to the partially assembled oligosaccharide tree in an orderly sequence. Partway through this process, the lipid-linked oligosaccharide is flipped, with the help of a transporter, from the cytosolic to the lumenal side of the ER membrane (Figure 12–33).

The *N*-linked oligosaccharides are by far the most common oligosaccharides, being found on 90% of all glycoproteins. Less frequently, oligosaccharides are linked to the hydroxyl group on the side chain of a serine, threonine, hydroxylysine, or hydroxyproline amino acid. The first sugar of these *O-linked oligosaccharides* is added in the ER. *N*-linked and *O-*linked oligosaccharides undergo extensive processing, modification, and extension in the Golgi apparatus (Chapter 13), producing the diversity of oligosaccharide structures observed on mature glycoproteins.

Oligosaccharides Are Used as Tags to Mark the State of Protein Folding

It has long been debated why glycosylation is such a common modification of proteins that enter the ER. One particularly puzzling observation has been that some proteins require N-linked glycosylation for proper folding in the ER, yet the precise location of the oligosaccharides attached to the protein's surface does not seem to matter. A clue to the role of glycosylation in protein folding came from studies of two ER chaperone proteins, which are called **calnexin** and **calreticulin** because they require Ca^{2+} for their activities. These chaperones are carbohydrate-binding proteins, or *lectins*, which bind to oligosaccharides on incompletely folded proteins

MBOC7_ptr_ch12_683-748.indd 715 02/12/21 12:32 PM

and retain them in the ER. Like other chaperones, they prevent incompletely folded proteins from irreversibly aggregating. Both calnexin and calreticulin also promote the association of incompletely folded proteins with another ER chaperone, which binds to cysteines that have not yet formed disulfide bonds.

How do calnexin and calreticulin distinguish properly folded from incompletely folded proteins? The answer lies in the structure of the oligosaccharide attached to the protein. Shortly after a newly made protein acquires an N-linked precursor oligosaccharide, ER glucosidases rapidly remove two glucoses, leaving behind a single terminal glucose. This singly glucosylated oligosaccharide is recognized by calnexin and calreticulin, ensuring that all newly made (and hence, likely to be not yet folded) glycoproteins bind to one of these chaperones. This last glucose is removed over time, leaving a de-glucosylated glycoprotein that no longer binds to calnexin or calreticulin. If the glycoprotein is folded, it can leave the ER. However, yet another ER enzyme, a glucosyl transferase, re-adds the terminal glucose selectively to glycoproteins that have not yet folded completely. The terminal glucose then causes re-association of the unfolded protein with calnexin or calreticulin. Thus, glucose trimming (by glucosidases) and glucose addition (by the glucosyl transferase) drive cycles of dissociation and re-association with calnexin and calreticulin until a newly made unfolded protein has achieved its fully folded state (Figure 12-34).

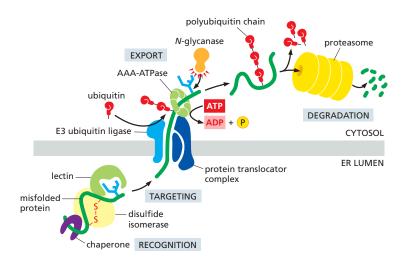

Improperly Folded Proteins Are Exported from the ER and Degraded in the Cytosol

Despite all the help from chaperones, many protein molecules translocated into the ER fail to achieve their properly folded or oligomeric state. Such proteins are exported from the ER back into the cytosol, where they are degraded in proteasomes (discussed in Chapter 6). In many ways, the mechanism of such retrotranslocation is similar to other post-translational modes of translocation.

Figure 12–34 The role of N-linked glycosylation in ER protein folding. The ER membrane-bound chaperone protein calnexin binds to incompletely folded proteins containing one terminal glucose on N-linked oligosaccharides, trapping the protein in the ER. Removal of the terminal glucose by a glucosidase releases the protein from calnexin. A glucosyl transferase is the crucial enzyme that determines whether the protein is folded properly or not; if the protein is still incompletely folded, the enzyme transfers a new glucose from UDP-glucose to the N-linked oligosaccharide, renewing the protein's affinity for calnexin and retaining it in the ER. The cycle repeats until the protein has folded completely. Calreticulin functions similarly, except that it is a soluble ER resident protein. Another ER chaperone, ERp57 (not shown), collaborates with calnexin and calreticulin in retaining an incompletely folded protein in the ER. ERp57 recognizes free sulfhydryl groups, which are a sign of incomplete disulfide bond formation. The longer a protein spends in this cycle without folding correctly, the more likely it is that ERresident mannosidase enzymes (not shown) remove the terminal mannoses from the N-linked oligosaccharide. The trimmed oligosaccharide with reduced mannoses is recognized by other ER lectins that route the polypeptide for degradation. Thus, only proteins that fold promptly and exit the ER avoid trimming by mannosidases and

escape degradation.

MBOC7_ptr_ch12_683-748.indd 716 02/12/21 12:32 PM

For example, like post-translational import into the ER, chaperone proteins are necessary to keep the polypeptide chain in an unfolded state prior to and during translocation. Similarly, a source of energy is required to provide directionality to the transport and to pull the protein into the cytosol. Finally, a translocator is necessary.

Selecting proteins from the ER for degradation is a challenging process: misfolded proteins or unassembled protein subunits should be degraded, but folding intermediates of newly made proteins should not. Help in making this distinction comes from the N-linked oligosaccharides, which serve as timers that measure how long a protein has spent in the ER. The slow trimming of a particular mannose on the core oligosaccharide tree by an enzyme (a mannosidase) in the ER creates a new oligosaccharide structure that ER-lumenal lectins of the retrotranslocation apparatus recognize. A protein that folds and exits from the ER faster than the mannosidase can remove its target mannose therefore escapes degradation.

In addition to the lectins in the ER that recognize the oligosaccharides, chaperones and protein disulfide isomerases associate with the proteins that must be degraded. The chaperones prevent the unfolded proteins from aggregating, and the disulfide isomerases break disulfide bonds that may have formed incorrectly, so that a linear polypeptide chain can be translocated back into the cytosol.

Multiple translocator complexes move different proteins from the ER membrane or lumen into the cytosol. Translocator complexes always contain an E3 ubiquitin ligase enzyme (Chapter 6), which attaches polyubiquitin tags to the unfolded proteins as they emerge into the cytosol, marking them for destruction. Fueled by the energy derived from ATP hydrolysis, a hexameric ATPase of the family of AAA-ATPases (see Figure 6-88) pulls the unfolded protein through the translocator into the cytosol. An *N*-glycanase removes *en bloc* any oligosaccharide chains attached to the retrotranslocated protein. Guided by its ubiquitin tag, the de-glycosylated polypeptide is rapidly fed into proteasomes, where it is degraded (Figure 12-35).

Misfolded Proteins in the ER Activate an Unfolded Protein Response

Cells carefully monitor the amount of misfolded protein in various compartments. An accumulation of misfolded proteins in the cytosol, for example, triggers a *heat-shock response* (discussed in Chapter 6), which stimulates the transcription of genes encoding cytosolic chaperones that help to refold the proteins. Similarly, an accumulation of misfolded proteins in the ER triggers an **unfolded**

Figure 12–35 The export and degradation of misfolded ER proteins.

Misfolded soluble proteins in the ER lumen are recognized and targeted to a translocator complex in the ER membrane. They first interact in the ER lumen with chaperones, disulfide isomerases, and lectins. The chaperones maintain the misfolded protein in an unfolded conformation and prevent their aggregation. The disulfide isomerases reduce disulfide bonds to fully unfold the protein. The lectins selectively recognize trimmed N-linked oligosaccharides that are generated when a protein spends too long in the ER. The lectins have binding sites on a membrane-embedded protein translocator built around an E3 ubiquitin ligase. The unfolded protein is then exported into the cytosol through the translocator. The E3 ubiquitin ligase ubiquitylates the unfolded protein as it emerges on the cytosolic side of the translocator. The ubiquitin prevents backsliding of the protein into the ER and provides a molecular handle for an AAA-ATPase that completes the extraction reaction. The unfolded protein is then de-glycosylated and degraded in proteasomes. Misfolded membrane proteins follow a similar pathway but are thought to engage the translocator sideways within the lipid bilayer. Multiple translocator complexes containing different E3 ubiquitin ligases reside in the ER. They are thought to handle different subsets of proteins that are misfolded in different ways.

MBOC7_ptr_ch12_683-748.indd 717 02/12/21 12:32 PM

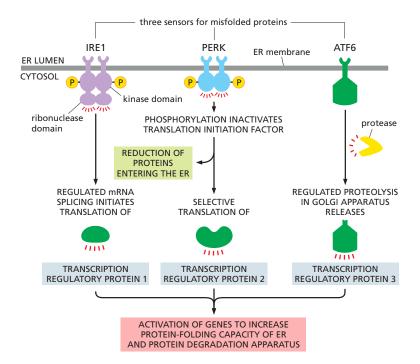

Figure 12-36 The unfolded protein response. Three parallel intracellular signaling pathways sense misfolded proteins in the ER lumen and lead to the activation of transcription in the nucleus. Each pathway begins with an ER-resident sensor of misfolded proteins. When these sensors are activated, they initiate different downstream signaling pathways. Although the downstream mechanisms are very different from each other, all of them culminate with the production of an active transcription factor. The overlapping targets of the transcription factors produce gene products that improve the proteinprocessing capacity of the ER and increase the protein degradation capacity of the cell.

protein response, which stimulates transcription of genes that collectively improve the protein-folding capacity of the ER. The stimulated genes code for ER chaperones, the machinery for protein retrotranslocation and degradation, factors for protein transport out of the ER, and factors for expansion of the ER. This multipronged response operates by coupling the detection of misfolded proteins in the ER lumen to the production of transcription regulatory proteins that enter the nucleus to tune the transcription of hundreds of genes.

How do misfolded proteins in the ER signal to the nucleus? There are three parallel pathways that execute the unfolded protein response (Figure 12-36). The first pathway, which was initially discovered in yeast cells, is conserved in all eukaryotic cells and is particularly remarkable. Misfolded proteins in the ER cause IRE1, a transmembrane protein kinase in the ER, to oligomerize and phosphorylate itself. This mechanism of activation is similar to how some cell-surface receptor kinases in the plasma membrane are activated (discussed in Chapter 15). Oligomeric and phosphorylated IRE1 enables its cytosolic endoribonuclease domain to remove an intron from a specific cytosolic mRNA molecule. IRE1 accomplishes this task by cleaving the mRNA at two positions that are then joined together by an RNA ligase. The mRNA produced by this splicing reaction is translated to produce an active transcription regulatory protein that increases expression of a subset of the genes of the unfolded protein response (Figure 12-37). The regulated splicing of a cytosolic mRNA by IRE1 is a unique exception to the rule that all mRNA splicing occurs in the nucleus and is catalyzed by the spliceosome.

Misfolded proteins also activate a second transmembrane kinase in the ER, PERK. The target of activated PERK is a translation initiation protein whose phosphorylation has two consequences. First, translation of new proteins is reduced throughout the cell, thereby reducing the load of proteins that need to be folded in the ER. Second, some proteins are preferentially translated when translation initiation factors are scarce, and one of these is a transcription regulator that helps activate the transcription of the genes that execute the unfolded protein response.

Finally, a third transcription regulator, ATF6, is initially synthesized as a transmembrane ER protein. Because it is embedded in the ER membrane, it cannot

MBOC7_ptr_ch12_683-748.indd 718 02/12/21 12:32 PM

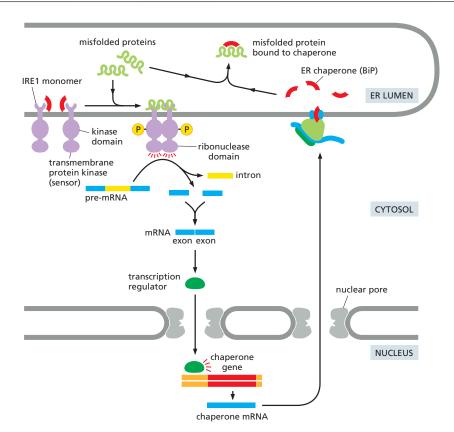

Figure 12-37 The IRE1 limb of the unfolded protein response. Regulated RNA splicing is a key regulatory switch in the unfolded protein response pathway initiated by IRE1 (Movie 12.4). During normal conditions, IRE1 is maintained in an inactive state by its association with the ER-lumenal chaperone BiP. Elevated levels of misfolded proteins activate IRE1 by a combination of two mechanisms. First, BiP dissociates from IRE1 to bind and protect misfolded proteins from aggregation. Second, misfolded proteins bind to the lumenal domain of IRE1 facilitating the formation of IRE1 oligomers. The oligomerized IRE1 phosphorylates itself on the cytosolic side, activating its ribonuclease domain. The activated ribonuclease catalyzes the splicing of a premRNA that codes for a transcription factor that ultimately activates numerous genes in the nucleus including those coding for chaperones. Elevated chaperones help reduce the level of misfolded proteins in the ER lumen, eventually turning off IRE1 signaling.

activate the transcription of genes in the nucleus. When misfolded proteins accumulate in the ER, the ATF6 protein is transported to the Golgi apparatus. Resident proteases in the Golgi apparatus membrane cleave off the cytosolic domain of ATF6, which can now migrate to the nucleus and help activate the transcription of genes encoding proteins involved in the unfolded protein response. This mechanism of activation of a latent membrane-embedded transcription factor is similar to how the transcription regulator that controls cholesterol biosynthesis is activated (discussed later in this chapter). The relative importance of each of these three pathways in the unfolded protein response differs in different cell types, enabling each cell type to tailor the unfolded protein response to its particular needs.

The signaling pathways that execute the unfolded protein response are used during normal physiological conditions to adjust ER capacity to closely match demand for the ER. For example, insulin production increases substantially in pancreatic β cells in response to eating a meal. The elevated demand for the processing capacity of the ER, where insulin is initially assembled, partially activates PERK so cells can adjust insulin synthesis rates to avoid overburdening the ER. In another example, IRE1 is activated when B cells begin differentiating into antibody-secreting plasma cells. IRE1 activation dramatically expands the ER content of the cell in preparation for the very high levels of immunoglobulins that will soon be assembled there.

The unfolded protein response ultimately increases the production of proteins that improve protein processing in the ER and reduce the burden of misfolded proteins. As homeostasis is restored, the activities of IRE1, PERK, and ATF6 abate. If homeostasis cannot be restored, persistently active signaling from the ER, particularly via PERK, activates genes that initiate apoptosis. In multicellular organisms, it is often less detrimental to eliminate a persistently dysfunctional cell than risk its aberrant interactions with neighboring cells.

MBOC7_ptr_ch12_683-748.indd 719 02/12/21 12:32 PM

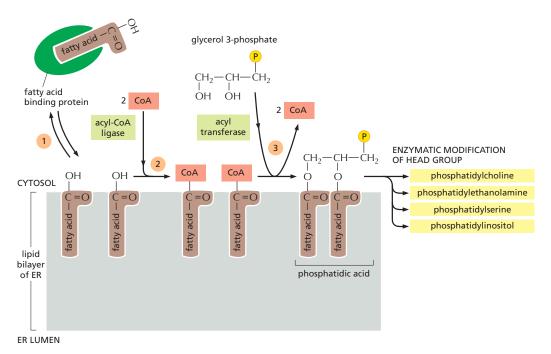

Figure 12–38 The synthesis of phospholipids at the ER membrane. As illustrated, fatty acids delivered to the ER by a cytosolic fatty acid binding protein are linked to glycerol 3-phosphate to produce phosphatidic acid, which serves as a precursor to make other phospholipids that differ in the structures of their polar head groups.

The ER Assembles Most Lipid Bilayers

The ER membrane is the site of synthesis of nearly all of the cell's major classes of lipids, including both phospholipids and cholesterol, required for the production of new cell membranes. The major phospholipid made is phosphatidylcholine, which can be formed in three steps from choline, two fatty acids, and glycerol phosphate (Figure 12-38). Each step is catalyzed by enzymes in the ER membrane, which have their active sites facing the cytosol, where all of the required metabolites are found. Thus, phospholipid synthesis occurs exclusively in the cytosolic leaflet of the ER membrane. Because fatty acids are not soluble in water, they are shepherded from their sites of synthesis in the cytosol to the ER by a fatty acid binding protein. After arrival in the ER membrane and activation with CoA, acyl transferases successively add two fatty acids to glycerol phosphate to produce phosphatidic acid. Phosphatidic acid is sufficiently water-insoluble to remain in the lipid bilayer; it cannot be extracted from the bilayer by the fatty acid binding proteins. It is therefore this first step that enlarges the ER lipid bilayer. The later steps determine the head group of a newly formed lipid molecule and therefore the chemical nature of the bilayer, but they do not result in net membrane growth. The two other major membrane phospholipids—phosphatidylethanolamine and phosphatidylserine (see Figure 10-3)—as well as the minor phospholipid phosphatidylinositol (PI), are all synthesized in this way.

Because phospholipid synthesis takes place in the cytosolic leaflet of the ER lipid bilayer, there needs to be a mechanism that transfers some of the newly formed phospholipid molecules to the lumenal leaflet of the bilayer. In synthetic lipid bilayers, lipids do not "flip-flop" in this way (see Figure 10–10). In the ER, however, phospholipids equilibrate across the membrane within minutes, which is almost 100,000 times faster than can be accounted for by spontaneous "flip-flop." This rapid trans-bilayer movement is mediated by a poorly characterized phospholipid translocator called a *scramblase*, which nonselectively equilibrates

MBOC7_ptr_ch12_683-748.indd 720 02/12/21 12:32 PM

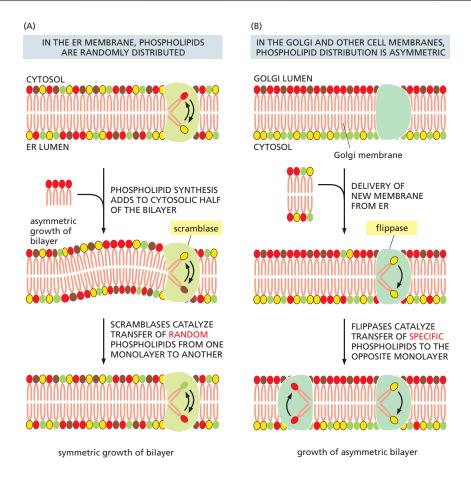

Figure 12-39 The role of phospholipid translocators in lipid bilayer synthesis. (A) Because new lipid molecules are added only to the cytosolic half of the ER membrane bilayer and lipid molecules do not flip spontaneously from one monolayer to the other, a transmembrane phospholipid translocator (called a scramblase) is required to transfer lipid molecules from the cytosolic half to the lumenal half so that the membrane grows as a bilayer. The scramblase is not specific for particular phospholipid head groups and therefore equilibrates the different phospholipids between the two monolayers. Scramblases do not need energy to catalyze phospholipid flipping and probably function by providing a hydrophilic path for passive movement of the phospholipid head group through the hydrophobic interior of the membrane. (B) The membranes of the Golgi apparatus. cell surface, and other compartments of the secretory and endocytic pathways are asymmetric. When new membrane is delivered via transport vesicles, the incoming lipids must be segregated to the appropriate side of the lipid bilayer to maintain its asymmetry. This is accomplished by enzymes called flippases, which move selective phospholipids unidirectionally from one side of the hilaver to the other. Flippases typically couple the transport of their substrate (the phospholipid head group) to ATP hydrolysis, and are therefore considered active transporters (see Chapter 11).

phospholipids between the two leaflets of the lipid bilayer (Figure 12–39). Thus, the different types of phospholipids are thought to be equally distributed between the two leaflets of the ER membrane.

The ER also produces cholesterol and ceramide (**Figure 12–40**). *Ceramide* is made by condensing the amino acid serine with a fatty acid to form the amino alcohol *sphingosine* (see Figure 10–3); a second fatty acid is then covalently added to form ceramide. The ceramide is exported to the Golgi apparatus, where it serves as a precursor for the synthesis of two types of lipids. *Glycosphingolipids* (glycolipids; see Figure 10–16) are formed when oligosaccharides are added to ceramide, while *sphingomyelin* (discussed in Chapter 10) results from the addition of phosphocholine. Because glycolipids and sphingomyelin are both produced by enzymes that have their active sites exposed to the lumen of the Golgi apparatus, they are restricted to the noncytosolic leaflet of the lipid bilayers that contain them.

As discussed in Chapter 13, the plasma membrane and the membranes of the Golgi apparatus, lysosomes, and endosomes all form part of a membrane system that communicates with the ER by means of transport vesicles. A large proportion of the lipids that compose the membranes of these organelles is acquired via the membranes delivered by transport vesicles. Despite exchange of membrane lipids through vesicular transport, the lipid composition of each organellar membrane is distinct and contributes to its unique identity and functional properties. This specialization is achieved by a combination of three mechanisms. First, a transport vesicle can have a different lipid composition than the organelle it is departing, thereby delivering only a subset of lipids to its destination. Second, proteins in an organelle's membrane can modify the head groups of certain lipids to change their identity (such as production of sphingomyelin from

ceramide) or use *flippases* to move certain phospholipids from one leaflet of the membrane to the other (Figure 12–39B). Third, specific lipids can be selectively transferred from one membrane to another by nonvesicular transport routes as discussed next.

Membrane Contact Sites Between the ER and Other Organelles Facilitate Selective Lipid Transfer

Mitochondria and plastids do not communicate with the ER by vesicular transport, so they require different mechanisms to import many of their lipids from the ER for growth. Carrier proteins in the cytosol called *lipid transfer proteins* ferry individual lipid molecules between membranes, functioning much like fatty acid binding proteins that shepherd fatty acids through the cytosol (see Figure 12–38). In many cases, lipid transfer proteins function at organelle contact sites where the originating and destination membranes are held within $\sim\!10\text{--}30\,\mathrm{nm}$ of each other by specific junction complexes. Different lipid transfer proteins shuttle phosphatidylcholine and phosphatidylserine from the ER to mitochondria at contact sites. Disruption of the junctional complexes or the lipid transfer proteins impairs lipid import into mitochondria and causes their dysfunction.

The extensive network of the ER participates in contact sites with most other cellular organelles (Figure 12-41). As with the ER-mitochondria contact sites (see Figure 12-16), one of the main functions of these other organelle contact sites is to exchange lipids (Figure 12-42). Cells contain several families of lipid transfer proteins. Each of these can typically bind one molecule of a specific lipid (or in some cases multiple related lipids) and has additional domains that can interact with specific cellular membranes. In this manner, they serve as shuttling proteins that have distinctive specificities for the donor and acceptor membranes and the lipid they transport. Contact sites between two organellar membranes favor recruitment of the lipid transfer protein that binds these membranes, thereby enhancing the efficiency of lipid exchange. Cholesterol uses a specialized transport system from lysosomes, where it is delivered as cholesterol esters in lipoproteins, to the plasma membrane and other locations in the cell (as we discuss in Chapter 13).

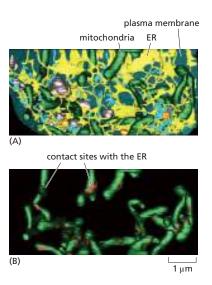

Figure 12–42 The transfer of lipids at organelle contact sites. (A) Proteins anchored to two different membranes (the ER and mitochondrion in the depicted example) interact with each other to hold the membranes 10–30 nm apart. Specialized lipid transfer proteins are recruited to these contact sites or in some cases are part of the junction complex. These transfer proteins have cavities that can bind lipids and facilitate their movement from one membrane to the other. (B) The structure of one such transfer protein is shown with lipid-like molecules bound inside its cavity. (PDB code: 4P42.)

PEROXISOMES 723

Summary

The extensive ER network serves as a factory for the production of almost all of the cell's lipids. In addition, a major portion of the cell's protein synthesis occurs on the cytosolic surface of the rough ER: virtually all proteins destined for secretion or for the ER itself, the Golgi apparatus, the lysosomes, the endosomes, and the plasma membrane are first imported into the ER from the cytosol. In the ER lumen, the proteins fold and oligomerize, disulfide bonds are formed, and N-linked oligosaccharides are added. The pattern of N-linked glycosylation is used to indicate the extent of protein folding, so that proteins leave the ER only when they are properly folded. Proteins that do not fold or oligomerize correctly are translocated back into the cytosol, where they are de-glycosylated, polyubiquitylated, and degraded in proteasomes. If misfolded proteins accumulate in excess in the ER, they trigger an unfolded protein response, which activates appropriate genes in the nucleus to help the ER cope.

Only proteins that carry a special ER signal sequence are imported into the ER. The signal sequence is recognized by a signal-recognition particle (SRP), which binds both the growing polypeptide chain and the ribosome and directs them to a receptor protein on the cytosolic surface of the rough ER membrane. This binding to the ER membrane initiates the translocation process that threads a loop of polypeptide chain across the ER membrane through the hydrophilic pore of a protein translocator.

Soluble proteins—destined for the ER lumen, for secretion, or for transfer to the lumen of other organelles—pass completely into the ER lumen. Transmembrane proteins destined for the ER or for other cell membranes become anchored in the ER membrane by one or more membrane-spanning α -helical segments in their polypeptide chains. As these hydrophobic portions of the protein emerge from the ribosome, they are recognized by the protein translocator, which provides a passageway into the membrane. When a polypeptide contains multiple hydrophobic segments, it will pass back and forth across the bilayer multiple times as a multipass transmembrane protein.

The asymmetry of protein insertion and glycosylation in the ER establishes the sidedness of the membranes of all the other organelles that the ER supplies with membrane proteins. Lipids are synthesized at the cytosolic face of the ER, equilibrate between both leaflets of the lipid bilayer, and are transported to other organelles often at interorganelle junctions by lipid transfer proteins localized there. Specific flippases establish and maintain lipid asymmetry in the plasma membrane, further contributing to its sidedness.

PEROXISOMES

Peroxisomes are major sites of oxygen utilization and are found in virtually all eukaryotic cells. They contain oxidative enzymes, such as catalase and urate oxidase, at such high concentrations that, in some cells, the peroxisomes stand out in electron micrographs because of the presence of a crystalloid protein core (Figure 12-43). The evolutionary origin of peroxisomes is not firmly established, but they are generally thought to represent a specialized offshoot of the membrane system that composes the secretory and endocytic pathways. One hypothesis is that peroxisomes are a vestige of an ancient organelle that performed all the oxygen metabolism in the primitive ancestors of eukaryotic cells. When the oxygen produced by photosynthetic bacteria first accumulated in the atmosphere, it would have been highly toxic to most cells. Peroxisomes might have lowered the intracellular concentration of oxygen, while also exploiting its chemical reactivity to perform useful oxidation reactions. According to this view, the later development of mitochondria rendered peroxisomes less critical for cellular metabolism because many of the same biochemical reactions—which had formerly been carried out in peroxisomes without producing energy-were now coupled to ATP formation by means of oxidative phosphorylation. The oxidation reactions performed by peroxisomes in present-day cells could therefore partly be those whose functions were not taken over by mitochondria.

Peroxisomes Use Molecular Oxygen and Hydrogen Peroxide to Perform Oxidation Reactions

Peroxisomes are so named because they usually contain one or more enzymes that use molecular oxygen to remove hydrogen atoms from specific organic substrates (designated here as R) in an oxidation reaction that produces *hydrogen peroxide* (H_2O_2):

$$RH_2 + O_2 \rightarrow R + H_2O_2$$

Catalase uses the H_2O_2 generated by other enzymes in the organelle to oxidize a variety of substrates—including formic acid, formaldehyde, and alcohol—by the "peroxidation" reaction: $H_2O_2 + R'H_2 \rightarrow R' + 2H_2O$. This type of oxidation reaction is particularly important in liver and kidney cells, where the peroxisomes detoxify various harmful molecules that enter the bloodstream. About 25% of the ethanol we drink is oxidized to acetaldehyde in this way. In addition, when excess H_2O_2 accumulates in the cell, catalase converts it to H_2O through the reaction

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

A major function of the oxidation reactions performed in peroxisomes is the breakdown of fatty acid molecules. The process, called β *oxidation*, shortens the alkyl chains of fatty acids sequentially in blocks of two carbon atoms at a time, thereby converting the fatty acids to acetyl CoA. The peroxisomes then export the acetyl CoA to the cytosol for use in biosynthetic reactions. In mammalian cells, β oxidation occurs in both mitochondria and peroxisomes; in fungi and plant cells, however, this essential reaction occurs exclusively in peroxisomes.

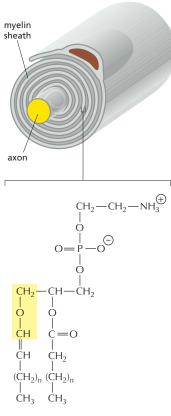

An essential biosynthetic function of animal peroxisomes is to catalyze the first reactions in the formation of *plasmalogens*. This abundant class of phospholipids is found in all human cells but is particularly enriched in brain, where it is a major constituent of myelin (Figure 12–44). Plasmalogen deficiencies cause profound abnormalities in the myelination of nerve-cell axons, which is one reason why many peroxisomal disorders lead to neurological disease.

Peroxisomes are unusually diverse organelles, and even in the various cell types of a single organism they may contain different sets of enzymes. For example, most plants have two major types of peroxisomes (Figure 12–45). One is present in leaves, where it participates in *photorespiration* (discussed in Chapter 14). The other type of peroxisome is present in germinating seeds, where it converts the fatty acids stored in seed lipids into the sugars needed for the growth of the young plant. Because this conversion of fats to sugars is accomplished by a series of reactions known as the *glyoxylate cycle*, these peroxisomes are also called *glyoxysomes*. In the glyoxylate cycle, two molecules of acetyl CoA produced by fatty acid breakdown in the peroxisome are used to make succinic acid, which then leaves the peroxisome and is converted into glucose in the cytosol. The glyoxylate cycle does not occur in animal cells, and animals are therefore unable to convert fats into carbohydrates.

In addition to diversification across different cell types or organisms, peroxisomes can adapt to changing conditions within a cell. Yeasts grown on sugar, for example, have a few small peroxisomes. But when some yeasts are grown on methanol, numerous large peroxisomes are formed that oxidize methanol; and when grown on fatty acids, they develop numerous large peroxisomes that break down fatty acids to acetyl CoA by β oxidation.

Short Signal Sequences Direct the Import of Proteins into Peroxisomes

The proteins that compose peroxisomes are delivered by two different routes (Figure 12-46). In the first route, some of the integral membrane proteins of the peroxisomal membrane are first inserted into the ER using the ER-resident Sec61 protein translocator. These peroxisome-destined proteins are then packaged into specialized peroxisomal precursor vesicles. New precursor vesicles

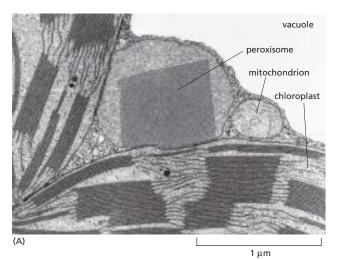

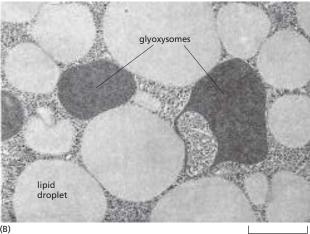

plasmalogen

Figure 12–44 The structure of a plasmalogen. Plasmalogens are very abundant in the myelin sheaths that insulate the axons of nerve cells. They make up some 80–90% of the myelin membrane phospholipids. In addition to an ethanolamine head group and a long-chain fatty acid attached to the same glycerol phosphate backbone used for phospholipids, plasmalogens contain an unusual fatty alcohol that is attached through an ether linkage highlighted in yellow (bottom left).

Figure 12–45 Electron micrographs of two types of peroxisomes found in plant cells. (A) A peroxisome with a paracrystalline core in a tobacco leaf mesophyll cell. Its close association with chloroplasts is thought to facilitate the exchange of materials between these organelles during photorespiration. The vacuole in plant cells is equivalent to the lysosome in animal cells. (B) Peroxisomes in a fat-storing cotyledon cell of a tomato seed 4 days after germination. Here the peroxisomes (glyoxysomes) are associated with the lipid droplets that store fat, reflecting their central role in fat mobilization and gluconeogenesis during seed germination. (A, © 1969 S.E. Frederick and E.H. Newcomb. Originally published in *J. Cell Biol.* https://doi.org/10.1083/jcb.43.2.343. With permission from Rockefeller University Press. B, from W.P. Wergin et al., *J. Ultrastruct. Res.* 30:533–557, 1970. With permission from Elsevier.)

then fuse with one another to form a new peroxisome or fuse with an existing peroxisome to facilitate its growth. In the second route, peroxisomal proteins can be imported into preexisting peroxisomes directly from the cytosol. A specific sequence of three amino acids (Ser-Lys-Leu) located at the C-terminus of many peroxisomal proteins functions as an import signal (see Figure 12–13). Other peroxisomal proteins contain a slightly longer and partially hydrophobic signal sequence near the N-terminus. If either sequence is attached to a cytosolic protein, the protein is imported into peroxisomes.

Peroxisomal protein import is driven by ATP hydrolysis and utilizes a collection of proteins, called **peroxins**, that catalyze the import cycle. C-terminal peroxisomal sorting signals are recognized by the peroxin Pex5 in the cytosol. This import receptor accompanies its cargo all the way into a protein translocator in the peroxisomal membrane. After cargo release inside the peroxisome, Pex5 is recycled back to the cytosol. This recycling step requires modification of Pex5 with ubiquitin, which is used as a handle by an ATPase complex composed of Pex1 and Pex6. The Pex1-Pex6 complex harnesses the energy of ATP hydrolysis to release Pex5 from peroxisomes so it can pick up the next cargo molecule.

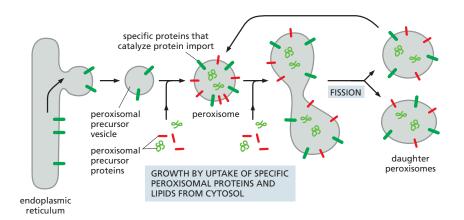

Figure 12-46 A model that explains how peroxisomes proliferate and how new peroxisomes arise. Peroxisomal precursor vesicles bud from the ER. At least two peroxisomal membrane proteins. Pex3 and Pex15, follow this route. The machinery that drives the budding reaction and that selects only peroxisomal proteins for packaging into these vesicles depends on Pex19 and other cytosolic proteins that are still unknown. Peroxisomal precursor vesicles may then fuse with one another or with preexisting peroxisomes. The peroxisomal membrane contains import receptors and protein translocators that are required for the import of peroxisomal proteins made on cytosolic ribosomes, including new copies of the import receptors and translocator components. Presumably, the lipids required for growth are also imported, although some may derive directly from the ER in the membrane of peroxisomal precursor vesicles.

MBOC7_ptr_ch12_683-748.indd 725 02/12/21 12:32 PM

N-terminal peroxisomal signal sequences are recognized by the peroxin Pex7. The Pex7-cargo complex, together with additional accessory peroxins, appear to participate in an import cycle similar to that mediated by Pex5.

The protein translocator in the peroxisomal membrane is composed of at least six different peroxins. Unlike protein translocators in the ER, the peroxisomal translocator can transport fully folded and even oligomeric proteins across the membrane. To allow the passage of large and variably sized cargo molecules, the transporter is thought to dynamically adapt in size to the particular cargo molecules to be transported. It is not known how such a large pore can be utilized for transport without leakage of contents between the cytosol and peroxisome.

The importance of protein import into peroxisomes is demonstrated by the inherited human disease *Zellweger syndrome*. Mutations in any of a dozen different peroxins, the most common being Pex1, cause an impairment in peroxisomal protein import. These individuals, whose cells contain "empty" peroxisomes, accumulate very-long-chain and branched-chain fatty acids that are normally broken down in peroxisomes. Furthermore, they are deficient in plasmalogens. These metabolic impairments cause severe abnormalities in the brain, liver, and kidneys of individuals, and they die soon after birth.

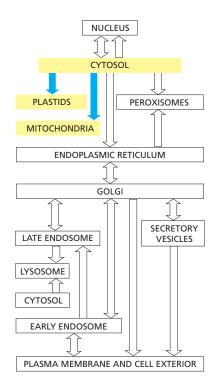

Summary

Peroxisomes are specialized for carrying out oxidation reactions using molecular oxygen. They generate hydrogen peroxide, which they employ for oxidative purposes—and contain catalase to destroy the excess. All peroxisomal proteins are encoded in the cell nucleus. Some of these proteins are conveyed to peroxisomes via peroxisomal precursor vesicles that bud from the ER, but most are synthesized in the cytosol and directly imported. A specific sequence of three amino acids near the C-terminus of many of the latter proteins functions as a peroxisomal import signal that is recognized by a complementary import receptor in the cytosol. Import proceeds through a protein translocator in the peroxisomal membrane, which differs from the protein translocators in the ER in that large and fully folded proteins are imported from the cytosol without unfolding.

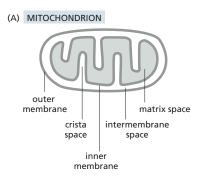

THE TRANSPORT OF PROTEINS INTO MITOCHONDRIA AND CHLOROPLASTS

Mitochondria and chloroplasts (a specialized form of plastids in green algae and plant cells) are double membrane-enclosed organelles. They specialize in ATP synthesis, using energy derived from electron transport and oxidative phosphorylation in mitochondria and from photosynthesis in chloroplasts (discussed in Chapter 14). Although both organelles contain their own DNA, ribosomes, and other components required for protein synthesis, almost all of their proteins are encoded in the cell nucleus and imported from the cytosol. Each imported protein must reach the particular organelle subcompartment in which it functions.

The different subcompartments in **mitochondria** are formed by the two concentric mitochondrial membranes (**Figure 12-47A**): the **inner mitochondrial membrane**, which encloses the **matrix space** and forms extensive invaginations called *cristae*, and the **outer mitochondrial membrane**, which is in contact with the cytosol. The space between the inner and outer membranes is subdivided into the crista space and **intermembrane space**, with protein complexes at the junctions where the cristae invaginate. Chloroplasts have an outer and inner membrane, which enclose an intermembrane space, and a stroma, which is the chloroplast equivalent of the mitochondrial matrix space (**Figure 12-47B**). They have an additional subcompartment, the *thylakoid space*, which is surrounded by the *thylakoid membrane*. The thylakoid membrane derives from the inner membrane during plastid development and is pinched off to become discontinuous with it. Each of the subcompartments in mitochondria and chloroplasts contains a distinct set of proteins.

MBOC7_ptr_ch12_683-748.indd 726 02/12/21 12:32 PM

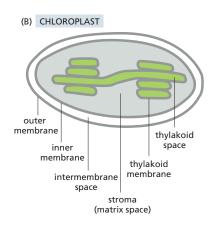

Figure 12–47 The subcompartments of mitochondria and chloroplasts. In contrast to the cristae of mitochondria (A), the thylakoids of chloroplasts (B) are not connected to the inner membrane and therefore form a sealed continuous compartment with a separate internal space.

New mitochondria and chloroplasts are produced by the growth of preexisting organelles, followed by fission (discussed in Chapter 14). The growth depends mainly on the import of proteins from the cytosol. Many of the core principles of protein import into mitochondria and chloroplasts are similar to the analogous process of protein import into the ER we discussed earlier. However, the presence of multiple membranes and subcompartments adds to the complexity of delivering newly imported proteins to the correct location. This section explains how it occurs.

Translocation into Mitochondria Depends on Signal Sequences and Protein Translocators

One or more signal sequences direct all mitochondrial precursor proteins to their appropriate mitochondrial subcompartment. Many proteins entering the matrix space contain a signal sequence at their N-terminus that a signal peptidase rapidly removes after import. Other imported proteins, including all outer membrane and many inner membrane and intermembrane-space proteins, have internal signal sequences that are not removed. The signal sequences are both necessary and sufficient for the import and correct localization of the proteins: when genetic engineering techniques are used to link these signals to a cytosolic protein, the signals direct the protein to the correct mitochondrial subcompartment. Thus, the principles of the signal hypothesis, conceived to explain how proteins are segregated to the ER, also apply to mitochondria.

Multisubunit protein complexes that function as protein translocators mediate protein movement across or into mitochondrial membranes (Figure 12–48A). To provide access to each mitochondrial subcompartment, protein translocator complexes are located in both the inner and outer mitochondrial membranes. In general, each translocator has the capacity to recognize particular types of signals and serves as a conduit across or into the membrane within which it resides. Together, these translocators direct ~ 1500 different precursor proteins from the cytosol to the appropriate subcompartment of mitochondria: the outer membrane, the intermembrane space and crista space, the inner membrane, and the matrix space.

The organization of signals in a precursor protein ultimately controls which translocator(s) the precursor protein engages and the order in which the signals are used to reach the protein's final destination inside mitochondria. This combinatorial system means that there is sometimes more than one route to reach a particular destination, the same way that different subway lines can take you from Brooklyn to Times Square in New York City. For example, membrane proteins residing in the inner mitochondrial membrane use at least three routes to arrive there. Figure 12–48B shows the possible routes to each mitochondrial subcompartment and the translocator complexes that direct proteins there.

The **TOM complex** is required for the import of nearly all nucleus-encoded mitochondrial proteins. It initially recognizes their signal sequences and transports

MBOC7_ptr_ch12_683-748.indd 727 02/12/21 12:32 PM

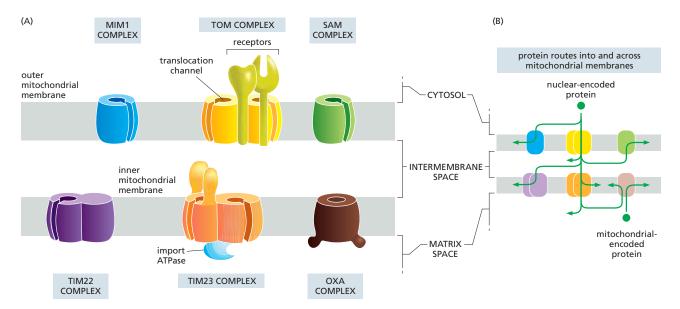

Figure 12–48 The protein translocators in the mitochondrial membranes. (A) The TOM, TIM, SAM, MIM, and OXA complexes are multimeric membrane protein assemblies that catalyze protein translocation across mitochondrial membranes. The protein components of the TIM22 and TIM23 complexes that line the import channel are structurally related, suggesting a common evolutionary origin of both TIM complexes. On the matrix side, the TIM23 complex is bound to a multimeric protein complex containing mitochondrial hsp70, which acts as an import ATPase, using ATP hydrolysis to pull proteins through the pore. In animal cells, subtle variations exist in the subunit composition of the translocator complexes to adapt the mitochondrial import machinery to the particular needs of specialized cell types. (B) Newly made proteins synthesized in the cytosol can use multiple routes to arrive at their final destination. The known routes via the different protein complexes are shown as green lines. There are multiple routes for a protein to become embedded into the inner and outer mitochondrial membranes, including one route for mitochondrially encoded proteins synthesized in the matrix space. SAM = sorting and assembly machinery; OXA = cytochrome oxidase activity; TIM = translocator of the inner mitochondrial membrane; MIM = mitochondrial import machinery.

them from the cytosol into the intermembrane space. From here, different mitochondrial proteins follow different itineraries depending on sequence features encoded in the protein. β -Barrel proteins, which are particularly abundant in the outer membrane, are passed to the **SAM complex** for insertion and folding in the outer membrane. Two different **TIM complexes** mediate protein transport at the inner membrane. Matrix proteins use the TIM23 complex for transport, while inner membrane proteins use the TIM22 complex, the TIM23 complex, or the **OXA complex** for insertion. The remainder of proteins stay in the intermembrane space where they function.

In addition to the \sim 99% of mitochondrial proteins that must be imported from the cytosol, a handful of membrane proteins are encoded by the mitochondrial genome in all eukaryotes. These proteins are synthesized by mitochondrial ribosomes and inserted into the inner membrane by the OXA complex. Mitochondrially encoded membrane proteins are assembled with nuclear-encoded membrane proteins imported from the cytosol to form functional protein complexes such as the respiratory-chain complexes used for energy production (see Chapter 14). How cells communicate between the mitochondria and nucleus to ensure equal expression of the proteins that build inner membrane complexes is not understood.

Mitochondrial Proteins Are Imported Post-translationally as Unfolded Polypeptide Chains

As we learned in an earlier section, protein translocation into the ER usually occurs as the protein is being synthesized by ribosomes that are tightly coupled to the ER protein translocator. The binding of ribosomes to the translocator during protein import is what gives the rough ER its characteristic appearance.

MBOC7_ptr_ch12_683-748.indd 728 02/12/21 12:32 PM

In contrast, the protein translocators in the mitochondrial outer membrane do not bind to ribosomes, and most mitochondrial proteins are imported by a post-translational mechanism. This is why very few ribosomes are observed on the surface of mitochondria.

As with ER translocation, mitochondrial protein import can be reconstituted in a cell-free reaction in the test tube. In such experiments, a radioactively labeled mitochondrial precursor protein is mixed with purified mitochondria to permit import into the organelle. By changing the conditions in the test tube, it is possible to establish the biochemical requirements for import, to trap intermediates in the process, and to identify which translocators are used. Most of our knowledge about the molecular mechanism of mitochondrial import comes from analysis in cell-free reactions.

Mitochondrial precursor proteins do not immediately fold into their native structures after they are synthesized; instead, they remain unfolded in the cytosol through interactions with other proteins. Some of these interacting proteins are general *chaperones* of the *hsp70 family* (discussed in Chapter 6), whereas others are dedicated to mitochondrial precursor proteins and bind directly to their signal sequences. All the interacting proteins help to prevent the precursor proteins from aggregating or folding up spontaneously before they engage with the TOM complex in the outer mitochondrial membrane. As a first step in the import process, the import receptors of the TOM complex bind the signal sequence of the mitochondrial precursor protein. The unfolded polypeptide chain is then fed—signal sequence first—into the translocation channel within the TOM complex as the cytosolic interacting proteins are stripped off.

Once the translocating protein protrudes into the intermembrane space, sequences within the polypeptide chain determine what happens next. For example, proteins destined for the matrix or inner membrane engage one of the TIM complexes and are either translocated across or inserted into the inner membrane. It is possible to rapidly cool a cell-free mitochondrial import reaction to arrest the proteins at an intermediate step during translocation. Experiments examining an arrested protein destined for the matrix show that it spans both the inner and outer mitochondrial membranes: its N-terminal signal sequence has been removed by the signal peptidase located in the matrix, while the C-terminal part of the protein is still exposed outside the mitochondria. We can therefore conclude that precursor proteins can pass through both mitochondrial membranes at once to enter the matrix space (Figure 12–49).

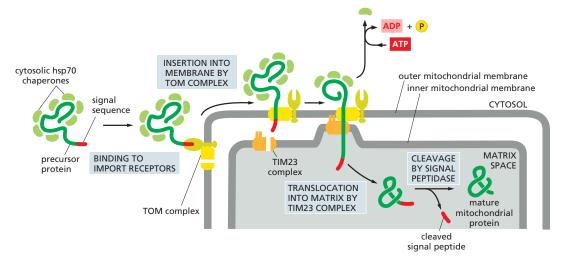

Figure 12–49 Protein import by mitochondria. The N-terminal signal sequence of the mitochondrial precursor protein is recognized by receptors of the TOM complex while the remainder of the protein is kept unfolded by cytosolic hsp70 chaperones. The protein is then translocated through the TIM23 complex so that it transiently spans both mitochondrial membranes (Movie 12.5). The signal sequence is cleaved off by a signal peptidase in the matrix space to form the mature protein. The free signal sequence is then rapidly degraded (not shown).

MBOC7_ptr_ch12_683-748.indd 729 02/12/21 12:32 PM

Although the TOM and TIM complexes usually work together to translocate precursor proteins across both membranes at the same time, they are capable of operating independently. In isolated outer membranes, for example, the TOM complex can translocate the signal sequence of precursor proteins across the membrane. Similarly, if the outer membrane is experimentally removed from isolated mitochondria, the exposed TIM23 complex can efficiently import precursor proteins into the matrix space. The experimental uncoupling of ordinarily linked processes allows each step and translocator system to be studied and understood in greater detail.

Protein Import Is Powered by ATP Hydrolysis, a Membrane Potential, and Redox Potential

Directional transport of proteins requires energy (Figure 12–50). Mitochondrial protein import utilizes three different sources of energy at four discrete sites. ATP, a common fuel in most biological systems, is used at two of these sites: outside the mitochondria and inside the matrix. The other two energy sources are contributed by the membrane potential across the inner mitochondrial membrane and the redox potential of the electron-transport chain. Not all mitochondrial precursor proteins need each of these energy sources to arrive at their final destination.

The initial use of energy, needed by most mitochondrial precursor proteins at the initial stage of the translocation process, serves to maintain the polypeptide in an unfolded state prior to import (see Figure 12–49). As discussed in Chapter 6,

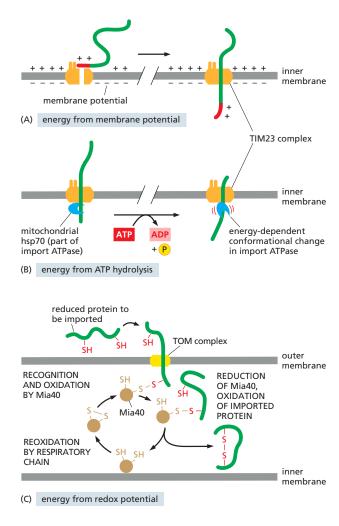

Figure 12-50 The role of energy in protein import into mitochondria. Three different sources of energy are used to import protein into the mitochondria. (A) After initial insertion of the signal sequence and of adjacent portions of the polypeptide chain into the TOM complex translocation channel (not shown), the signal sequence interacts with a TIM23 complex (orange). The signal sequence is then translocated into the matrix space in a process that requires the energy in the membrane potential across the inner membrane. Positively charged amino acids in the signal sequence facilitate this membrane potential-dependent translocation reaction. (B) Mitochondrial hsp70, which is part of an import ATPase complex, binds to regions of the polypeptide chain as they become exposed in the matrix space, pulling the protein through the translocation channel, using the energy of ATP hydrolysis. (C) Polypeptides with multiple cysteines can sample the intermembrane space via partial translocation through the TOM complex. In the intermembrane space, these cysteines are oxidized to disulfide bonds by the enzyme Mia40, which becomes reduced in the process. The oxidized polypeptide is now partially folded, preventing it from sliding back into the cytosol. Reduced Mia40 is reoxidized by electrons provided by the respiratory chain so it can function again in the import reaction.

MBOC7_ptr_ch12_683-748.indd 730 02/12/21 12:32 PM

the chaperones that carry out this task use cycles of ATP binding and hydrolysis to control their interactions with newly synthesized polypeptides. Chaperone interaction is required to prevent premature folding in the cytosol, while chaperone dissociation is needed to permit transport through the TOM complex.

Once the signal sequence has passed through the TOM complex and is bound to a TIM complex, further translocation through the TIM translocation channel requires the membrane potential (Figure 12–50A), which is the electrical component of the electrochemical H⁺ gradient across the inner membrane (see Figure 11–4). Pumping of H⁺ from the matrix space to the intermembrane space, driven by electron-transport processes in the inner membrane (discussed in Chapter 14), maintains the electrochemical gradient. The energy in the electrochemical H⁺ gradient across the inner membrane drives the translocation of the positively charged signal sequences through the TIM complexes by electrophoresis. The same H⁺ gradient also powers most of the cell's ATP synthesis by ATP synthase complexes in the inner mitochondrial membrane.

Once the initial segment of a precursor protein reaches the matrix, **mitochondrial hsp70** is crucial for completing the import process similar to how BiP is needed for post-translation protein import into the ER. The mitochondrial hsp70 is bound to the matrix side of the TIM23 complex and acts as a motor to pull the precursor protein into the matrix space. Like its cytosolic cousin, mitochondrial hsp70 has a high affinity for unfolded polypeptide chains, and it binds tightly to an imported protein chain as soon as the chain emerges from the TIM translocator in the matrix space. The hsp70 then undergoes an ATP-dependent conformational change that exerts a pulling force on the protein being imported before releasing it. This energy-driven cycle of binding, pulling, and release continues until the protein has completed import through the TIM23 complex (Figure 12–50B). Many imported matrix proteins are passed on to another chaperone protein, *mitochondrial hsp60*, to assist their folding through cycles of ATP hydrolysis (see Chapter 6).

Certain intermembrane-space proteins that contain cysteine motifs use the difference in redox potential between the cytosol and mitochondria as a source of energy. When a portion of these proteins initially emerges into the intermembrane space, they form a transient covalent disulfide bond to the Mia40 protein (Figure 12–50C). This interaction prevents backsliding of the protein through the TOM complex into the cytosol. The imported proteins are eventually released from Mia40 in an oxidized form containing intrachain disulfide bonds, resulting in a folded protein that is now trapped in the intermembrane space. Mia40 becomes reduced in the process and is then reoxidized by passing electrons to the electron-transport chain in the inner mitochondrial membrane. In this way, the energy stored in the redox potential in the mitochondrial electron-transport chain is tapped to drive protein import.

Transport into the Inner Mitochondrial Membrane Occurs Via Several Routes

The three different translocators in the inner mitochondrial membrane (see Figure 12–48) are all capable of membrane protein insertion. Different subsets of inner mitochondrial membrane proteins take different routes to reach one of these translocators for insertion into the membrane.

In the most common translocation route, a precursor that begins in the cytosol uses the TOM and TIM23 complexes to begin import into the matrix. However, only the N-terminal signal sequence of the transported protein actually enters the matrix space (Figure 12–51A). A hydrophobic amino acid sequence, strategically located after the N-terminal signal sequence, is recognized as a transmembrane domain by the TIM23 complex. This allows insertion of the transmembrane domain into the inner membrane and prevents further translocation into the matrix, perhaps through a lateral gate analogous to that found in the ER-resident Sec61 translocator. The remainder of the protein enters the intermembrane space through the TOM complex, and the signal sequence is cleaved off in the matrix.

MBOC7_ptr_ch12_683-748.indd 731 02/12/21 12:32 PM

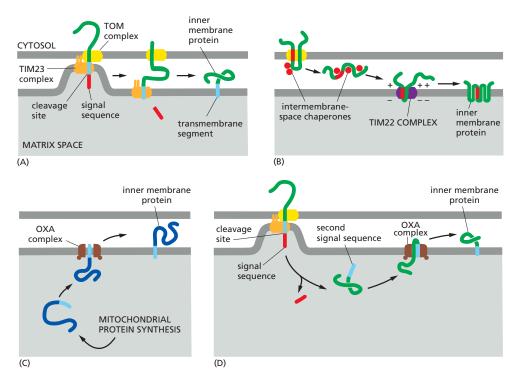

Figure 12–51 Routes for the production of inner mitochondrial membrane proteins. (A) The N-terminal signal sequence (red) initiates import into the matrix space (see Figure 12–49). A hydrophobic transmembrane segment (blue) that follows the matrix-targeting signal sequence binds to the TIM23 translocator (orange) in the inner membrane and stops translocation. The remainder of the protein is then pulled into the intermembrane space through the TOM translocator in the outer membrane, and the transmembrane segment is released into the inner membrane, anchoring the protein there. (B) Multipass inner membrane proteins that function as metabolite transporters contain internal signal sequences and snake through the TOM complex as a loop. They then bind to the chaperones in the intermembrane space, which guide the proteins to the TIM22 complex. The TIM22 complex is specialized for the insertion of multipass inner membrane proteins. (C) The OXA complex mediates membrane protein insertion into the inner membrane for proteins that are encoded by the mitochondrial genome and translated in the matrix space. (D) The OXA complex in the inner membrane can mediate protein insertion from the matrix space. To access this route, nuclear-encoded proteins must first translocate completely into the matrix space via the TOM and TIM23 complexes. Cleavage of the signal sequence (red) used for the initial translocation unmasks an adjacent hydrophobic signal sequence (blue) at the new N-terminus. This signal then directs the protein into the inner membrane.

The second transport route to the inner membrane is specialized for a family of metabolite-specific transporters that transfer a vast number of small molecules across the inner membrane. These transporters supply substrates for metabolic enzymes in the mitochondrial matrix, such as those of the citric acid cycle, and export their products back to the cytosol. These multipass transmembrane proteins use internal signal sequences to enter the intermembrane space through the TOM complex. They engage intermembrane-space chaperones that guide them to the TIM22 complex, where hydrophobic transmembrane regions partition into the inner membrane. This insertion process requires the membrane potential to ensure that appropriate regions of the protein are transported to the matrix side so that the transporter acquires the correct topology (Figure 12–51B).

The final insertion route into the inner membrane uses the OXA complex. As mentioned earlier, the OXA complex also inserts the few membrane proteins that are encoded and translated in the mitochondrial matrix (Figure 12–51C). Thus, the OXA complex can only be accessed from the matrix side of the membrane. For this reason, nuclear-encoded membrane proteins that rely on the OXA complex for insertion must first use TIM23 to translocate into the matrix (Figure 12–51D). Here, the N-terminal signal sequence is removed to expose a hydrophobic signal sequence that is then used by the OXA complex for insertion into the inner membrane.

MBOC7_ptr_ch12_683-748.indd 732 02/12/21 12:32 PM

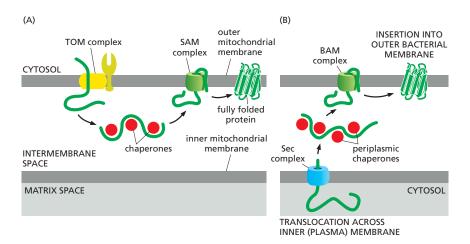

Figure 12–52 Integration of porins into the outer mitochondrial and bacterial membranes. (A) After translocation through the TOM complex in the outer mitochondrial membrane, β -barrel proteins bind to chaperones in the intermembrane space. The SAM complex then inserts the unfolded polypeptide chain into the outer membrane and helps the chain fold. (B) A structurally related BAM complex in the outer membrane of Gram-negative bacteria catalyzes β -barrel protein insertion and folding (see Figure 11–17).

Bacteria and Mitochondria Use Similar Mechanisms to Insert ß Barrels into Their Outer Membrane

As discussed earlier in this chapter, mitochondria evolved from an ancestral endosymbiont bacterium inside the primordial eukaryotic cell. The outer mitochondrial membrane is therefore evolutionarily related to the outer membrane of Gram-negative bacteria (see Figure 11–17). Both membranes contain **porins**, abundant pore-forming β -barrel proteins that are permeable to inorganic ions and metabolites (but not to most proteins). The TOM complex only allows proteins containing hydrophobic α helices to exit laterally and thus cannot integrate porins or other β -barrel proteins into the lipid bilayer. Instead, they are first transported through the TOM complex as unfolded proteins into the intermembrane space. Specialized chaperone proteins in the intermembrane space keep the β -barrel proteins from aggregating (**Figure 12–52A**) until they are inserted and folded by the SAM complex in the outer membrane.

One of the central subunits of the SAM complex is homologous to a bacterial outer membrane protein that helps insert β -barrel proteins into the bacterial outer membrane. In bacteria, β -barrel proteins are inserted from the periplasmic space, which is the topological equivalent of the intermembrane space in mitochondria (Figure 12–52B). This conserved pathway for inserting β -barrel proteins further underscores the endosymbiotic origin of mitochondria. Notably, the central subunits of the TOM and SAM complexes are themselves β -barrel proteins. Thus, preexisting TOM and SAM complexes are required to make more copies of these essential protein translocators.

Two Signal Sequences Direct Proteins to the Thylakoid Membrane in Chloroplasts

Protein transport into **chloroplasts** resembles transport into mitochondria. Both processes occur post-translationally, use separate translocation complexes in each membrane, require energy, and use multiple types of signal sequences to direct a precursor to the appropriate organelle subcompartment. However, many of the protein components that form the translocation complexes differ. Moreover, whereas mitochondria harness the electrochemical H⁺ gradient across their inner membrane to drive transport, chloroplasts, which have an electrochemical H⁺ gradient across their thylakoid membrane but not their inner membrane, use GTP and ATP hydrolysis to power import across their double-membrane envelope. The functional similarities thus result from convergent evolution, reflecting the common requirements for translocation across a double membrane.

Although the signal sequences for import into chloroplasts superficially resemble those for import into mitochondria, a plant cell can have both mitochondria and chloroplasts, so proteins must partition appropriately between the

MBOC7_ptr_ch12_683-748.indd 733 02/12/21 12:32 PM

two organelles. Experiments have shown that a cytosolic protein can be directed specifically to a plant cell's mitochondria if it is experimentally joined to an N-terminal signal sequence of a mitochondrial protein; the same protein joined to an N-terminal signal sequence of a chloroplast protein ends up in chloroplasts. Thus, the import receptors on each organelle distinguish between the different signal sequences.

The same compartments that are found in mitochondria are also in chloroplasts, and each has its distinctive complement of proteins that are selectively delivered there using mechanisms analogous to the mitochondrial systems. However, chloroplasts have an extra membrane-enclosed compartment, the thylakoid. Many chloroplast proteins, including the protein subunits of the photosynthetic system and of the ATP synthase (discussed in Chapter 14), are located in the thylakoid membrane. Many of the components of these vital complexes are encoded in the nuclear genome, and those residing in the thylakoid lumen therefore have to be imported across three membranes. The precursors of these proteins are translocated from the cytosol to their final destination in two steps using bipartite signal sequences. First, they pass across the outer and inner membranes into the stroma guided by an N-terminal chloroplast signal sequence. There, a stromal signal peptidase removes the N-terminal chloroplast signal sequence, unmasking a thylakoid signal sequence that follows it in the sequence of the precursor protein. The thylakoid signal sequence initiates integration into the thylakoid membrane or translocation into the thylakoid space (Figure 12-53A).

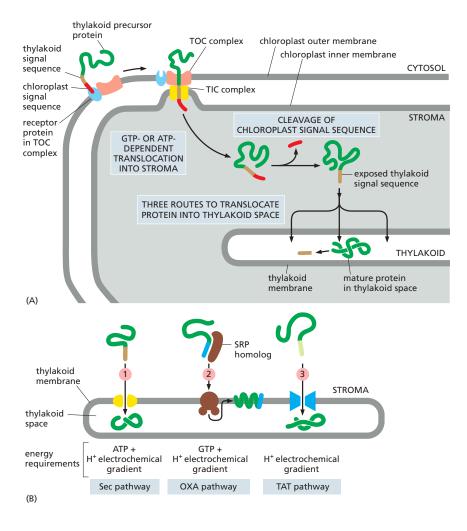

Figure 12-53 Translocation of chloroplast precursor proteins into the thylakoid space. (A) The precursor protein contains an N-terminal chloroplast signal sequence (red), followed immediately by a thylakoid signal sequence (brown). The chloroplast signal sequence initiates translocation into the stroma by a mechanism similar to that used for the translocation of mitochondrial precursor proteins into the matrix space, although the translocator complexes, named TOC and TIC (for translocator in the outer and inner chloroplast membrane, respectively). are different. The signal sequence is then cleaved off, unmasking the thylakoid signal sequence, which initiates translocation across the thylakoid membrane. (B) Translocation into the thylakoid space or thylakoid membrane can occur by any one of at least three routes: (1) a Sec pathway, so called because it uses components that are homologs of Sec proteins, which mediate protein translocation across the ER and bacterial plasma membrane; (2) an OXA-like pathway, so called because it uses a chloroplast homolog of the OXA translocase; (3) a TAT (twin arginine translocation) pathway, so called because two arginines are critical in the signal sequences that direct proteins into this pathway, which depends on the Hgradient across the thylakoid membrane. The OXA-like pathway makes use of a chloroplast SRP that lacks an RNA subunit. This specialized SRP located in the stroma recognizes a thylakoid-directed signal sequence and functions exclusively post-translationally because it is found in a separate compartment from the ribosome that made the thylakoid precursor protein.

MBOC7_ptr_ch12_683-748.indd 734 02/12/21 12:32 PM

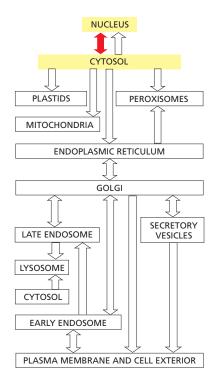

There are three different protein translocators in the thylakoid membrane, each of which recognizes a different type of signal sequence, handles a different subset of thylakoid precursors, and uses energy in different ways (Figure 12–53B). As we saw earlier, the thylakoid membrane is developmentally derived from the inner chloroplast membrane, which is evolutionarily related to the bacterial inner membrane. It is therefore not surprising that each of the three translocators in the thylakoid membrane has homologs that are used for translocation or membrane insertion in bacteria.

Summary

Although mitochondria and chloroplasts have their own genetic systems, they produce less than 1% of their own proteins. Instead, the two organelles import most of their proteins from the cytosol, using similar mechanisms. In both cases, multiple protein translocator complexes in the outer and inner membranes recognize different types of signal sequences to direct a precursor to the correct organelle subcompartment. Proteins are transported in an unfolded state by a post-translational mechanism. Chaperone proteins of the cytosolic hsp70 family maintain the precursor proteins in an unfolded state prior to translocation, and a second set of hsp70 proteins in the matrix space or stroma pulls the polypeptide chain across the inner membrane. Translocation into mitochondria is powered by ATP hydrolysis, a membrane potential across the inner membrane, and the redox potential of the electron-transport chain. Translocation into chloroplasts is powered by GTP and ATP hydrolysis and a membrane potential across the thylakoid membrane. In chloroplasts, import from the stroma into the thylakoid can occur by several routes, distinguished by the protein translocator complex and energy source used.

THE TRANSPORT OF MOLECULES BETWEEN THE NUCLEUS AND THE CYTOSOL

The **nuclear envelope** encloses the DNA and defines the *nuclear compartment*. This envelope consists of two concentric membranes, which are perforated by nuclear pore complexes (**Figure 12–54**). Although the inner and outer nuclear membranes are continuous, they maintain distinct protein compositions. The **inner nuclear membrane** contains proteins that act as binding sites for the **nuclear lamina**, a meshwork of polymerized protein subunits called **nuclear lamins**. The lamin proteins are members of the intermediate filament family of cytoskeletal proteins (see Chapter 16). The lamina provides structural support for

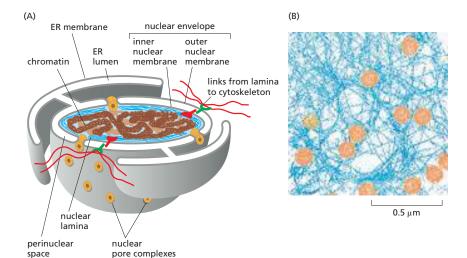

Figure 12-54 The nuclear envelope. (A) The double membrane of the nuclear envelope is penetrated by nuclear pore complexes. Transmembrane proteins in the inner and outer nuclear membranes link the nuclear lamina to the cytosolic cytoskeleton. The outer nuclear membrane is continuous with the endoplasmic reticulum (ER). The ribosomes that are normally bound to the cytosolic surface of the ER membrane and outer nuclear membrane are not shown. (B) The nuclear lamina is a fibrous protein meshwork underlying the inner membrane. Nuclear pores are seen in light brown. (B, from Y. Turgay et al., Nature 543:261-264, 2017.)

MBOC7_ptr_ch12_683-748.indd 735 02/12/21 12:32 PM

the nuclear envelope and acts as an anchoring site for chromosomes and nuclear pore complexes. The lamina is also connected to the cytoplasmic cytoskeleton via protein complexes that span the nuclear envelope, thereby providing structural links between the DNA, nuclear envelope, and cytoskeleton. The **outer nuclear membrane** is continuous with the membrane of the ER and is studded with ribosomes engaged in protein synthesis (see Figure 12–15). The proteins made on these ribosomes are transported into the space between the inner and outer nuclear membranes (the *perinuclear space*), which is continuous with the ER lumen.

Nuclear pores conduct extensive bidirectional traffic between the cytosol and the nucleus. The many proteins that function in the nucleus-including histones, DNA polymerases, RNA polymerases, transcriptional regulators, and RNA-processing proteins—are selectively imported into the nuclear compartment from the cytosol, where they are made. At the same time, all RNAs that function in the cytosol-including mRNAs, rRNAs, tRNAs, and miRNAs-are exported after they are synthesized and processed in the nucleus. Like the import process, the export process is selective; mRNAs, for example, are exported only after they have been properly modified by RNA-processing reactions in the nucleus. In some cases, multiple selective transport steps are needed to assemble a complex structure. Ribosomes, for instance, are made from proteins that are synthesized in the cytosol, imported into the nucleus, and exported back to the cytosol only after their assembly with newly made ribosomal RNA. These pre-ribosomal particles then complete their assembly into functional ribosomes in the cytosol, with certain assembly and transport factors returning to the nucleus to help assemble the next ribosome.

Nuclear Pore Complexes Perforate the Nuclear Envelope

Large and elaborate nuclear pore complexes (NPCs) perforate the nuclear envelope in all eukaryotes. Each NPC is composed of a set of approximately 30 different proteins, or nucleoporins. NPCs display eightfold rotational symmetry, with axial symmetry of the central core. Hence, each nucleoporin is present in multiple copies, resulting in 500-1000 protein molecules in the fully assembled NPC, with an estimated mass of 66 million daltons in yeast and 125 million daltons in vertebrates (Figure 12-55). Most nucleoporins are composed of repetitive protein domains of only a few different types, which have evolved through extensive gene duplication. Some of the scaffold nucleoporins that abut the membrane (see Figure 12-55) are evolutionarily and structurally related to vesicle coat protein complexes, such as clathrin and the COPII coat (discussed in Chapter 13), which shape transport vesicles. One protein is even used as a common building block in both NPCs and vesicle coats. It appears that an ancestral membrane-bending protein that helped shape the elaborate membrane systems of eukaryotic cells evolved into a family of proteins that stabilize the sharp membrane bends at nuclear pores and budding transport vesicles.

The nuclear envelope of a typical mammalian cell contains 3000–4000 NPCs, although that number varies widely, from a few hundred in glial cells to almost 20,000 in Purkinje neurons. Each NPC can transport a staggering 1000 macromolecules per second and can transport in both directions at the same time. The internal diameter of each NPC is $\sim\!40$ nm, large enough to accommodate ribosomal subunits and even viral particles. However, this enormous pore is not empty; instead, it is filled with unstructured protein regions contributed by the channel nucleoporins.

These unstructured domains contain numerous repeats of phenylalanine-glycine (FG) motifs whose weak affinity for each other creates a gel-like mesh inside the NPC. This mesh acts as a sieve that restricts the diffusion of large macromolecules while allowing smaller molecules to pass. Researchers have determined the effective size of the sieve by injecting labeled water-soluble molecules of different sizes into the cytosol and then measuring their rate of diffusion into the nucleus. Small molecules (5000 daltons or less) diffuse in so fast that we

MBOC7_ptr_ch12_683-748.indd 736 02/12/21 12:32 PM

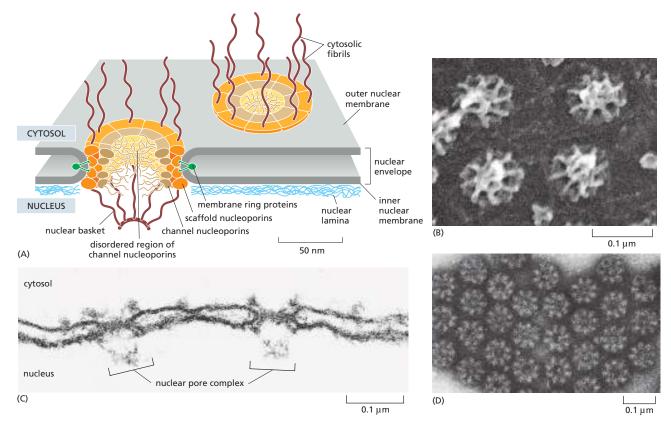

Figure 12-55 The arrangement of NPCs in the nuclear envelope. (A) In a vertebrate NPC, nucleoporins are arranged with striking eightfold rotational symmetry. In addition, immunoelectron microscope studies show that the proteins that make up the central portion of the NPC are oriented symmetrically across the nuclear envelope, so that the nuclear and cytosolic sides look identical. The eightfold rotational and twofold transverse symmetry explains how such a huge structure can be formed from only about 30 different proteins: many of the nucleoporins are present in 8, 16, or 32 copies. On the basis of their approximate localization in the central portion of the NPC, nucleoporins can be classified into (1) transmembrane ring proteins that span the nuclear envelope and anchor the NPC to the envelope; (2) scaffold nucleoporins that form layered ring structures (some scaffold nucleoporins are membrane-bending proteins that stabilize the sharp membrane curvature where the nuclear envelope is penetrated); and (3) channel nucleoporins that line a central pore. In addition to folded domains that anchor the proteins in specific places, many channel nucleoporins contain extensive unstructured regions, where the polypeptide chains are intrinsically disordered. The central pore is filled with a high concentration of these disordered domains whose weak interactions with each other form a gel that blocks the passive diffusion of large macromolecules. The disordered regions contain a large number of phenylalanine-glycine (FG) repeats. Fibrils protrude from both the cytosolic and the nuclear sides of the NPC. By contrast to the twofold transverse symmetry of the NPC core, the fibrils facing the cytosol and nucleus are different: on the nuclear side, the fibrils converge at their distal end to form a basketlike structure. The precise arrangement of individual nucleoporins in the assembled NPC is still a matter of intense debate, because atomic resolution analyses have been hindered by the sheer size and flexible nature of the NPC and by difficulties in purifying sufficient amounts of homogeneous material. A combination of electron microscopy, computational analyses, and crystal structures of nucleoporin subcomplexes has been used to develop the current models of the NPC architecture. (B) A scanning electron micrograph of the nuclear side of the nuclear envelope of an oocyte, showing NPCs with their basketlike fibrils. (C) An electron micrograph showing a side view of two NPCs (brackets); note that the inner and outer nuclear membranes are continuous at the edges of the pore. (D) An electron micrograph showing face-on views of negatively stained NPCs. The membrane has been removed by detergent extraction. Note that some of the NPCs contain material in their center, which is thought to be trapped macromolecules in transit through these NPCs. (A, adapted from A. Hoelz et al., Annu. Rev. Biochem. 80:613-643, 2011. B, © 1992 M.W. Goldberg and T.D. Allen. Originally published in J. Cell Biol. https://doi.org/10.1083/ jcb.119.6.1429. With permission from Rockefeller University Press. C, courtesy of Werner Franke and Ulrich Scheer. D, courtesy of Ron Milligan.)

can consider the nuclear envelope freely permeable to them. The barrier is progressively restrictive to larger molecules such that proteins greater than $\sim\!40,\!000$ daltons or $\sim\!5$ nm in diameter cannot enter by passive diffusion.

Because many cell proteins are too large to diffuse passively through the NPCs, the nuclear compartment and the cytosol can maintain different protein compositions. Mature cytosolic ribosomes, for example, are about 30 nm in diameter and

MBOC7_ptr_ch12_683-748.indd 737 02/12/21 12:32 PM

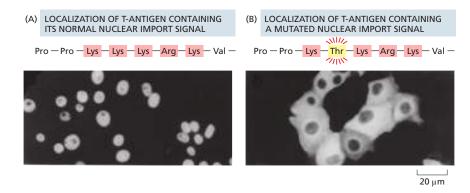

Figure 12-56 The function of a nuclear localization signal. Immunofluorescence micrographs showing the cell location of SV40 virus T-antigen containing or lacking a short sequence that serves as a nuclear localization signal. (A) The normal T-antigen protein contains the lysinerich sequence indicated and is imported to its site of action in the nucleus, as indicated by immunofluorescence staining with antibodies against the T-antigen. (B) T-antigen with an altered nuclear localization signal (a threonine replacing a lysine) remains in the cytosol. (From D. Kalderon et al., Cell 39:499-509, 1984. With permission from Elsevier.)

thus cannot diffuse through the NPC, confining protein synthesis to the cytosol. But how does the nucleus export newly made ribosomal subunits or import large molecules, such as DNA polymerases and RNA polymerases, which have subunit molecular masses of 100,000–200,000 daltons? As we discuss next, these and most other transported protein and RNA molecules bind to specific receptor proteins that ferry large molecules through NPCs. Even small proteins such as histones frequently use receptor-mediated mechanisms to cross the NPC, thereby increasing transport efficiency.

Nuclear Localization Signals Direct Proteins to the Nucleus

When proteins are experimentally extracted from the nucleus and reintroduced into the cytosol, even the very large ones reaccumulate efficiently in the nucleus. Sorting signals called **nuclear localization signals (NLSs)** are responsible for the selectivity of this active nuclear import process. The signals have been precisely defined by using recombinant DNA technology for numerous proteins that are imported into the nucleus (**Figure 12–56**). The most commonly used signal consists of one or two short sequences that are rich in the positively charged amino acids lysine and arginine (see Figure 12–13), with the precise sequence varying for different proteins. Some nuclear proteins contain different types of signals, some of which are not yet characterized.

NLSs can be located almost anywhere in the amino acid sequence and are thought to form loops or patches on the protein surface. Many NLSs function even when linked as short peptides to the surface of a cytosolic protein, suggesting that the precise location of the signal within the amino acid sequence of a nuclear protein is not important. Moreover, as long as one of the protein subunits of a multicomponent complex displays a nuclear localization signal, the entire complex will be imported into the nucleus.

Macromolecular transport across NPCs differs fundamentally from the transport of proteins across the membranes of other organelles: NPC transport occurs through a large, constitutively open, mesh-filled pore, rather than through a much smaller protein translocator whose aqueous pore is typically gated by the protein being transported. For this reason, fully folded proteins and large multiprotein complexes can be transported in either direction through the nuclear pore. By contrast, transport through organellar protein translocators of the ER, mitochondria, and chloroplasts is unidirectional and usually requires the protein to be extensively unfolded.

One can visualize the transport of nuclear proteins through NPCs by coating tiny colloidal gold particles with a nuclear localization signal, injecting the particles into the cytosol, and then following their fate by electron microscopy (Figure 12–57). The particles first arrive at the tentacle-like fibrils that extend from the scaffold nucleoporins at the rim of the NPC into the cytosol, and then proceed through the center of the NPC. This observation illustrates that NLSs impart the ability of large particles to navigate through the otherwise impermeable diffusion barrier posed by the disordered mesh inside the nuclear pore.

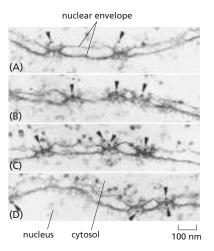

Figure 12-57 Visualizing active import through NPCs. This series of electron micrographs shows 5- to 10-nm-diameter colloidal gold spheres (arrowheads) coated with peptides containing nuclear localization signals entering the nucleus through NPCs. The gold particles were injected into the cytosol of living cells, which then were fixed and prepared for electron microscopy at various times after injection. (A) Gold particles are first seen in proximity to the cytosolic fibrils of the NPCs. (B, C) They are then seen at the center of the NPCs, exclusively on the cytosolic face. (D) They then appear on the nuclear face. These gold particles have much larger diameters than those of the diffusion channels in the NPC and are imported by active transport. (From N. Panté and U. Aebi, Science 273:1729-1732, 1996. With permission from AAAS.)

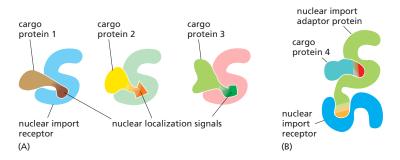

Figure 12–58 Nuclear import receptors. (A) Different nuclear import receptors bind different nuclear localization signals and thereby different cargo proteins. (B) Cargo protein 4 requires an adaptor protein to bind to its nuclear import receptor. The adaptors are structurally related to nuclear import receptors and recognize nuclear localization signals on cargo proteins. They also contain a nuclear localization signal that binds them to an import receptor, but this signal only becomes exposed when they are loaded with a cargo protein.

Nuclear Import Receptors Bind to Both Nuclear Localization Signals and NPC Proteins

To initiate nuclear import, nuclear localization signals must be recognized by **nuclear transport receptors**. Most of these receptors are part of a large family of proteins called *karyopherins*. In yeast, there are 14 genes encoding karyopherins; in animal cells, the number is significantly larger. Karyopherin family members that mediate nuclear import are called **nuclear import receptors**, while those for nuclear export (discussed later) are called **nuclear export receptors**. Each import receptor can bind and transport the subset of cargo proteins containing the appropriate nuclear localization signal (**Figure 12–58A**). Nuclear import receptors sometimes use adaptor proteins that form a bridge between the import receptors and the nuclear localization signals on the proteins to be transported (**Figure 12–58B**). Some adaptor proteins are structurally related to nuclear import receptors, suggesting a common evolutionary origin. By using a variety of import receptors and adaptors, cells are able to recognize the broad repertoire of nuclear localization signals that are displayed on nuclear proteins.

The import receptors are soluble cytosolic proteins that contain multiple low-affinity binding sites for the FG repeats found in the unstructured domains of several nucleoporins. The FG repeats in the fibrils of cytosol-facing nucleoporins serve to initially recruit import receptors and their bound cargo proteins to NPCs. The import receptors can then bind the FG repeats that form the mesh inside the nuclear pore to disrupt interactions between the repeats. In this way, the receptor-cargo complex locally dissolves the gel-like mesh and can diffuse into and within the NPC pore (Figure 12–59).

It is possible to re-create in a test tube a gel consisting of unstructured polypeptides containing FG repeats. This gel displays restricted diffusion of inert cargoes in a size-dependent manner similar to diffusion through NPCs. Diffusion into this artificial gel is more than 1000-fold faster for cargoes bound to an import receptor. At this rate, a cargo in complex with an import receptor could traverse the distance across an NPC in a few milliseconds, consistent with the rate

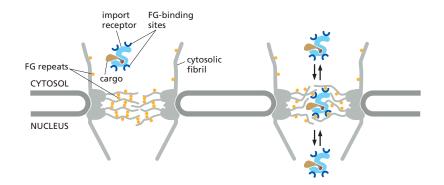

Figure 12–59 Interaction of nuclear import receptors with FG repeats.

Left: Nuclear import receptors contain various low-affinity FG repeat-binding sites on their surface. This facilitates their initial recruitment to NPCs because of interactions with FG repeats found on the cytosolic fibrils of the NPCs. The interior of the NPC is filled with a mesh of FG repeat-containing proteins whose weak interactions with each other restrict nonspecific diffusion of proteins and other macromolecules through the pore. Right: Cargo receptors can rapidly partition into the FG repeat mesh by interacting with the FG repeats and locally melting the mesh. This partitioning into and out of the mesh substantially accelerates diffusion of the cargo receptor (and its bound cargo) through the NPC. Proteins without surface FG repeat-binding sites cannot melt the mesh, and their diffusion through the NPC is comparatively slow.

MBOC7_ptr_ch12_683-748.indd 739 02/12/21 12:33 PM

of transport observed in cells. It is important to realize that in this model, diffusion is not directional; instead, the import receptor simply accelerates diffusion to provide cargo access to the nuclear compartment. As we will see, it is the selective dissociation of cargo only on the nuclear side of the NPC that confers directionality to the import process. The import receptor then returns back to the cytosol for transport of the next cargo.

The Ran GTPase Imposes Directionality on Nuclear Import Through NPCs

The import of nuclear proteins through NPCs concentrates specific proteins in the nucleus and thereby increases order in the cell. The cell fuels this ordering process by harnessing the energy of GTP hydrolysis by the GTPase Ran, which is required for both nuclear import and export.

Like other GTPases, Ran is a molecular switch that can exist in two conformational states, depending on whether GDP or GTP is bound (Figure 3–63). Two Ran-specific regulatory proteins trigger the conversion between the two states: a cytosolic *GTPase-activating protein* (*GAP*) triggers GTP hydrolysis and thus converts Ran-GTP to Ran-GDP, and a nuclear *guanine nucleotide exchange factor* (*GEF*) promotes the exchange of GDP for GTP and thus converts Ran-GDP to Ran-GTP. Because *Ran GAP* is located in the cytosol and *Ran GEF* is located in the nucleus, the cytosol contains mainly Ran-GDP, and the nucleus contains mainly Ran-GTP (Figure 12–60A). The partitioning of the GAP and GEF between the cytosol and nucleus in a cell is due to their preferential association with the cytosolic cytoskeleton and nuclear chromatin, respectively.

The gradient of the two conformational forms of Ran drives nuclear transport in the appropriate direction. Import receptors, facilitated by FG-repeat binding, accelerate diffusion through the mesh inside the NPC channel. When an import receptor reaches the nuclear side of the pore complex, Ran-GTP binds to it and causes the receptor to release its cargo (Figure 12–60B). Because this occurs only

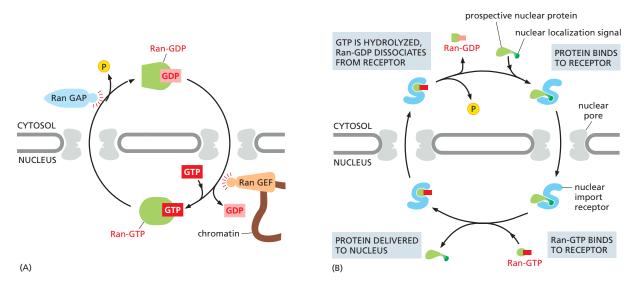

Figure 12–60 The compartmentalization of Ran-GDP and Ran-GTP provides directionality to nuclear transport.

(A) Localization of Ran-GDP in the cytosol and Ran-GTP in the nucleus results from the localization of two Ran regulatory proteins: Ran GTPase-activating protein (Ran GAP) is located in the cytosol, and Ran guanine nucleotide exchange factor (Ran GEF) binds to chromatin and is therefore located in the nucleus. Ran-GDP is imported into the nucleus by its own import receptor (not shown), which is specific for the GDP-bound conformation of Ran. The Ran-GDP receptor is structurally unrelated to the main family of nuclear transport receptors. However, it also binds to FG repeats in NPC channel nucleoporins. (B) The interaction between a nuclear import receptor and its cargo is reversed by Ran-GTP. This means the receptor–cargo interaction is favored in the cytosol but disfavored in the nucleus. This results in net cargo transport from the cytosol to the nucleus.

MBOC7_ptr_ch12_683-748.indd 740 02/12/21 12:33 PM

on the nuclear side of the pore where the Ran-GTP concentration is high, the import process becomes rectified (that is, unidirectional), even though diffusion of the cargo-import receptor complex through the pore is governed by random back-and-forth diffusion.

Having discharged its cargo in the nucleus, the empty import receptor with Ran-GTP bound is transported back through the pore complex by the same mechanism of facilitated diffusion. When the complex of Ran-GTP and the import receptor reaches the cytosol, Ran GAP triggers Ran-GTP to hydrolyze its bound GTP. The resulting Ran-GDP lacks affinity for the import receptor, releasing it for another cycle of nuclear import. Thus, Ran-GDP permits cargo binding in the cytosol, while Ran-GTP stimulates cargo discharge in the nucleus, thereby imparting directionality to the import process.

Nuclear Export Works Like Nuclear Import, but in Reverse

The nuclear export of large molecules, such as new ribosomal subunits and RNA molecules, occurs through NPCs and also depends on a selective transport system. The transport system relies on **nuclear export signals** on the macromolecules to be exported. Export receptors bind to both the export signal, either directly or via an adaptor, and to NPC proteins to guide their cargo to the cytosol. As might be expected from the structural and evolutionary similarity of import receptors and export receptors, the import and export transport systems work in similar ways but in opposite directions: the import receptors bind their cargo molecules in the cytosol, release them in the nucleus, and are then exported to the cytosol for reuse, while the export receptors function in the opposite fashion (**Figure 12–61**).

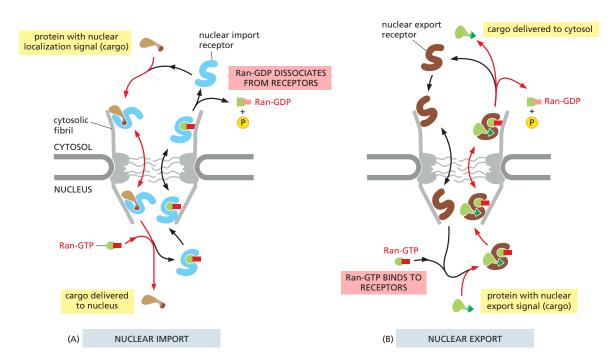

Figure 12–61 Nuclear import and nuclear export both use the Ran GTPase cycle. Movement through the NPC of loaded nuclear transport receptors occurs along the FG repeats displayed by certain NPC proteins. The differential localization of Ran-GTP in the nucleus and Ran-GDP in the cytosol provides directionality (red arrows) to both nuclear import (A) and nuclear export (B). Ran GAP stimulates the hydrolysis of GTP to produce Ran-GDP on the cytosolic side of the NPC (see Figure 12–60A). The critical difference between Ran-mediated nuclear import and nuclear export is the nature of cargo binding by the cargo receptor. In nuclear import, cargo binding is mutually exclusive of Ran-GTP; in nuclear export, cargo binding requires Ran-GTP. Thus, the locations where cargo is picked up and released are exactly reversed in nuclear export compared to nuclear import.

MBOC7_ptr_ch12_683-748.indd 741 02/12/21 12:33 PM

The ability of export receptors to work in reverse derives from the way they interact with the Ran GTPase. Ran-GTP in the nucleus promotes cargo binding to the export receptor, rather than promoting cargo dissociation as in the case of import receptors. Once the export receptor moves through the pore to the cytosol, it encounters Ran GAP, which induces the receptor to hydrolyze its GTP to GDP. As a result, the export receptor flips its conformation and releases both its cargo and Ran-GDP in the cytosol. Free export receptors and free Ran-GDP use the nuclear import pathway to enter the nucleus and complete the cycle.

As we discuss in detail in Chapter 6, cells control the export of RNAs from the nucleus. snRNAs, miRNAs, and tRNAs bind to nuclear export receptors, and they use the Ran-GTP gradient to fuel the transport process. By contrast, the export of mRNAs out of the nucleus uses a different mechanism that does not use export receptors or the Ran GTPase system. Instead, the spliced and processed mRNA is assembled with several nuclear RNA-binding proteins, some of which can bind the nuclear side of NPCs and others that bind FG repeats (see Figure 6–40). This export-competent mRNA ribonucleoprotein (mRNP) complex can then navigate through the FG repeat mesh within the NPC. A helicase complex that resides on the cytosolic side of NPCs uses the energy of ATP hydrolysis to strip several proteins from the mRNP, including the FG repeat-binding protein. This prevents the exported mRNA from reentering the NPC, making the export process unidirectional. The stripped RNA-binding proteins are rapidly imported back to the nucleus (using the import receptor and Ran GTPase system) for another round of transport.

Transport Through NPCs Can Be Regulated by Controlling Access to the Transport Machinery

Some proteins continually shuttle back and forth between the nucleus and the cytosol. This can happen if a protein is small enough to diffuse through the nuclear pore but contains an import or export signal that constantly retrieves it to the nucleus or cytosol. Other proteins contain both nuclear localization signals and nuclear export signals. The relative rates of their import and export determine the steady-state localization of such *shuttling proteins*: if the rate of import exceeds the rate of export, a protein will be located mainly in the nucleus; conversely, if the rate of export exceeds the rate of import, a protein will be located mainly in the cytosol. Thus, changing the rate of import, export, or both, can change the location of a protein.

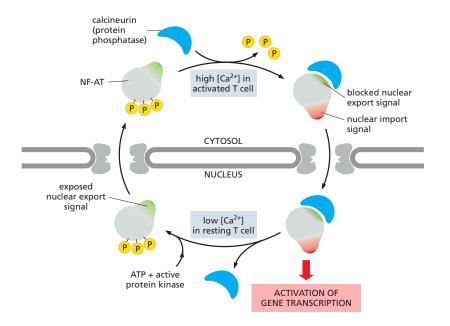

As discussed in Chapter 7, cells control the activity of some transcription regulators by keeping them out of the nucleus until they are needed there (Figure 12–62); similarly, cells can control the translation of certain mRNAs by retaining them in the nucleus until their protein products are needed. In many cases, cells control transport by regulating nuclear localization and export signals—turning them on or off, often by phosphorylation of amino acids close to the signal sequences (Figure 12–63). Other transcription regulators are bound to inhibitory cytosolic proteins that either anchor them in the cytosol (through interactions with the cytoskeleton or specific organelles) or mask their nuclear localization signals so that they cannot interact with nuclear import receptors. An appropriate stimulus releases the transcription regulatory protein from its cytosolic anchor or mask, and it is then transported into the nucleus.

One important example is the latent transcription regulatory protein that controls the transcription of genes involved in cholesterol metabolism. The protein is made and stored in an inactive form as a transmembrane protein in the ER. When a cell is deprived of cholesterol, the protein is transported from the ER to the Golgi apparatus where it encounters specific proteases that cleave off the cytosolic domain, releasing it into the cytosol. This domain is then imported into the nucleus, where it activates the transcription of genes required for both cholesterol uptake and synthesis (Figure 12–64). Earlier in this chapter, we discussed a similar mechanism that controls the activation of the ATF6 arm of the unfolded protein response (see Figure 12–36).

Figure 12-62 The control of nuclear transport in the early Drosophila embryo. The embryo at this stage is a syncytium, shown here in cross section, with many nuclei in a common cytoplasm, arranged around the periphery, just beneath the plasma membrane. The transcription regulatory protein Dorsal is produced uniformly throughout the peripheral cytoplasm, but it can act only when inside the nuclei. The Dorsal protein has been stained with an enzyme-coupled antibody that yields a brown product, revealing that Dorsal is excluded from the nuclei at the dorsal side (top) of the embryo but is concentrated in the nuclei toward the ventral side (bottom) of the embryo. The regulated traffic of Dorsal into the nuclei controls the differential development between the back and belly of the animal. (Courtesy of Siegfried Roth.)

The Nuclear Envelope Disassembles and Reassembles During Mitosis

In animal cells, the nuclear envelope is dismantled during mitosis so that microtubules can access the replicated chromosomes for segregation between the two daughter cells (discussed in Chapter 17). At the end of mitosis, the nuclear envelope reassembles, and the asymmetrical distribution of cellular contents between the cytosol and nucleus is reestablished. The major structures that must be reversibly disassembled are the nuclear lamina, the NPCs, and the membranes of the nuclear envelope.

The dismantling process is initiated by the cyclin-dependent kinase (Cdk) that is activated at the onset of mitosis (discussed in Chapter 17). Cdk

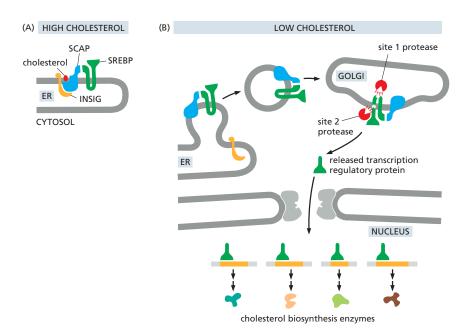

Figure 12-63 The control of nuclear import during T cell activation. The nuclear factor of activated T cells (NF-AT) is a transcription regulatory protein that, in the resting T cell, is found in the cytosol in a phosphorylated state. When T cells are activated by foreign antigen (discussed in Chapter 24), the intracellular Ca²⁺ concentration increases. At high concentrations of Ca²⁺, the protein phosphatase calcineurin binds to NF-AT and dephosphorylates it. The dephosphorylation exposes nuclear import signals and blocks a nuclear export signal. The complex of NF-AT and calcineurin is therefore imported into the nucleus, where NF-AT activates the transcription of numerous genes required for T cell activation. The response shuts off when Ca2+ levels decrease, releasing NF-AT from calcineurin. Rephosphorylation of NF-AT inactivates the nuclear import signals and reexposes the nuclear export signal, causing NF-AT to relocate to the cytosol. Some of the most potent immunosuppressive drugs, including cyclosporin A and FK506, inhibit the ability of calcineurin to dephosphorylate NF-AT and thereby block the nuclear accumulation of NF-AT and T cell activation (Movie 12.6).

Figure 12-64 Feedback regulation of cholesterol biosynthesis. (A) SREBP (sterol response element binding protein), a latent transcription regulator that controls expression of cholesterol biosynthetic enzymes, is initially synthesized as an ER membrane protein. It is anchored in the ER if there is sufficient cholesterol in the membrane by interaction with a membrane protein complex composed of the proteins INSIG and SCAP (SREBP cleavage activation protein), which binds cholesterol. (B) If the cholesterolbinding site on SCAP is empty (at low cholesterol concentrations), SCAP changes conformation and dissociates from INSIG. Dissociation from INSIG frees the SCAP-SREBP complex so it can be packaged together into transport vesicles that are delivered to the Golgi apparatus. In the Golgi apparatus, two Golgi-resident proteases cleave SREBP to free its cytosolic domain from the membrane. The cytosolic domain, which is a transcription regulatory protein, then moves into the nucleus, where it binds to the promoters of genes that encode proteins involved in cholesterol biosynthesis and activates their transcription. In this way, more cholesterol is made when its concentration falls below a threshold.

MBOC7_ptr_ch12_683-748.indd 743 02/12/21 12:33 PM

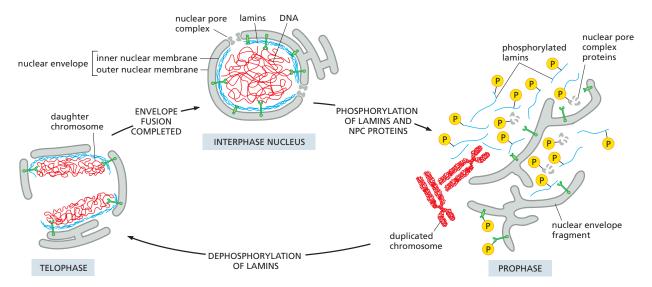

Figure 12-65 The breakdown and re-formation of the nuclear envelope and lamina during mitosis. Phosphorylation of the lamins triggers the disassembly of the nuclear lamina, which initiates the breakup of the nuclear envelope. Dephosphorylation of the lamins reverses the process. An analogous phosphorylation and dephosphorylation cycle occurs for some nucleoporins and proteins of the inner nuclear membrane, and some of these dephosphorylation events are also involved in the reassembly process. The lamin network beings to re-form around regions of individual decondensing daughter chromosomes. The lamins recruit membranes that contain interacting lamin receptors that were in the inner nuclear membrane. Eventually, as decondensation progresses, these membrane structures fuse to form a single complete nucleus. Mitotic breakdown of the nuclear envelope occurs in all metazoan cells. However, in many other species, such as yeasts, the nuclear envelope remains intact during mitosis, and the nucleus divides by fission.

phosphorylates nucleoporins, lamins, and inner nuclear membrane proteins to disrupt their interactions with each other and with chromatin. During this process, some NPC proteins become bound to nuclear import receptors, which play an important part in the reassembly of NPCs at the end of mitosis. Nuclear envelope membrane proteins—no longer tethered to the pore complexes, lamina, or chromatin—disperse throughout the ER membrane. The dynein motor protein, which moves along microtubules (discussed in Chapter 16), is recruited to the outer nuclear membrane early in mitosis and exerts a pulling force. Transmembrane proteins that tether the outer nuclear membrane to the inner nuclear membrane and lamina help transduce this force and pull the nuclear envelope off the chromatin. Together, these processes break down the barriers that normally separate the nucleus and cytosol, and the nuclear proteins that are not bound to membranes or chromosomes intermix completely with the proteins of the cytosol (Figure 12–65).

One protein that remains bound to chromatin even after the nuclear envelope breaks down is Ran GEF. This means Ran molecules close to chromatin are mainly in their GTP-bound conformation. By contrast, Ran molecules further away are in their GDP-bound conformation because of the action of cytosolic Ran GAP. As a result, the chromosomes in mitotic cells are surrounded by a cloud of Ran-GTP, which is important for assembling the mitotic spindle that segregates chromosome into the newly forming daughter cells (discussed in Chapter 17). After chromosome segregation, Cdk is inactivated, allowing dephosphorylation of nucleoporins, lamins, and nuclear membrane proteins. This triggers reassembly of the nuclear envelope on the surface of the complete set of chromosomes in each daughter cell. The positional marker for recruitment of nuclear envelope components to chromosomes is the surrounding cloud of Ran-GTP.

Ran-GTP releases the NPC proteins from nuclear import receptors in proximity to the chromosomes. The free NPC proteins attach to the chromosome surface, where they assemble into new NPCs. At the same time, dephosphorylated lamins bind again to chromatin and recruit ER membranes via the inner

MBOC7_ptr_ch12_683-748.indd 744 02/12/21 12:33 PM

nuclear membrane proteins that reside within them. The ER progressively wraps around the entire group of chromosomes until the ER forms a sealed nuclear envelope, engulfing the chromosomes and proteins bound to them (Movie 12.7). The newly formed inner nuclear envelope is closely applied to the surface of the chromosomes, is enriched for inner nuclear membrane proteins, and excludes all proteins except those initially bound to the mitotic chromosomes, thus conferring a high level of selectivity to the engulfment process. Because Ran-GTP is inside the nucleus and Ran-GDP remains outside, unidirectional import of proteins that contain nuclear localization signals can occur through NPCs. In this way, the nuclear protein content is replenished, while all other large proteins, including ribosomes, are kept out of the newly assembled nucleus.

Summary

The nuclear envelope consists of an inner and an outer nuclear membrane that are connected with each other at perforations formed by nuclear pore complexes (NPCs). The outer nuclear membrane is continuous with the ER membrane, and the space between the inner and outer nuclear membranes is continuous with the ER lumen. RNA molecules, which are made in the nucleus, and ribosomal subunits, which are assembled there, are exported to the cytosol; in contrast, all the proteins that function in the nucleus are synthesized in the cytosol and are then imported. The extensive traffic of materials between the nucleus and cytosol occurs through NPCs, which provide a direct passageway across the nuclear envelope. The interior of NPCs contains a mesh of unstructured proteins that allows passage of small molecules but imposes a diffusion barrier that requires large macromolecules to be actively transported.

Nuclear localization signals and nuclear export signals on proteins to be transported through NPCs are recognized by corresponding nuclear transport receptors. These receptors function by binding their cargoes selectively on one side of the nuclear envelope, increasing the diffusion rate through NPCs, and releasing cargoes selectively on the other side. The free energy of GTP hydrolysis by the monomeric GTPase Ran is harnessed to provide the directionality for nuclear transport. Messenger RNAs are exported from the nucleus through NPCs as parts of large ribonucleoprotein complexes; they use a different transport route that uses ATP hydrolysis to remodel the complexes at the cytosolic side of NPCs. Cells regulate the transport of nuclear proteins and RNA molecules through the NPCs by controlling the access of these molecules to the transport machinery. Because nuclear localization signals are not removed, nuclear proteins can be imported repeatedly, as is required each time that the nucleus reassembles after mitosis.

MBOC7_ptr_ch12_683-748.indd 745 02/12/21 12:33 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **12–1** Like the lumen of the ER, the interior of the nucleus is topologically equivalent to the outside of the cell.
- **12–2** ER-bound and free ribosomes, which are structurally and functionally identical, differ only in the proteins they happen to be making at a particular time.
- **12–3** The signal sequence binds to a hydrophobic site on the ribosome causing a slowdown in protein synthesis, which resumes when SRP binds to the signal sequence.
- **12–4** Peroxisomes are found in only a few specialized types of eukaryotic cell.
- **12–5** The two signal sequences required for insertion of nucleus-encoded proteins into the mitochondrial inner membrane via the TIM23 complex are cleaved off the protein in different mitochondrial compartments.
- **12–6** To avoid the collisions that would occur if two-way traffic through a single pore were allowed, nuclear pore complexes are specialized so that some mediate import while others mediate export.

Discuss the following problems.

12–7 Biomolecular condensates form just under the membrane during T cell receptor signal transduction in immune responses. Three components are critical: the transmembrane protein LAT (linker for activation of T cells), which is phosphorylated at three cytoplasmic tyrosine residues (pY); Grb2, which contains one SH2 domain and two SH3 domains; and Sos1, which contains four binding sites for SH3 domains (**Figure Q12–1A**).

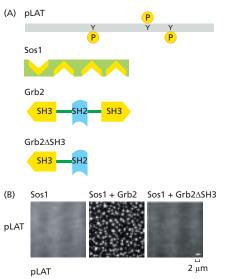

Figure Q12-1 Condensate formation during T cell receptor signal transduction (Problem 12-7). (A) Key molecular components. (B) Appearance of small condensates (bright spots) when the critical components are present. (Modified from Figure 1A and D in X. Su et al., Science 352:595-599, 2016. With permission from AAAS.)

When you insert phosphorylated LAT (pLAT) in an artificial lipid bilayer and add Grb2 and Sos1, micrometer-sized condensates form just below the bilayer (Figure Q12–1B). However, if you use a form of Grb2 that contains just one SH3 domain (Grb2 Δ SH3), instead of two, the condensates do not form (Figure Q12–1B). Why do you suppose that Grb2 supports condensate formation, while Grb2 Δ SH3, which is still multivalent, does not?

- **12–8** What is the fate of a protein with no sorting signal?
- 12–9 Are proteins bound for the plasma membrane common or rare among all ER membrane proteins? A few simple considerations allow one to answer this question. In a typical growing cell that is dividing once every 24 hours, the equivalent of one new plasma membrane must transit the ER every day. If the ER membrane is 20 times the area of a plasma membrane, what is the ratio of plasma membrane proteins to other membrane proteins in the ER? (Assume that all proteins on their way to the plasma membrane remain in the ER for 30 minutes on average before exiting, and that the ratio of proteins to lipids in the ER and plasma membranes is the same.)
- **12–10** A multipass transmembrane protein with several membrane-spanning segments is shown schematically in **Figure Q12–2**. The boxes represent membrane-spanning segments, and the arrow represents the site for cleavage of the signal sequence. In which compartments—cytosol or ER lumen—will the N- and C-termini of the mature protein be located?

Figure Q12–2 A multipass transmembrane protein with a cleavable signal sequence (Problem 12–10).

- 12–11 All new phospholipids are added to the cytosolic leaflet of the ER membrane, yet the ER membrane has a symmetrical distribution of different phospholipids in its two leaflets. By contrast, the plasma membrane, which receives all its membrane components ultimately from the ER, has a very asymmetrical distribution of phospholipids in the two leaflets of its lipid bilayer. How is the symmetry generated in the ER membrane, and how is the asymmetry generated and maintained in the plasma membrane?
- **12–12** Cells with functional peroxisomes incorporate 9-(1'-pyrene)nonanol (P9OH) into membrane lipids. Exposure of such cells to ultraviolet (UV) light causes cell death by generating reactive oxygen species, which are toxic. Cells that do not make peroxisomes lack a critical enzyme responsible for incorporating P9OH into

MBOC7_ptr_ch12_683-748.indd 746 02/12/21 12:33 PM

PROBLEMS 747

membrane lipids. How might you make use of P9OH to select for cells that are missing peroxisomes?

12–13 Components of the TIM complexes were initially identified using a genetic trick. The yeast *Ura3* gene, which encodes an enzyme that is normally located in the cytosol where it is essential for synthesis of uracil, was modified so that the protein carried an import signal for the mitochondrial matrix. A population of cells carrying the modified *Ura3* gene in place of the normal gene was then grown in the absence of uracil. Most cells died, but the rare cells that grew were shown to be defective for mitochondrial import. Explain how this selection system works. Why do most of the cells die, and why do the import-defective cells grow?

12–14 If the enzyme dihydrofolate reductase (DHFR), which is normally located in the cytosol, is engineered to carry a mitochondrial targeting sequence at its N-terminus, it is efficiently imported into mitochondria. If the modified DHFR is first incubated with methotrexate, which binds tightly to the active site, the enzyme remains in the cytosol. How do you suppose that the binding of methotrexate interferes with mitochondrial import?

12–15 Why do mitochondria need a special translocator to import proteins across the outer membrane, when the membrane already has large pores formed by porins?

12–16 Assuming that 32 million histone octamers are required to package the human genome, how many histone molecules must be transported per second per nuclear pore complex in cells whose nuclei contain 3000 nuclear pores and are dividing once per day?

12–17 Selective permeability of the nuclear pore complex (NPC) is controlled by protein components with unstructured tails that extend into the central pore. These tails are characterized by periodic repeats of the hydrophobic amino acids phenylalanine (F) and glycine (G). In a test tube at a concentration of 50 mM, the FG repeat domains of these proteins form a gel, which is held together by weak interactions between the hydrophobic FG repeats. These gels allow passive diffusion of small molecules, which fit through the holes in the mesh, but they prevent entry of larger proteins such as the fluorescent protein mCherry fused to maltose-binding protein (MBP) (**Figure Q12–3A**). However, if the nuclear import receptor, importin, is fused to a similar protein, MBP-GFP, the importin–MBP-GFP fusion readily enters the gel (**Figure Q12–3B**).

Is diffusion of importin–MBP–GFP through the FG repeat gel fast enough to account for the efficient flow of materials between the nucleus and cytosol? From experiments of the type shown in Figure Q12–3B, the diffusion coefficient (D) of importin–MBP–GFP through the FG repeat gel was determined to be about 0.1 μ m²/sec. The equation for diffusion is $t=x^2/2D$, where t is time and x is distance. About how long would it take importin–MBP–GFP to diffuse through a yeast nuclear pore (a distance of 30 nm) if the pore consisted of a gel of FG repeats?

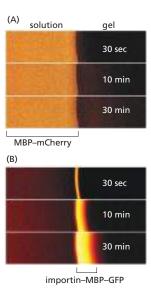

Figure Q12–3 Diffusion of proteins through FG repeat gels (Problem 12–17). Diffusion of MBP–mCherry (A) and importin–MBP–GFP (B) into a gel of FG repeats (on the *right*). The bright areas indicate regions that contain the fluorescent proteins. (Modified from Figure 2 of S. Frey & D. Görlich, *EMBO J.* 28:2554–2567, 2009.)

12–18 A classic experiment that addressed whether nuclear proteins diffused passively into the nucleus or were actively imported used several forms of radioactive nucleoplasmin, which is a large pentameric protein involved in chromatin assembly. In this experiment, either the intact protein or the nucleoplasmin heads, tails, or heads with a single tail were injected into the cytosol or the nucleus of a frog oocyte (**Figure Q12–4**). All forms of nucleoplasmin, except heads, accumulated in the nucleus when injected into the cytoplasm, and all forms were retained in the nucleus when injected there.

How do these experiments distinguish between active transport, in which a nuclear localization signal triggers transport by the nuclear pore complex, and passive diffusion, in which a binding site for a nuclear component allows accumulation in the nucleus?

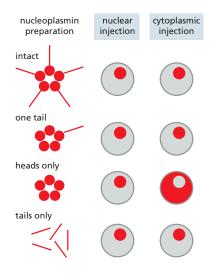

Figure Q12–4 Cellular location of injected nucleoplasmin components (Problem 12–18). The location of nucleoplasmin is indicated by the *red* areas.

Intracellular Membrane Traffic

CHAPTER

13

Every cell must eat, communicate with the world around it, and quickly respond to changes in its environment. To help accomplish these tasks, cells continually adjust the composition of their plasma membrane and internal compartments in response to need. Eukaryotic cells use an elaborate internal membrane system to add and remove cell-surface proteins, such as receptors, ion channels, and transporters (Figure 13–1). Through the process of *exocytosis*, the secretory pathway delivers newly synthesized proteins, carbohydrates, and lipids either to the plasma membrane or to the extracellular space. By the converse process of *endocytosis*, cells take in components of the plasma membrane and extracellular space and deliver them to internal compartments called *endosomes*.

The proteins, nutrients, lipids, and receptors delivered by endocytosis to endosomes are sorted and either recycled to the plasma membrane or delivered to *lysosomes* where they are broken down into building blocks and transported to the cytosol for use in various biosynthetic processes. Lysosomes also break down and recycle intracellular macromolecules through a process called *autophagy*. This pathway engulfs parts of the cytosol or whole organelles into a newly assembled compartment, which then fuses with lysosomes to deliver its contents for degradation. In development, cells often use autophagy to remodel their cytoplasm as they differentiate and adapt to new physiological tasks.

The interior space, or lumen, of each membrane-enclosed compartment along the secretory and endocytic pathways is topologically equivalent to the cell exterior. This means proteins can travel from the lumen of one compartment to another by means of numerous membrane-enclosed transport containers without ever having to cross a membrane (Figure 13–2). These containers are formed by membrane budding from a compartment and are either small spherical *vesicles*, larger irregular vesicles, or tubules. We shall use the term **transport vesicle** to apply to all forms of these containers.

Transport vesicles continually bud off from one membrane compartment and fuse with another, carrying membrane components and soluble lumenal molecules, which are referred to as **cargo**. This vesicular traffic flows along highly

IN THIS CHAPTER

Transport from the *Trans* Golgi Network to the Cell Exterior and Endosomes

Transport into the Cell from the Plasma Membrane: Endocytosis

The Degradation and Recycling of Macromolecules in Lysosomes

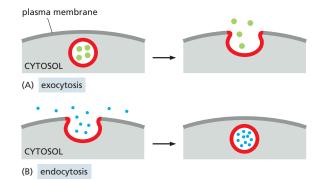

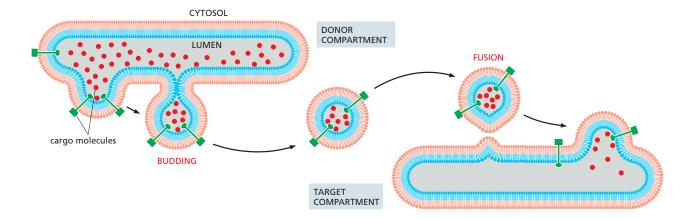

Figure 13–1 Exocytosis and endocytosis. (A) In exocytosis, a transport vesicle fuses with the plasma membrane. Its content is released into the extracellular space, while the vesicle membrane (red) becomes continuous with the plasma membrane. (B) In endocytosis, a plasma membrane patch (red) is internalized, forming a transport vesicle. Its content derives from the extracellular space. The interior of the transport vesicles in panels A and B is topologically equivalent to the extracellular space.

MBOC7_ptr_ch13_749-810.indd 749 08/12/21 11:39 AM

organized, directional routes, which allow the cell to secrete, eat, and remodel its plasma membrane and organelles (Figure 13–3). The *secretory pathway* leads outward from the endoplasmic reticulum (ER) toward the Golgi apparatus and cell surface, with a side route leading to endosomes, while the *endocytic pathway* leads inward from the plasma membrane. In each case, *retrieval pathways* bring membrane and selected proteins back to the compartment of origin to balance the flow of materials between compartments.

Figure 13–2 Vesicle transport. Transport vesicles bud off from one compartment and fuse with another. As they do so, they carry material as cargo from the *lumen* (the space within a membrane-onclosed compartment) and membrane of the donor compartment to the lumen and membrane of the target compartment, as shown.

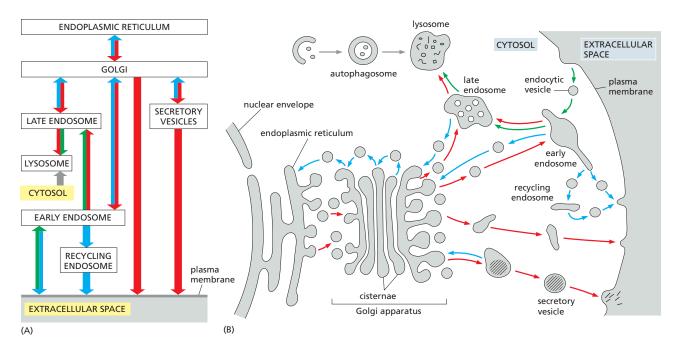

Figure 13–3 A "road map" of the secretory and endocytic pathways. (A) In this schematic road map, which was introduced in Chapter 12, the endocytic and secretory pathways are illustrated with *green* and *red arrows*, respectively. In addition, *blue arrows* denote retrieval pathways for the backflow of selected components. Engulfment during autophagy is illustrated with a *gray arrow*. (B) The compartments of the eukaryotic cell involved in vesicle transport. The lumens of most membrane-enclosed compartments are topologically equivalent to each other and to the outside of the cell. All compartments shown communicate with one another and the outside of the cell by means of transport vesicles. In the secretory pathway (*red arrows*), protein molecules are transported from the endoplasmic reticulum (ER) to the plasma membrane or (via endosomes) to lysosomes. In the endocytic pathway (*green arrows*), molecules are ingested in endocytic vesicles derived from the plasma membrane and delivered to early endosomes and then (via late endosomes) to lysosomes. In autophagy (*gray arrows*), cytoplasmic components engulfed into an autophagosome are delivered to lysosomes. Many endocytosed molecules are retrieved from early endosomes and returned (some via recycling endosomes) to the cell surface for reuse; similarly, some molecules are retrieved from the early and late endosomes and returned to the Golgi apparatus, and some are retrieved from the Golgi apparatus and returned to the ER. All of these retrieval pathways are shown with *blue arrows*, as in panel A.

MBOC7_ptr_ch13_749-810.indd 750 08/12/21 11:39 AM

To perform its function, each transport vesicle that buds from a compartment must be selective. It must take up only the appropriate molecules and must fuse only with the appropriate target membrane. A vesicle carrying cargo from the ER to the Golgi apparatus, for example, must exclude most other proteins that are to stay in the ER, and it must fuse only with the Golgi apparatus and not with any other organelle.

We begin this chapter by considering the molecular mechanisms of budding and fusion that underlie all vesicle transport. We then discuss the fundamental problem of how, in the face of this transport, the cell maintains the molecular and functional differences between its compartments. Finally, we consider the function of the Golgi apparatus, secretory vesicles, endosomes, and lysosomes as we trace the pathways that connect these organelles.

MECHANISMS OF MEMBRANE TRANSPORT AND COMPARTMENT IDENTITY

Vesicle transport mediates a continual exchange of components between the 10 or more chemically distinct, membrane-enclosed compartments that collectively compose the secretory and endocytic pathways. In this section, we discuss how transport vesicles form, how they concentrate cargo within them, and how they deliver their contents selectively to another compartment. Transport begins when a special coat of proteins is assembled on a region of the cytosolic face of a membrane compartment. The coat is used to collect specific cargo components from the membrane and compartment lumen for delivery to another compartment. The coat, with the help of additional proteins, shapes the membrane into a transport vesicle that buds from the originating compartment. These vesicles selectively dock at the appropriate destination membrane and then fuse with it to deliver their cargo.

Despite the constant exchange of components between membrane-enclosed compartments, each compartment maintains its special identity of molecular markers, such as proteins or specific lipids, that are displayed on the cytosolic surface of the membrane. Cells achieve this by tightly controlling the membrane components that are packaged into departing transport vesicles. The identity markers of a compartment serve as guidance cues for outgoing traffic by recruiting the appropriate coat and for incoming traffic to ensure that transport vesicles fuse only with the correct compartment. Many of these membrane markers, however, are found on more than one compartment, and it is the specific combination of marker molecules that gives each compartment its molecular address.

There Are Various Types of Coated Vesicles

Most transport vesicles form from specialized, coated regions of membranes. They bud off as **coated vesicles**, which have a distinctive cage of proteins covering their cytosolic surface. Before the vesicles fuse with a target membrane, they shed their coat so that the membrane surfaces of the vesicle and destination compartment can interact directly and fuse.

The coat performs two main functions that are reflected in a common twolayered structure. First, an inner coat layer concentrates specific membrane proteins in a specialized patch, which then gives rise to the vesicle membrane. In this way, the inner layer selects the appropriate membrane molecules for transport. Second, an outer coat layer assembles into a curved, basketlike lattice that deforms the membrane patch and thereby shapes the vesicle.

There are four well-characterized types of coated vesicles, distinguished by their major coat proteins: *clathrin-coated*, *COPI-coated*, *COPII-coated*, and *retromer-coated* (Figure 13–4). Each type is used for different transport steps (Figure 13–5). Clathrin-coated vesicles mediate transport originating from the Golgi apparatus, endosome, and the plasma membrane. COPI-coated and COPII-coated vesicles mediate transport originating from the Golgi cisternae and the ER, respectively. Retromer forms coats on transport vesicles for a retrieval

MBOC7_ptr_ch13_749-810.indd 751 08/12/21 11:39 AM

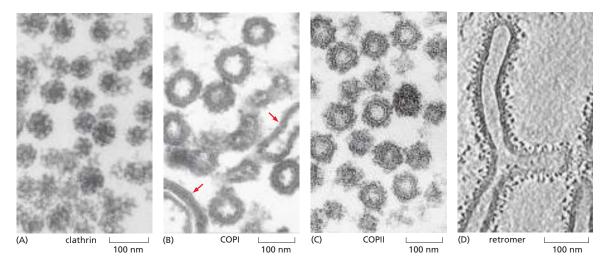

Figure 13–4 Electron micrographs of clathrin-coated, COPI-coated, and retromer-coated vesicles. All coated vesicles are shown in electron micrographs at the same scale. (A) Clathrin-coated vesicles. (B) COPI-coated vesicles and Golgi cisternae (red arrows) from a cell-free system in which COPI-coated vesicles bud in the test tube. (C) COPII-coated vesicles. (D) Retromer-coated tubules formed in a cell-free system containing large membrane vesicles and purified retromer. (A and B, from L. Orci et al., Cell 46:171–184, 1986. With permission from Elsevier; C, courtesy of Charles Barlowe and Lelio Orci; D, courtesy of John Briggs.)

pathway from endosomes to the Golgi apparatus. There is, however, much more variety in coated vesicles and their functions than this short list suggests. As we discuss shortly, there are several types of clathrin-coated vesicles, each specialized for a different transport step, and the COPI-coated and COPII-coated vesicles may be similarly diverse. We discuss clathrin-coated vesicles first, as they provide a good example of how vesicles form.

The Assembly of a Clathrin Coat Drives Vesicle Formation

The major protein component of **clathrin-coated vesicles** is clathrin, which forms the outer layer of the coat. **Clathrin** is composed of a large subunit (the heavy chain) and a small subunit (the light chain). Three heavy chains and three light chains assemble into a three-legged structure called a *triskelion* (**Figure 13–6A and B**). Clathrin triskelions assemble into a basketlike framework of hexagons and pentagons on the cytosolic surface of membranes. Clathrin assembly induces the formation of coated buds (called coated pits when on the plasma membrane), which eventually pinch off to become clathrin-coated vesicles (**Figure 13–7**). Under appropriate conditions, isolated triskelions spontaneously self-assemble into typical polyhedral cages in a test tube, even

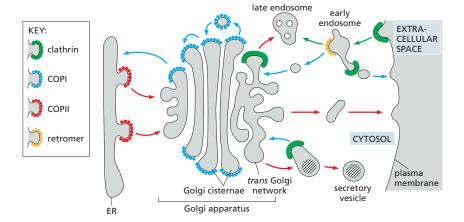

Figure 13-5 Use of different coats for different steps in vesicle traffic. Different coat proteins select different cargo and shape the transport vesicles that mediate the various steps in the secretory and endocytic pathways. When the same coats function in different places in the cell, they usually incorporate different coat protein subunits that modify their properties (not shown). Many differentiated cells have additional pathways besides those shown here, including a sorting pathway from the trans Golgi network to the apical surface of epithelial cells and a specialized recycling pathway for proteins of synaptic vesicles in the nerve terminals of neurons (see Figure 11-38). The arrows are colored as in Figure 13-3.

MBOC7_ptr_ch13_749-810.indd 752 08/12/21 11:39 AM

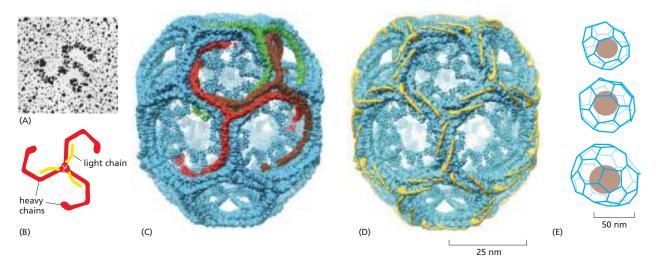

Figure 13–6 The structure of a clathrin coat. (A) Electron micrograph of a clathrin triskelion shadowed with platinum. (B) Each triskelion is composed of three clathrin heavy chains and three clathrin light chains, as shown in the diagram. (C and D) A cryo-electron micrograph taken of a clathrin coat composed of 36 triskelions organized in a network of 12 pentagons and 6 hexagons, with some heavy chains (C) and light chains (D) highlighted (Movie 13.1). The light chains link to the actin cytoskeleton, which helps generate force for membrane budding and vesicle movement, and their phosphorylation regulates clathrin coat assembly. The interwoven legs of the clathrin triskelions form an outer shell from which the N-terminal domains of the triskelions protrude inward. These domains bind to the adaptor proteins shown in Figure 13–8. The coat shown was assembled biochemically from pure clathrin triskelions and is too small to enclose a membrane vesicle. (E) Structures of clathrin-coated vesicles isolated from bovine brain. The clathrin coats are constructed similarly to but in a less regular way than the coat of panels C and D, utilizing pentagons, a larger number of hexagons, and sometimes heptagons, resembling the architecture of deformed soccer balls. The structures were determined by cryo-electron microscopy and tomographic reconstruction. (A, from E. Ungewickell and D. Branton, Nature 289:420–422, published 1981 by Nature Publishing Group; reproduced with permission of SNCSC; C and D, from A. Fotin et al., Nature 432:573–579, published 2004 by Nature Publishing Group; all reproduced with permission of SNCSC; E, from Y. Cheng et al., J. Mol. Biol. 365:892–899, 2007. With permission from Elsevier.)

in the absence of the membrane vesicles that these baskets normally enclose (Figure 13-6C and D). Thus, the clathrin triskelions determine the geometry of the clathrin cage (Figure 13-6E).

Adaptor Proteins Select Cargo into Clathrin-coated Vesicles

Adaptor proteins, another major coat component in clathrin-coated vesicles, form a discrete inner layer of the coat, positioned between the clathrin cage and the cytosolic face of the membrane. They bind to various transmembrane protein cargoes and transmembrane receptors that capture soluble cargo molecules inside the vesicle—so-called *cargo receptors*. Adaptor proteins also bind to clathrin and recruit it to the membrane surface where it assembles and bends the membrane. In this way, the specific set of transmembrane and soluble cargoes selected by adaptor proteins is packaged into a newly formed clathrin-coated transport vesicle (Figure 13–8).

The assembly of adaptor proteins on the membrane is tightly controlled, in part by the cooperative interaction of the adaptor proteins with the membrane, transmembrane cargoes, and other components of the coat. The adaptor protein AP2 serves as a well-understood example. When it binds to a specific phosphory-lated phosphatidylinositol lipid (a *phosphoinositide*), AP2 acquires a different conformation that exposes binding sites for cargo receptors in the membrane. The simultaneous binding to the cargo receptors and lipid head groups greatly enhances the binding of AP2 to the membrane (**Figure 13–9**). Upon binding, AP2 induces membrane curvature, which makes the binding of additional AP2 proteins in its proximity more likely. The cooperative assembly of the AP2 coat layer then is further amplified by clathrin binding, which leads to the formation and budding of a transport vesicle.

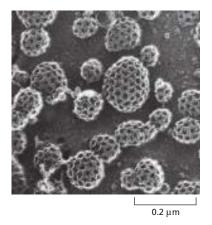

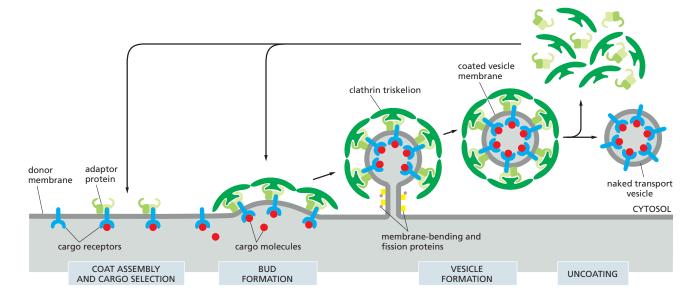

Figure 13–7 Clathrin-coated pits and vesicles. This rapid-freeze, deep-etch electron micrograph shows numerous clathrin-coated pits and vesicles on the inner surface of the plasma membrane of cultured fibroblasts. The cells were rapidly frozen in liquid helium, fractured, and deepetched to expose the cytoplasmic surface of the plasma membrane. (Courtesy of John Heuser.)

MBOC7_ptr_ch13_749-810.indd 753 08/12/21 11:39 AM

There are several types of adaptor proteins. The best characterized, like AP2, have four different protein subunits; others are single-chain proteins. Many of the adaptor proteins bind to phosphoinositides. As we will see next, different types of phosphoinositides are located in different membrane compartments, serving as one of the molecular markers of that compartment's identity. Each type of adaptor protein is specific for transmembrane cargoes and cargo receptors that share a particular amino acid sequence motif displayed on the cytosolic side of the membrane. Because different adaptor proteins have different specificities for both the type of phosphoinositide and the sequence motif they recognize, each type of adaptor protein directs assembly of a clathrin-coated vesicle only at particular membranes.

Phosphoinositides Mark Organelles and Membrane Domains

Although inositol phospholipids typically compose less than 10% of the total phospholipids in a membrane, they have important regulatory functions. They can undergo rapid cycles of phosphorylation and dephosphorylation at the 3′, 4′, and 5′ positions of their inositol sugar head groups to produce various types of **phosphoinositides** (**phosphatidylinositol phosphates, or PIPs**). The interconversion of phosphatidylinositol (PI) and PIPs is highly compartmentalized: different organelles in the endocytic and secretory pathways have distinct sets of PI and PIP kinases and PIP phosphatases (**Figure 13–10**). The distribution, regulation, and local balance of these enzymes determine the steady-state distribution

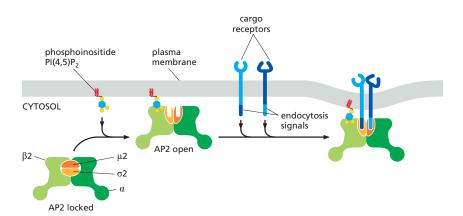

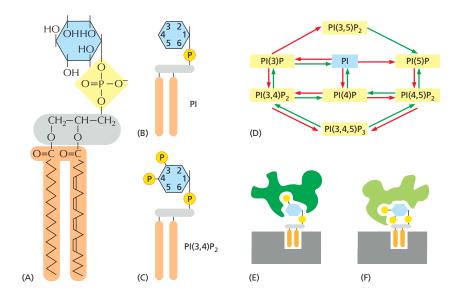

Figure 13-8 The assembly and disassembly of a clathrin coat. The assembly of the coat introduces curvature into the membrane, which leads in turn to the formation of a coated bud (called a coated pit if it is in the plasma membrane). The adaptor proteins bind both clathrin triskelions and membrane-bound cargo receptors, thereby mediating the selective recruitment of both membrane and soluble cargo molecules into the vesicle. Other membrane-bending and fission proteins are recruited to the neck of the budding vesicle, where sharp membrane curvature is introduced. The coat is rapidly lost shortly after the vesicle buds off.

Figure 13-9 Lipid-induced conformation switching of AP2. The AP2 adaptor protein complex has four subunits (α , β 2, μ 2, and σ 2). Upon interaction with the phosphoinositide PI(4,5)P2 (see Figure 13-10) in the cytosolic leaflet of the plasma membrane, AP2 rearranges so that binding sites for cargo receptors become exposed. Each AP2 complex binds four PI(4,5)P2 molecules (for clarity, only one is shown). In the open AP2 complex, the μ 2 and σ 2 subunits bind the cytosolic tails of cargo receptors that display the appropriate endocytosis signals. These signals consist of short amino acid sequence motifs. When AP2 binds tightly to the membrane, it induces curvature. which favors the binding of additional AP2 complexes in the vicinity.

MBOC7_ptr_ch13_749-810.indd 754 08/12/21 11:39 AM

of each PIP species. As a consequence, the distribution of PIPs varies from organelle to organelle, and often within a continuous membrane from one region to another, thereby defining specialized membrane domains.

Many proteins involved at different steps in vesicle transport contain domains that bind with high specificity to the head groups of particular PIPs, distinguishing one phosphorylated form from another (see Figure 13–10). Local control of the PI and PIP kinases and PIP phosphatases can therefore be used to rapidly control the binding of proteins to a membrane or membrane domain. The production of a particular type of PIP recruits proteins containing matching PIP-binding domains. The PIP-binding proteins then help regulate vesicle formation and other steps in the control of vesicle traffic (Figure 13–11). The same strategy is widely used to recruit specific intracellular signaling proteins to the plasma membrane in response to extracellular signals (discussed in Chapter 15).

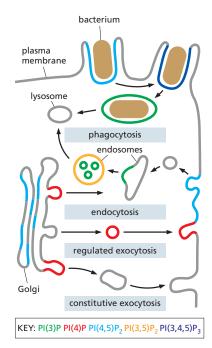

Membrane-bending Proteins Help Deform the Membrane During Vesicle Formation

Although vesicle-budding is similar at various locations in the cell, each cell membrane poses its own special challenges. The plasma membrane, for example, is comparatively flat and stiff, owing to its cholesterol-rich lipid composition and underlying actin-rich cortex. Thus, the forces generated by clathrin coat assembly alone are not sufficient to shape and pinch off a vesicle from the plasma membrane. Other membrane-bending and force-generating proteins participate at every stage of the process.

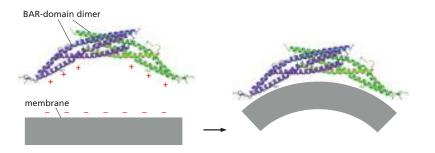

Membrane-bending proteins that contain crescent-shaped domains, called *BAR domains*, bind to and impose their shape on the underlying membrane

Figure 13–11 The intracellular location of phosphoinositides. Different types of PIPs are located in different membranes and membrane domains, where they are often associated with specific vesicle transport events. The membrane of secretory vesicles, for example, contains PI(4)P. When the vesicles fuse with the plasma membrane, a phosphoinositide 5-kinase (PI 5-kinase) that is localized there converts the PI(4)P into PI(4,5)P₂. The PI(4,5)P₂, in turn, helps recruit adaptor proteins, which initiate the formation of a clathrin-coated pit, as the first step in clathrin-mediated endocytosis. Once the clathrin-coated vesicle buds off from the plasma membrane, a PI(5)P phosphatase hydrolyzes PI(4,5)P₂, which weakens the binding of the adaptor proteins, promoting vesicle uncoating. We discuss phagocytosis and the distinction between regulated and constitutive exocytosis later in the chapter. (Modified from M.A. De Matteis and A. Godi, *Nat. Cell Biol.* 6: 487–492, 2004.)

Figure 13-10 Phosphatidylinositol (PI) and phosphoinositides (phosphatidylinositol phosphates, or PIPs). (A, B) The structure of PI shows the free hydroxyl groups in the inositol sugar that can be modified. (C) Phosphorylation of one, two, or three of the hydroxyl groups on PI by PI and PIP kinases produces a variety of PIP species. They are named according to the ring position (in parentheses) and the number of phosphate groups (subscript) added to Pl. Phosphatidylinositol 3,4-bisphosphate [PI(3,4)P₂] is shown. (D) Animal cells have several PI and PIP kinases and a similar number of PIP phosphatases, which are localized to different organelles. where they are regulated to catalyze the production of particular PIPs. The red and green arrows show the kinase and phosphatase reactions, respectively. (F. F) Phosphoinositide head groups are recognized by protein domains that discriminate between the different forms. In this way, select groups of proteins containing such domains are recruited to regions of membrane in which these phosphoinositides are present. Phosphatidylinositol 3-phosphate [PI(3)P] in the endosome membrane, and phosphatidylinositol 4,5-bisphosphate [Pl(4.5)P₂] in the plasma membrane, are shown. (D. modified from M.A. De Matteis and A. Godi, Nat. Cell Biol. 6:487-492, 2004.)

MBOC7_ptr_ch13_749-810.indd 755 08/12/21 11:39 AM

via electrostatic interactions with the lipid head groups (Figure 13–12; also see Figure 10–40). Some of these proteins also contain amphiphilic helices that induce membrane curvature after being inserted as wedges into the cytoplasmic leaflet of the membrane. The curved membrane generated by BAR-domain proteins is thought to help AP2 nucleate the formation of a clathrin-coated bud.

Other BAR-domain proteins are important in shaping the neck of a budding vesicle, where stabilization of sharp membrane bends is essential. These BAR-domain proteins, together with the clathrin machinery they help nucleate, stimulate the local assembly of actin filaments (Figure 13–13). The growing filaments push on the membrane surrounding the budding vesicle and further help propel it away from the membrane.

Cytoplasmic Proteins Regulate the Pinching off and Uncoating of Coated Vesicles

As a clathrin-coated bud grows, soluble cytoplasmic proteins, including **dynamin**, assemble at the neck of the bud and ultimately pinch off the membrane to release the fully formed clathrin-coated vesicle (**Figure 13–14**). Dynamin contains a phosphoinositide-binding domain, which tethers the protein to the membrane, and a GTPase domain, which regulates the rate at which vesicles pinch off from the membrane. The pinching-off process brings the two noncytosolic leaflets of the membrane at the bud neck into close proximity and seals off the forming vesicle (see Figure 13–2). To perform this task, dynamin assembles in a ring around the neck, then undergoes a conformational change when it hydrolyzes its bound GTP. This constricts the dynamin ring together with the underlying membrane at the bud neck. In addition, dynamin may recruit lipid-modifying enzymes that change the lipid composition locally at the neck of the bud to facilitate membrane fusion.

Once released from the membrane, the vesicle rapidly loses its clathrin coat because factors that are co-packaged into a clathrin-coated vesicle initiate reactions that lead to coat disassembly. A phosphoinositide phosphatase in the vesicle depletes the phosphoinositide that binds to the adaptor proteins of the coat. In addition, *auxilin*, another vesicle protein, activates the ATPase of an hsp70 chaperone protein (see Figure 6–80) that uses the energy of ATP hydrolysis to peel off the clathrin coat. The release of the coat, however, must not happen prematurely, so additional control mechanisms must somehow prevent the clathrin from being removed before it has formed a complete vesicle.

Monomeric GTPases Control Coat Assembly

So far we have discussed clathrin-coated vesicles at the plasma membrane to illustrate several principles of coat formation, membrane budding, and uncoating. The formation of COPI coats, COPII coats, retromer coats, and other types of clathrin coats works by similar principles but differs in many important ways. A critical difference is the mechanism cells use to determine when and where to initiate coat formation. While local production of PIPs plays a major part in regulating the assembly of clathrin coats on the plasma membrane and Golgi apparatus, *coat-recruitment GTPases* control the assembly of COPI coats on Golgi

Figure 13-12 The structure of BAR domains. BAR-domain proteins are diverse and enable many membrane-bending processes in the cell. BAR domains are built from coiled coils that dimerize into modules that have a positively charged inner surface, which preferentially interacts with negatively charged lipid head groups to bend membranes. Local membrane deformations caused by BAR-domain proteins facilitate the binding of additional BAR-domain proteins, thereby generating a positive feedback cycle for curvature propagation. Individual BAR-domain proteins contain a distinctive curvature and often have additional features that adapt them to their specific tasks: some have short amphiphilic helices that cause further membrane deformation by wedge insertion; others are flanked by PIP-binding domains that direct them to membranes enriched in cognate phosphoinositides. (PDB code: 1ZWW.)

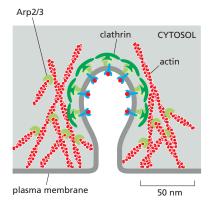

Figure 13–13 Local actin polymerization helps drive budding of membrane vesicles. Polymerization of actin filaments occurs near the vesicle neck, helping propel the budding vesicle away from the plasma membrane.

MBOC7_ptr_ch13_749-810.indd 756 08/12/21 11:39 AM

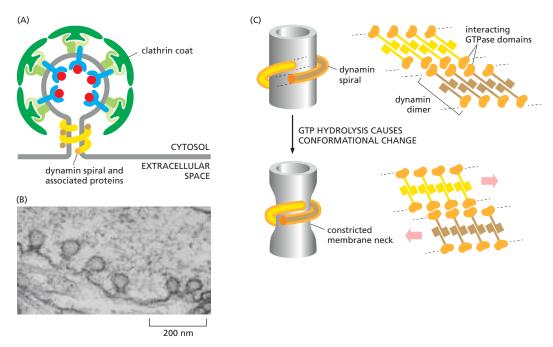

Figure 13-14 The role of dynamin in pinching off clathrin-coated vesicles. (A) Multiple dynamin molecules assemble into a spiral around the neck of the forming bud. The dynamin spiral is thought to recruit other proteins to the bud neck, which, together with dynamin, destabilize the interacting lipid bilayers so that the noncytoplasmic leaflets flow together. The newly formed vesicle then pinches off from the membrane. Specific mutations in dynamin can either enhance or block the pinchingoff process. (B) Dynamin was discovered as the protein defective in the shibire mutant of Drosophila. These mutant flies become paralyzed because clathrin-mediated endocytosis stops, and the synaptic vesicle membrane fails to recycle, blocking neurotransmitter release. Deeply invaginated clathrin-coated pits form in the nerve endings of the fly's nerve cells, with a belt of mutant dynamin assembled around the neck, as shown in this thin-section electron micrograph. The pinching-off process fails because the required membrane fusion does not take place. (C) A model of how conformational changes in the GTPase domains of membrane-assembled dynamin can power a conformational change that constricts the neck of the bud. In this model, dynamin dimers polymerize to form the dynamin spiral. Where two rungs of the spiral meet, the GTPase domains of one rung's dynamins interact with the GTPase domains of the other rung's dynamins. GTP hydrolysis by the GTPase domains induces conformational changes that cause compaction of individual dynamin molecules, leading to partial constriction of the dynamin spiral. Loss of GTP weakens the interactions of the GTPase domains with each other, and rebinding of GTP reverses the compacted state to allow the GTPase domains to bind at the adjacent position on the opposite rung (this step is not shown). In this way, the dynamin molecules can undergo a stepping motion in the direction indicated by the pink arrows. Cycles of dynamin compaction and stepping, powered by cycles of GTP binding and hydrolysis, is one model for how dynamin constricts the neck of a budding vesicle. (B, from J.H. Koenig and K. Ikeda, J. Neurosci. 9:3844-3860, 1989. Copyright 1989 Society for Neuroscience. With permission from the Society for Neuroscience.)

membranes, COPII coats on ER membranes, and retromer and clathrin coats on endosomes.

Coat-recruitment GTPases are members of a family of monomeric GTPases. They include the ARF proteins, which are responsible for the assembly of both COPI and clathrin coats at Golgi membranes, the Sar1 protein, which is responsible for the assembly of COPII coats at the ER membrane, and Rab7, which initiates the assembly of retromer coats at the endosome membrane. As discussed in Chapter 3, GTP-binding proteins regulate many processes in eukaryotic cells. They act as molecular switches, which toggle between an active state with GTP bound and an inactive state with GDP bound. Two classes of proteins regulate the toggling: guanine nucleotide exchange factors (GEFs) activate the proteins by catalyzing the exchange of GDP for GTP, and GTPase-activating proteins (GAPs) inactivate the proteins by triggering the hydrolysis of the bound GTP to GDP (see Figures 3–68 and 15–7).

Coat-recruitment GTPases are usually found in high concentration in the cytosol in an inactive, GDP-bound state. When a **COPII-coated vesicle** is to bud from the ER membrane, a specific **Sar1 GEF** embedded in the ER membrane binds to cytosolic Sar1, causing the Sar1 to release its GDP. Because GTP is present in

MBOC7_ptr_ch13_749-810.indd 757 08/12/21 11:39 AM

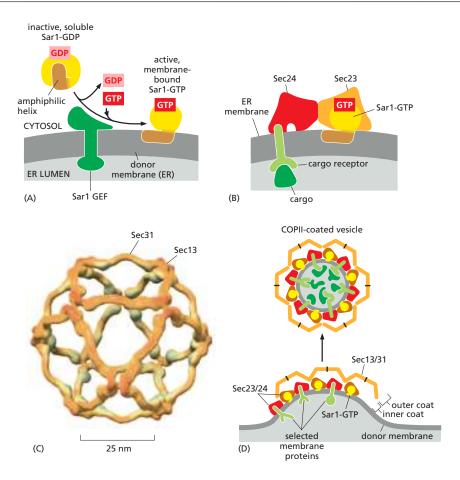

Figure 13-15 Formation of a COPIIcoated vesicle. (A) Inactive, soluble Sar1-GDP binds to a Sar1 GEF in the ER membrane, causing Sar1 to release its GDP and bind GTP. A GTP-triggered conformational change in Sar1 exposes an amphiphilic helix, which inserts into the cytoplasmic leaflet of the ER membrane, initiating membrane bending (which is not shown). (B) GTP-bound Sar1 binds to a complex of two COPII adaptor coat proteins, called Sec23 and Sec24, which form the inner coat. Sec24 has several different binding sites for the cytosolic tails of cargo receptors. The entire surface of the complex that attaches to the membrane is gently curved, matching the diameter of COPII-coated vesicles. (C) A complex of two additional COPII coat proteins, called Sec13 and Sec 31, forms the outer shell of the coat. Like clathrin, they can assemble on their own into symmetrical cages with appropriate dimensions to enclose a COPII-coated vesicle. (D) Membrane-bound, active Sar1-GTP recruits COPII adaptor proteins to the membrane. They select certain transmembrane proteins and cause the membrane to deform. The adaptor proteins then recruit the outer coat proteins, which help form a bud. A subsequent sealing event pinches off the coated vesicle. Other coated vesicles are thought to form in a similar way. (C, modified from S.M. Stagg et al., Nature 439:234-238, published 2006 by Nature Publishing Group. Reproduced with permission of SNCSC.)

much higher concentration in the cytosol than GDP, Sar1 binds GTP as soon as GDP is released. In its GTP-bound state, the Sar1 protein exposes an amphiphilic helix, which inserts into the cytoplasmic leaflet of the lipid bilayer of the ER membrane. The tightly bound Sar1 now recruits adaptor coat protein subunits to the ER membrane to initiate budding (Figure 13–15). Other GEFs and coat-recruitment GTPases operate in a similar way on other membranes (Movie 13.2). Some of the small monomeric GTPases use an amphiphilic helix, whereas others use an attached lipid to anchor them to membranes. Thus, GEFs located in different compartments serve as important spatial cues that control where different coat-recruitment GTPases are activated to initiate the formation of different types of transport vesicles.

Coat-recruitment GTPases Participate in Coat Disassembly

As with clathrin-coated vesicles at the plasma membrane, other types of coats must also disassemble once the transport vesicle has budded off the originating compartment. Without coat disassembly, the vesicle membrane could not fuse with that of its target compartment, and coated vesicles would permanently accumulate in the cell with no place to go. Budding vesicles therefore incorporate proteins that initiate coat disassembly only after the vesicle has fully formed. This critical switch from coat formation to coat disassembly is triggered by coat-recruitment GTPases. The hydrolysis of bound GTP to GDP causes the GTPase to change its conformation so that its hydrophobic tail pops out of the membrane, causing the vesicle's coat to disassemble. Thus, the rate at which coat-recruitment GTPases hydrolyze GTP determines the length of time their associated coats stay assembled.

COPII coats accelerate GTP hydrolysis by Sar1, and a fully formed vesicle will be produced only when bud formation occurs faster than the timed disassembly

MBOC7_ptr_ch13_749-810.indd 758 08/12/21 11:39 AM

process; otherwise, disassembly will be triggered before a vesicle pinches off, and the process will have to start again, perhaps at a more appropriate time and place. Once a vesicle pinches off, GTP hydrolysis releases Sar1, but the sealed coat is sufficiently stabilized through many cooperative interactions, including binding to the cargo receptors in the membrane, that it may stay on the vesicle until the vesicle arrives at a target membrane. There, a kinase phosphorylates the coat proteins, which completes coat disassembly and readies the vesicle for fusion.

Clathrin-coated and COPI-coated vesicles, by contrast, shed their coat soon after they pinch off. For **COPI-coated vesicles**, the curvature of the vesicle membrane serves as a trigger to begin uncoating. An ARF GAP that is recruited to the COPI coat as it assembles senses the lipid packing density. When the curvature of the membrane approaches that of a transport vesicle, the ARF GAP is activated. It then stimulates ARF to hydrolyze its GTP, causing the coat to disassemble.

The Shape and Size of Transport Vesicles Are Diverse

The types of cargoes that need to be transported through the cell are diverse in size, shape, and topology. Transport vesicles can similarly be diverse in their morphology to accommodate the cargoes they carry. Collagen, for example, is assembled in the ER as 300-nm-long, stiff procollagen rods that then are secreted from the cell where they are eventually embedded into the extracellular matrix (discussed in Chapter 19). Procollagen rods do not fit into the 60- to 80-nm-diameter COPII vesicles that normally carry smaller cargoes. To circumvent this problem, the procollagen cargo molecules bind to transmembrane *packaging proteins* in the ER, which control the assembly of the COPII coat components (Figure 13–16). These events are thought to drive the local assembly of much larger COPII vesicles that accommodate the oversized cargo. Human mutations in genes encoding such packaging proteins result in collagen defects with severe consequences, such as skeletal abnormalities and other developmental defects. Similar mechanisms must regulate the sizes of vesicles required to secrete other large macromolecular complexes, including the lipoprotein particles that transport lipids out of cells.

Another variation on small spherical transport vesicles is thin membrane tubules. Tubules have a higher surface-to-volume ratio than vesicles or the larger organelles from which they form. They are therefore relatively enriched in membrane proteins compared with soluble cargo proteins. As we discuss later, this property of tubules is an important feature for sorting proteins in endosomes. The retromer coat, which is specialized for transporting membrane proteins from endosomes to the Golgi apparatus, preferentially drives the formation of tubular transport vesicles (Figure 13–4).

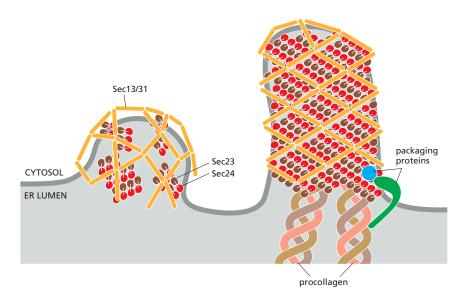

Figure 13–16 Packaging of procollagen into large tubular COPII-coated vesicles.

The diagrams show models for two COPII coat assembly modes. The models are based on cryo-electron tomography images of reconstituted COPII vesicles. On a spherical membrane (left), the Sec23/24 inner COPII coat proteins assemble in patches that anchor the Sec13/31 outer coat COPII protein cage. The Sec13/31 rods assemble a cage of triangles, squares, and pentagons. When procollagen needs to be packaged (right), special packaging proteins sense the cargo and modify the coat assembly process. This interaction recruits the COPII inner coat protein Sec24 and locally enhances the rate with which Sar1 cycles on and off the membrane (not shown). In addition, a monoubiquitin (not shown) is added to the Sec31 protein. changing the assembly properties of the outer cage. Sec23/24 proteins arrange in larger arrays, and Sec13/31 proteins arrange in a regular lattice of diamond shapes. As a result, a large tubular vesicle is formed that can accommodate the large cargo molecules. The packaging proteins are not part of the budding vesicle but remain in the ER. (Modified from G. Zanetti et al., eLife 2:e00951, 2013. With permission from the authors.)

MBOC7_ptr_ch13_749-810.indd 759 08/12/21 11:39 AM

Rab Proteins Guide Transport Vesicles to Their Target Membrane

To ensure an orderly flow of vesicle traffic, transport vesicles must be highly accurate in recognizing the correct target membrane with which to fuse. Because of the diversity and crowding of membrane systems in the cytoplasm, a vesicle is likely to encounter many potential target membranes before it finds the correct one. Specificity in targeting is ensured because all transport vesicles display surface markers that identify them according to their origin and type of cargo, and target membranes display complementary receptors that recognize the appropriate markers. Two types of markers act sequentially to ensure the specificity of vesicle targeting. First, *Rab proteins* direct the vesicle to specific spots on the correct target membrane. Second, *SNARE proteins* enable the fusion of the lipid bilayers.

Like the coat-recruitment GTPases discussed earlier (see Figure 13–15), Rab proteins are also monomeric GTPases. With more than 60 known members in mammalian cells, the Rab subfamily is the largest of the monomeric GTPase subfamilies. Each Rab protein is associated with one or more membrane-enclosed organelles of the secretory or endocytic pathway, and each of these organelles has at least one Rab protein on its cytosolic surface (Table 13–1). Different Rab proteins are also found on the different types of transport vesicles that ferry cargoes between organelles. Their selective distribution on these membrane systems makes Rab proteins ideal molecular markers for identifying each type of transport vesicle and target membrane in order to guide vesicle traffic.

Rab proteins cycle between a membrane and the cytosol and regulate the reversible assembly of protein complexes on the membrane. In their GDP-bound state, they are inactive and bound to another protein (*GDP dissociation inhibitor*, or *GDI*) that keeps them soluble in the cytosol. Membrane-bound Rab GEFs activate Rab proteins by catalyzing the exchange of GDP for GTP. Once in the GTP-bound state, the Rab protein's lipid anchor inserts into the membrane where the Rab binds to a diverse set of proteins called **Rab effectors** (**Figure 13–17**). The rate of GTP hydrolysis sets the concentration of active Rab and, consequently, the concentration of its effectors on the membrane.

A Rab protein is activated on a transport vesicle when a specific component of the vesicle, often a coat component, recruits a Rab GEF. Rab protein activation has several consequences. First, the Rab protein itself serves as a specific molecular cue that can be recognized by *tethering proteins* localized at the target membrane. Tethering proteins are typically protein complexes that often contain threadlike domains that serve as "fishing lines" capable of capturing a vesicle up to 200 nm away. Second, the Rab protein can interact with *motor proteins*, common Rab effectors that propel vesicles along actin filaments or microtubules to their target membrane. Third, the Rab protein can recruit a Rab effector that selectively binds proteins on the target membrane, such as the SNARE proteins located there.

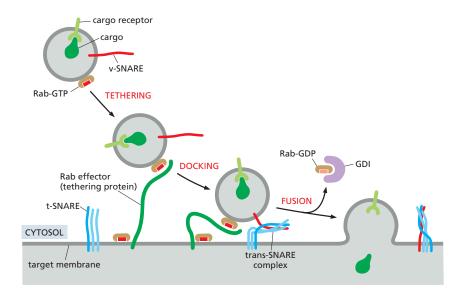

Figure 13-17 Tethering of a transport vesicle to a target membrane. Rab effector proteins interact with active Rab proteins (Rab-GTPs, brown) located on the target membrane, vesicle membrane. or both, to establish the first connection between the two membranes that are going to fuse. In the example shown here, the Rab effector is a filamentous tethering protein (dark green). Next, SNARE proteins on the two membranes (red and blue) pair. docking the vesicle to the target membrane and catalyzing the fusion of the two apposed lipid bilayers. During docking and fusion, a Rab GAP (not shown) induces the Rab protein to hydrolyze its bound GTP to GDP, causing the Rab to dissociate from the membrane and return to the cytosol as Rab-GDP, where it is bound by a GDP dissociation inhibitor (GDI) protein that keeps the Rab soluble and inactive.

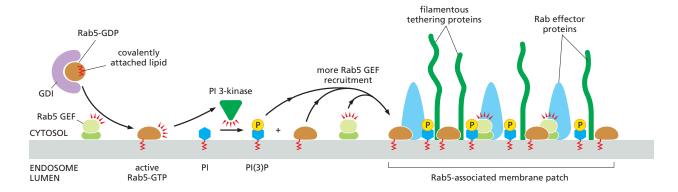

Through one or more of these mechanisms, a Rab protein selectively activated on a transport vesicle guides and docks it at the correct target membrane. Some Rab proteins, such as Rab7 discussed earlier, also function as coat-recruitment GTPases that initiate new budding events as organelles mature, as we discuss next.

Rab Proteins Create and Change the Identity of an Organelle

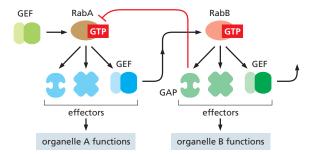

In addition to acting on vesicles, Rab proteins also function on organelle membranes. As on vesicles, a specific Rab GEF at the organelle catalyzes Rab protein activation and insertion at the membrane surface. Many of the effector proteins recruited by an activated Rab protein help give the organelle its identity by directly controlling incoming and outgoing transport vesicles. These effectors include tethering proteins mentioned previously, SNAREs that mediate membrane fusion of incoming vesicles, and enzymes that generate or modify specific phosphoinositides.

The assembly of Rab proteins and their effectors on an organelle membrane can be cooperative and results in the formation of large, specialized membrane patches that define the identity of that organelle. Active Rab5 on the endosome membrane, for example, recruits more copies of the same Rab5 GEF that initially activated Rab5. This stimulates the recruitment of more Rab5 to the same site. At the same time, active Rab5 activates a PI 3-kinase, which locally converts PI to PI(3)P, which in turn binds some of the Rab effectors including tethering proteins and stabilizes their local membrane attachment (Figure 13–18). This type of positive feedback greatly amplifies the assembly process and helps to establish functionally distinct membrane domains within a continuous organelle membrane.

Figure 13–18 The formation of a Rab5associated patch on the endosome membrane. A Rab5 GEF on the endosome membrane binds a Rab5 protein and induces it to exchange GDP for GTP. GDI is lost, and GTP binding alters the conformation of the Rab protein to expose a covalently attached lipid group, which anchors the Rab5-GTP to the membrane. Active Rab5 activates PI 3-kinase, which converts PI into PI(3)P. PI(3)P and active Rab5 together bind a variety of Rab effector proteins that contain PI(3)P-binding sites, including filamentous tethering proteins that catch incoming clathrin-coated endocytic vesicles from the plasma membrane. With the help of another effector, active Rab5 also recruits more Rab5 GEF, further enhancing the assembly of the Rab5-associated patch on the membrane. Controlled cycles of GTP hydrolysis and GDP-GTP exchange dynamically regulate the size and activity of such Rab-associated membrane patches. Unlike SNAREs, which are integral membrane proteins, the GDP-GTP cycle, coupled to the membranecytosol translocation cycle, endows the Rab machinery with the ability to undergo assembly and disassembly on the membrane. (Adapted from M. Zerial and H. McBride Nat. Rev. Mol. Cell Biol. 2:107-117, 2001.)

MBOC7_ptr_ch13_749-810.indd 761 08/12/21 11:39 AM

It is thought that different Rab proteins and their effectors help to create multiple specialized membrane domains, each fulfilling a particular set of functions. Thus, while the Rab5-associated membrane patch receives incoming endocytic vesicles from the plasma membrane, distinct Rab11- and Rab4-associated patches in the same endosome organize the budding of recycling vesicles that return proteins from the endosome to the plasma membrane. As we have already discussed, Rab7 on the endosome membrane serves as a coat-recruitment GTPase for retromer, initiating the formation of transport vesicles destined for the Golgi.

One Rab protein can be replaced by a different Rab protein, and this can change the identity of its associated organelle. This is accomplished by one Rab protein selectively recruiting and activating a different Rab protein whose complement of effectors includes proteins that inactivate the first Rab protein and thereby disassemble its associated membrane patch. Such ordered recruitment of sequentially acting Rab proteins is called a Rab cascade (Figure 13-19). Over time, for example, Rab5-associated membrane patches are replaced by Rab7associated membrane patches on endosomal membranes. This converts an early endosome, marked by Rab5, into a late endosome, marked by Rab7. Because the set of Rab effectors recruited by Rab7 is different from that recruited by Rab5, this change reprograms the compartment including the incoming and outgoing traffic and repositions the organelle away from the plasma membrane toward the cell interior. All of the cargo contained in the early endosome that has not been recycled to the plasma membrane is now part of a late endosome. This process is also referred to as endosome maturation. The self-amplifying nature of the Rab-associated membrane patches renders the process of endosome maturation unidirectional and irreversible.

SNAREs Mediate Membrane Fusion

Once a transport vesicle has budded from its originating compartment and shed its coat, membrane fusion allows it to unload its cargo at its destination compartment. Membrane fusion requires bringing the lipid bilayers of two membranes to within 1.5 nm of each other so that they can merge. When the membranes are in such close proximity, lipids can flow from one bilayer to the other. For this close approach, water must be displaced from the hydrophilic surface of the membrane—a process that is highly energetically unfavorable and requires specialized *fusion proteins* that overcome this energy barrier. We have already discussed the role of dynamin in the related task of squeezing membranes close together during the pinching off of clathrin-coated vesicles (see Figure 13–14).

The SNARE proteins (also called SNAREs, for short) catalyze the membrane fusion reactions in vesicle transport. There are at least 35 different SNAREs in an animal cell, each associated with a particular organelle in the secretory or endocytic pathway. These transmembrane proteins exist as complementary sets, with v-SNAREs usually found on vesicle membranes and t-SNAREs usually found on target membranes (see Figure 13–17). A v-SNARE is a single polypeptide chain, whereas a t-SNARE is usually composed of three proteins. The v-SNAREs and t-SNAREs have characteristic helical domains that are mostly unstructured in isolation. When a v-SNARE interacts with a t-SNARE, the helical domains of one zipper up with the helical domains of the other to form a very stable four-helix

Figure 13-19 A model for a generic Rab cascade. The local activation of a RabA GEF leads to assembly of a RabAassociated membrane patch (sometimes called a "Rab domain") on the membrane. Active RabA recruits its effector proteins, one of which is a GEF for RabB. The RabB GEF then recruits RabB to the membrane, which in turn begins to recruit its effectors, among them a GAP for RabA. The RabA GAP activates RabA GTP hydrolysis leading to the inactivation of the RabA and the disassembly of the RabA-associated membrane patch as the RabB-associated membrane patch grows. In this way, the RabA-associated membrane patch is irreversibly replaced by the RabB-associated membrane patch. In principle, this sequence can be continued by the recruitment of a next GEF by RabB. (Adapted from A.H. Hutagalung and P.J. Novick, Physiol. Rev. 91:119-149, 2011.)

MBOC7_ptr_ch13_749-810.indd 762 08/12/21 11:39 AM

Figure 13–20 A model for how SNARE proteins catalyze membrane fusion. Bilayer fusion occurs in multiple steps. A tight pairing between v- and t-SNAREs forces lipid bilayers into close apposition and expels water molecules from the interface. Lipid molecules in the two interacting (cytosolic) leaflets of the bilayers then flow between the membranes to form a connecting stalk. Lipids of the two noncytosolic leaflets then contact each other, forming a new bilayer, which widens the fusion zone (hemifusion, or half-fusion). Rupture of the new bilayer completes the fusion reaction.

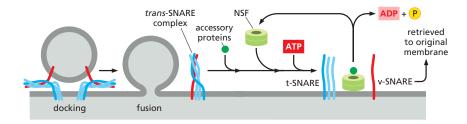

bundle. The resulting *trans-SNARE complex* locks the two membranes together. Biochemical membrane fusion assays with all different SNARE combinations show that v- and t-SNARE pairing is highly specific. The SNAREs thus provide an additional layer of specificity in the transport process by helping to ensure that vesicles fuse only with their correct target membrane.

The extremely high stability of the trans-SNARE complex means that its assembly from initially unstructured v- and t-SNAREs is energetically favorable. This energy is exploited to pull the membrane faces together, simultaneously squeezing out water molecules from the interface to initiate lipid bilayer fusion (Figure 13–20). When liposomes containing purified v-SNAREs are mixed with liposomes containing complementary t-SNAREs, their membranes fuse, albeit slowly. In the cell, fusion is greatly accelerated by factors that interact with v-SNARE and t-SNARE pairs to align them precisely so they can initiate zippering. Fusion does not always follow immediately after v-SNAREs and t-SNAREs pair. As we discuss later, in the process of regulated exocytosis, zippering of the last part of the trans-SNARE complex is delayed until secretion is triggered by a specific extracellular signal.

Interacting SNAREs Need to Be Pried Apart Before They Can Function Again

After SNARE proteins have participated in membrane fusion, the highly stable trans-SNARE complexes have to disassemble before the SNAREs can mediate new rounds of transport. A crucial protein called NSF cycles between membranes and the cytosol and catalyzes the disassembly process. NSF is a hexameric ATPase of the family of AAA-proteins (see Figure 6–88) that uses the energy of ATP hydrolysis to unravel the intimate interactions between the helical domains of paired SNARE proteins (Figure 13–21). After disassembly, the SNARE proteins can again exploit the energy gained by their assembly to drive another fusion reaction. Thus, the energy for SNARE-mediated fusion reactions ultimately comes from the ATP consumed by NSF to pry them apart. After trans-SNARE complex disassembly at the destination compartment, v-SNAREs are selectively retrieved and returned to their compartment of origin so that they can be reused in newly formed transport vesicles. Such selective retrieval pathways (discussed later) are critical for maintaining the identity of each compartment in the face of constant outgoing traffic.

Membrane fusion is important in other processes besides vesicle transport. The plasma membranes of a sperm and an egg fuse during fertilization, myoblasts fuse with one another during the development of multinucleate muscle fibers (discussed in Chapter 22), and the epithelial cells in the human placenta fuse into a giant syncytium that separates the mother from the fetus. Likewise, the ER network and mitochondria fuse and fragment in a dynamic way (discussed in Chapters 12 and 14). All cell membrane fusions require special proteins and are tightly regulated to ensure that only appropriate membranes fuse. The controls

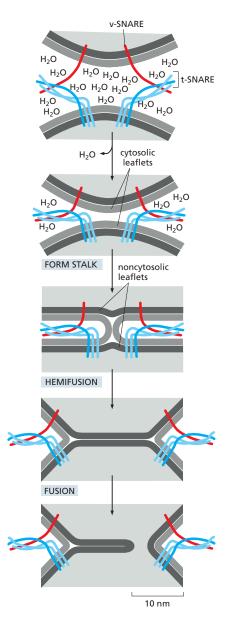

Figure 13–21 Dissociation of SNARE pairs by NSF after a membrane fusion cycle. After a v-SNARE and t-SNARE have effected the fusion of a transport vesicle with a target membrane, NSF binds to the SNARE complex and, with the help of accessory proteins, hydrolyzes ATP to pry the SNAREs apart.

MBOC7_ptr_ch13_749-810.indd 763 08/12/21 11:39 AM

are crucial for maintaining both the identity of cells and the individuality of each type of intracellular compartment.

Viruses Encode Specialized Membrane Fusion Proteins Needed for Cell Entry

Enveloped viruses, which have a lipid bilayer-based membrane coat, enter the cells that they infect when the viral membrane fuses with a cell's membrane (discussed in Chapters 5 and 23). For example, viruses such as the human immunodeficiency virus (HIV), which causes AIDS, bind to cell-surface receptors and then fuse with the plasma membrane of the target cell (Figure 13–22). This fusion event allows the viral nucleic acid inside the nucleocapsid to enter the cytosol, where it replicates. Other viruses, such as the influenza virus, first enter the cell by receptor-mediated endocytosis (discussed later) and are delivered to endosomes; the low pH in endosomes activates a fusion protein in the viral envelope that catalyzes the fusion of the viral and endosomal membranes, releasing the viral nucleic acid into the cytosol. In the case of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), which causes COVID-19, the fusion reaction requires host proteases that cleave the virus surface protein to activate its fusion activity.

The membrane fusion reactions catalyzed by viral fusion proteins are well understood. Unlike SNARE-mediated fusion, which involves proteins in both membranes, viral fusion typically requires only the viral protein. These viral fusion proteins unfurl in the appropriate environment and insert a partially hydrophobic patch into the host membrane. The fusion protein then undergoes compaction to bring the two membranes close together to drive their fusion in a reaction analogous to SNARE-mediated fusion.

Summary

Directed and selective transport of particular membrane components from one membrane-enclosed compartment to another in a eukaryotic cell maintains the differences between those compartments. Transport vesicles, which can be spherical, tubular, or irregularly shaped, bud from specialized coated regions of the donor membrane. The assembly of the coat helps to collect specific membrane and soluble cargo molecules for transport and to drive the formation of the vesicle.

There are various types of coated vesicles. Clathrin-coated vesicles mediate transport from the plasma membrane, endosomes, and the trans Golgi network. COPI-coated and COPII-coated vesicles mediate transport between Golgi cisternae and between the ER and the Golgi apparatus. Retromer forms a coat at the endosome membrane for transport to the Golgi. Coats have a common two-layered structure: an inner layer formed of adaptor proteins traps specific cargo molecules for packaging into the vesicle and an outer layer that forms a cage and helps deform the membrane into a vesicle. The coat is shed before the vesicle fuses with its appropriate target membrane.

The specificity of membrane transport is mediated by several types of molecular markers that determine where transport vesicles originate and where they deliver their cargo. Local synthesis of specific phosphoinositides creates binding sites that trigger clathrin coat assembly and vesicle budding. In addition, the coat-recruitment GTPases, including Sar1 and the ARF proteins, regulate coat assembly and disassembly. Rab proteins are a large family of GTPases that function on both transport vesicles and target membranes to control the specificity of membrane transport. Active Rab proteins recruit Rab effectors, such as motor proteins, which transport vesicles along actin filaments or microtubules, and filamentous tethering proteins, which help ensure that the vesicles deliver their contents only to the appropriate target membrane. Specialized membrane domains that help determine an organelle's identity can be generated and changed in a dynamic manner by the assembly and disassembly of Rab proteins and their effectors. Complementary v-SNARE proteins on transport vesicles and t-SNARE proteins on the target membrane form stable trans-SNARE complexes,

which force the two membranes into close apposition so that their lipid bilayers can fuse.

TRANSPORT FROM THE ENDOPLASMIC RETICULUM THROUGH THE GOLGI APPARATUS

As discussed in Chapter 12, newly synthesized proteins cross the endoplasmic reticulum (ER) membrane from the cytosol to enter the secretory pathway. These proteins are successively modified as they pass through a series of compartments from the ER to the Golgi apparatus and from the Golgi apparatus to the cell surface and elsewhere. Transfer from one compartment to the next involves a delicate balance between forward and backward (retrieval) transport pathways. Some transport vesicles select cargo molecules and move them to the next compartment in the pathway, while others retrieve escaped proteins and return them to a previous compartment where they normally function. Thus, the pathway from the ER to the cell surface consists of many sorting steps, which continually select membrane and soluble lumenal proteins for packaging and transport.

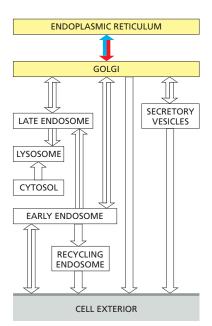

In this section, we focus mainly on the **Golgi apparatus** (also called the Golgi complex). It is a major site of carbohydrate synthesis, as well as a sorting and dispatching station for products delivered to it from the ER. The cell makes many polysaccharides in the Golgi apparatus, including the pectin and hemicellulose of the cell wall in plants and most of the glycosaminoglycans of the extracellular matrix in animals (discussed in Chapter 19). The Golgi apparatus also builds and attaches oligosaccharide chains to the many proteins and lipids that the ER sends to it. Some of these oligosaccharides serve as tags to direct specific proteins carrying them into vesicles that are then transported to endosomes for eventual delivery to lysosomes. But most proteins and lipids, once they have acquired their appropriate oligosaccharides in the Golgi apparatus, are recognized in other ways for targeting into the transport vesicles going to the cell surface and other destinations.

Proteins Leave the ER in COPII-coated Transport Vesicles

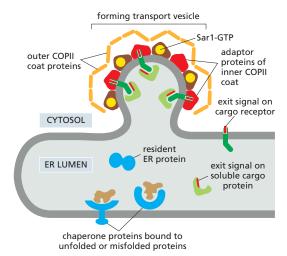

To initiate their journey along the secretory pathway, proteins that have entered the ER and are destined for the Golgi apparatus or beyond are first packaged into COPII-coated transport vesicles. These vesicles bud from specialized regions of the ER called *ER exit sites*, whose membrane lacks bound ribosomes. Most animal cells have ER exit sites dispersed throughout the ER network.

Entry into vesicles that leave the ER can be a selective process or can happen by default. Many transmembrane proteins are actively recruited into such vesicles, where they become concentrated. These transmembrane proteins display exit (transport) signals on their cytosolic surface that adaptor proteins of the inner COPII coat recognize (Figure 13-23). Soluble cargo proteins in the ER lumen have exit signals that are recognized by some of these transmembrane proteins, which serve as cargo receptors. These receptors are recycled back to the ER after they have delivered their cargo to the Golgi apparatus. Proteins without exit signals can also enter transport vesicles, including protein molecules that normally function in the ER (so-called *ER resident proteins*). These resident proteins slowly leak out of the ER and need retrieval pathways to bring them back from the Golgi apparatus. Different cargo proteins enter the transport vesicles with substantially different rates and efficiencies. These differences can be due to their folding and oligomerization efficiencies and kinetics, as well as their different capacities to engage cargo receptors and the COPII coat. The exit step from the ER is a major checkpoint at which quality control is exerted on the proteins that a cell secretes or displays on its surface, as we discussed in Chapter 12.

The exit signals that direct soluble proteins out of the ER for transport to the Golgi apparatus and beyond are not well understood. Some transmembrane proteins that serve as cargo receptors for packaging some secretory proteins into COPII-coated vesicles are lectins that bind to oligosaccharides on the secreted

MBOC7_ptr_ch13_749-810.indd 765 08/12/21 11:39 AM

proteins. One such lectin, for example, binds to mannose on two secreted blood-clotting factors (Factor V and Factor VIII), thereby packaging the proteins into transport vesicles in the ER; its role in protein transport was identified because humans who lack it owing to an inherited mutation have lowered serum levels of Factors V and VIII, and they therefore bleed excessively.

Only Proteins That Are Properly Folded and Assembled Can Leave the ER

To exit from the ER, proteins must be properly folded, and, if they are subunits of multiprotein complexes, they need to be completely assembled. Those that are misfolded or incompletely assembled transiently remain in the ER, where they are bound to chaperone proteins (discussed in Chapter 6) such as *BiP* or *calnexin*. The chaperones may cover up the exit signals or somehow anchor the proteins in the ER. Such failed proteins are eventually transported back into the cytosol, where they are degraded by proteasomes (discussed in Chapters 6 and 12). This quality-control step prevents the onward transport of misfolded or misassembled proteins that could potentially interfere with the functions of normal proteins. Such failures are surprisingly common. Most of the newly synthesized subunits of the T cell receptor (discussed in Chapter 24) and of the acetylcholine receptor (discussed in Chapter 11), for example, are normally degraded without ever reaching the cell surface where they function. Thus, cells must make a large excess of some protein molecules to produce a select few that fold, assemble, and function properly.

Sometimes, however, there are drawbacks to the stringent quality-control mechanism. The predominant mutations that cause cystic fibrosis, a common inherited disease, result in the production of a slightly misfolded form of a plasma membrane protein important for Cl⁻ transport. Although the mutant protein would function almost normally if it reached the plasma membrane, it is retained in the ER and then is degraded by cytosolic proteasomes. This devastating disease thus results not because the mutation inactivates the protein but because potentially active protein is discarded before it reaches the plasma membrane.

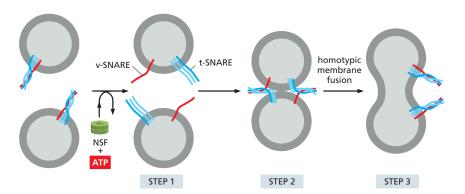

Vesicular Tubular Clusters Mediate Transport from the ER to the Golgi Apparatus

After transport vesicles have budded from ER exit sites and have shed their coat, they begin to fuse with one another. The fusion of membranes from the same compartment is called *homotypic fusion*, to distinguish it from *heterotypic fusion*, in which a membrane from one compartment fuses with the membrane of a different compartment. As with heterotypic fusion, homotypic fusion requires a set

Figure 13–23 The recruitment of membrane and soluble cargo molecules into ER transport vesicles.

Transmembrane proteins are packaged into budding transport vesicles through interactions of exit signals on their cytosolic tails with adaptor proteins of the inner COPII coat. Some of these transmembrane proteins function as cargo receptors, binding soluble proteins in the ER lumen and helping to package them into vesicles. Other proteins may enter the vesicle by bulk flow. A typical 50-nm transport vesicle contains about 200 transmembrane proteins, which can be of many different types. As indicated, unfolded or incompletely assembled proteins are bound to chaperones and transiently retained in the ER compartment.

MBOC7_ptr_ch13_749-810.indd 766 08/12/21 11:39 AM

of matching SNAREs. In this case, however, the interaction is symmetrical, with both membranes contributing v-SNAREs and t-SNAREs (Figure 13–24).

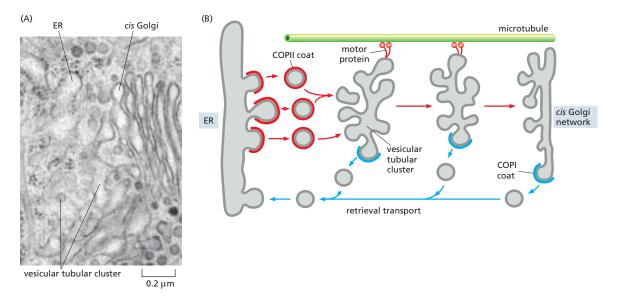

The structures formed when ER-derived vesicles fuse with one another are called *vesicular tubular clusters*, because they have a convoluted appearance in the electron microscope (Figure 13–25A). These clusters constitute a compartment that is separate from the ER and lacks many of the proteins that function in the ER. They are generated continually and function as transport containers that bring material from the ER to the Golgi apparatus. The clusters move quickly along microtubules to the Golgi apparatus with which they fuse (Figure 13–25B and Movie 13.3).

As soon as vesicular tubular clusters form, they begin to bud off transport vesicles of their own. Unlike the COPII-coated vesicles that bud from the ER, these vesicles are COPI-coated (see Figure 13–25B). COPI-coated vesicles are unique in that the components that make up the inner and outer coat layers are recruited as a preassembled complex, called *coatomer*. They function as a *retrieval pathway*, carrying back ER resident proteins that have escaped, as well as proteins such as cargo receptors and SNAREs that participated in the ER budding and vesicle fusion reactions. This retrieval process demonstrates the exquisite control mechanisms that regulate coat assembly reactions. The COPI coat assembly begins only seconds after the COPII coats have been shed; it remains a mystery how this switch in coat assembly is controlled.

The retrieval (or retrograde) transport continues as the vesicular tubular clusters move toward the Golgi apparatus. Thus, the clusters continually mature, gradually changing their composition as selected proteins are returned to the ER.

Figure 13-24 Homotypic membrane fusion. In step 1, NSF pries apart identical pairs of v-SNAREs and t-SNAREs in both membranes (see Figure 13-21). In steps 2 and 3, the separated matching SNAREs on adjacent identical membranes interact, which leads to membrane fusion and the formation of one continuous compartment. Subsequently, the compartment grows by further homotypic fusion with vesicles from the same kind of membrane displaying matching SNAREs. Homotypic fusion occurs when ER-derived transport vesicles fuse with one another, but also when endosomes fuse to generate larger endosomes. Rab proteins help regulate the extent of homotypic fusion and hence the size of a cell's compartments (not shown).

Figure 13-25 Vesicular tubular clusters. (A) An electron micrograph of vesicular tubular clusters forming around an exit site. Many of the vesicle-like structures seen in the micrograph are cross sections of tubules that extend above and below the plane of this thin section and are interconnected. (B) Vesicular tubular clusters move along microtubules to carry proteins from the ER to the Golgi apparatus. COPI coats mediate the budding of vesicles that return to the ER from these clusters (and from the Golgi apparatus). (A, courtesy of Judith Klumperman, from J.A. Martínez-Menárguez et al., Cell 98:81-90, 1999.)

MBOC7_ptr_ch13_749-810.indd 767 08/12/21 11:39 AM

The retrieval continues from the Golgi apparatus, after the vesicular tubular clusters have delivered their cargo.

The Retrieval Pathway to the ER Uses Sorting Signals

The retrieval pathway for returning escaped proteins back to the ER depends on *ER retrieval signals*. Resident ER membrane proteins, for example, contain signals that bind directly to COPI coats and are thus packaged into COPI-coated transport vesicles for retrograde delivery to the ER. The best-characterized retrieval signal of this type consists of two lysines, followed by any two other amino acids, at the extreme C-terminal end of the ER membrane protein. It is called a *KKXX sequence*, based on the single-letter amino acid code. Most membrane proteins that function at the interface between the ER and Golgi apparatus, including v- and t-SNAREs and some cargo receptors, use this retrieval pathway to come back to the ER.

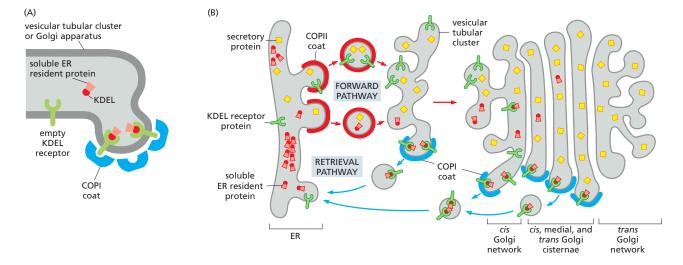

Soluble ER resident proteins, such as BiP, also contain a short ER retrieval signal at their C-terminal end, but it is different: it consists of a Lys-Asp-Glu-Leu or a similar sequence. If this signal (called the *KDEL sequence*) is removed from BiP by genetic engineering, the protein is slowly secreted from the cell. If the signal is transferred to a protein that is normally secreted, the protein is now efficiently returned to the ER, where it accumulates. Unlike the retrieval signals on ER membrane proteins, which can interact directly with the COPI coat, soluble ER resident proteins must bind to specialized receptor proteins such as the *KDEL receptor*—a multipass transmembrane protein that binds to the KDEL sequence and packages any protein displaying it into COPI-coated retrograde transport vesicles (Figure 13–26).

The KDEL receptor accomplishes this task by cycling between the ER and the Golgi apparatus, selectively binding proteins with the KDEL sequence in the Golgi apparatus and releasing them in the ER. The markedly different affinity between the receptor and the KDEL sequence in these two compartments is due to the lower pH in the Golgi apparatus, which is regulated by $\rm H^+$ pumps. A critical histidine in the KDEL receptor is protonated in the lower-pH environment of the Golgi apparatus, strongly favoring its interaction with the KDEL sequence. As we discuss later, pH-sensitive protein–protein interactions form the basis for many of the protein-sorting steps in the cell.

Many Proteins Are Selectively Retained in the Compartments in Which They Function

The KDEL retrieval pathway only partly explains how ER resident proteins are maintained in the ER. As mentioned, cells that express genetically modified ER resident proteins, from which the KDEL sequence has been experimentally removed, secrete these proteins. But the rate of secretion is much slower than that

Figure 13-26 Retrieval of soluble ER resident proteins. ER resident proteins that escape from the ER are returned by vesicle transport. (A) The KDEL receptor present in both vesicular tubular clusters and the Golgi apparatus captures the soluble ER resident proteins and carries them in COPI-coated transport vesicles back to the ER. (Recall that the COPIcoated vesicles shed their coats as soon as they are formed.) Upon binding its ligands in the tubular cluster or Golgi apparatus, the KDEL receptor may change conformation, so as to facilitate its recruitment into budding COPI-coated vesicles. (B) The retrieval of ER proteins begins in vesicular tubular clusters and continues in later parts of the Golgi apparatus. In the environment of the ER, the ER resident proteins dissociate from the KDEL receptor, which is then returned to the Golgi apparatus for reuse. We discuss the different compartments of the Goldi apparatus shortly.

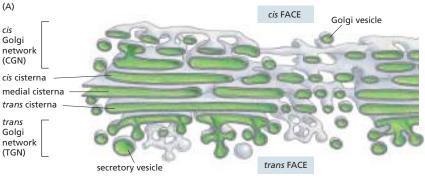

MBOC7_ptr_ch13_749-810.indd 768 08/12/21 11:39 AM

for a normal secretory protein. It seems that a mechanism that is independent of their KDEL signal normally retains ER resident proteins and that only those proteins that escape this retention mechanism are captured and returned via the KDEL receptor.

A suggested retention mechanism is that ER resident proteins bind to one another, thus forming complexes that are too big to enter transport vesicles efficiently. Because ER resident proteins are present in the ER at very high concentrations (estimated to be millimolar), relatively low-affinity interactions would suffice to retain most of the proteins in such complexes. Aggregation of proteins that function in the same compartment is a general mechanism that compartments use to organize and retain their resident proteins. Golgi enzymes that function together, for example, also bind to each other and are thereby restrained from entering transport vesicles leaving the Golgi apparatus.

The Golgi Apparatus Consists of an Ordered Series of Compartments

Because it could be selectively visualized by silver stains, the Golgi apparatus was one of the first organelles described by early light microscopists. It consists of a collection of flattened, membrane-enclosed compartments called *cisternae*, that somewhat resemble a stack of pita breads. Each Golgi stack typically consists of four to six cisternae (Figure 13–27), although some unicellular flagellates can have more than 20. In animal cells, tubular connections between corresponding cisternae link many stacks, thus forming a single complex, which is usually located near the cell nucleus and close to the centrosome (Figure 13–28A). This localization depends on microtubules. If microtubules are experimentally depolymerized, the Golgi apparatus reorganizes into individual stacks that are found throughout the cytoplasm, adjacent to ER exit sites. Some cells, including most plant cells, have hundreds of individual Golgi stacks

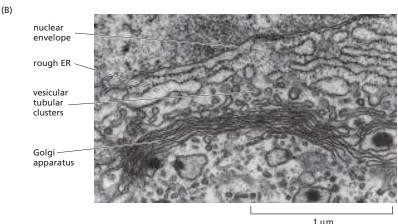

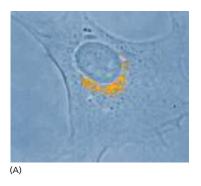

Figure 13–27 The Golgi apparatus.

(A, courtesy of John Henley and Mark McNiven; B, courtesy of Chris Hawes.)

dispersed throughout the cytoplasm where they are typically found adjacent to ER exit sites (Figure 13-28B).

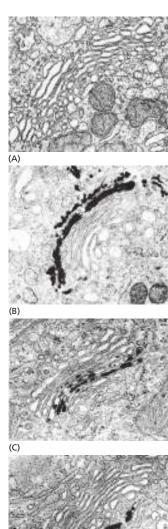

During their passage through the Golgi apparatus, many transported molecules undergo an ordered series of covalent modifications. Each Golgi stack has two distinct faces: a *cis* face (or entry face) and a *trans* face (or exit face). Both *cis* and *trans* faces are closely associated with special compartments, each composed of a network of interconnected tubular and cisternal structures: the *cis* Golgi network (CGN) and the *trans* Golgi network (TGN), respectively. The CGN is a collection of fused vesicular tubular clusters arriving from the ER. Proteins and lipids enter the *cis* Golgi network and exit from the *trans* Golgi network, bound for the cell surface or another compartment. Both networks are important for protein sorting: proteins entering the CGN can either move onward in the Golgi apparatus or be returned to the ER. Similarly, proteins exiting from the TGN move onward and are sorted according to their next destination: endosomes, secretory vesicles, or the cell surface. They also can be returned to an earlier compartment. Some membrane proteins are retained in the part of the Golgi apparatus where they function.

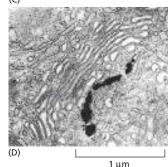

As described in Chapter 12, a single species of *N-linked oligosaccharide* is attached *en bloc* to many proteins in the ER and then trimmed while the protein is still in the ER. The oligosaccharide intermediates created by the trimming reactions serve to help proteins fold and to help transport misfolded proteins to the cytosol for degradation in proteasomes. Thus, they play an important role in controlling the quality of proteins exiting from the ER. Once these ER functions have been fulfilled, the cell reutilizes the oligosaccharides for new functions. This begins in the Golgi apparatus, which generates the heterogeneous oligosaccharide structures seen in mature proteins. After arrival in the CGN, proteins enter the first of the Golgi processing compartments (the *cis* Golgi cisterna). They then move to the next compartment (the medial cisterna) and finally to the *trans* cisterna, where glycosylation is completed. The lumen of the *trans* cisterna is thought to be continuous with the TGN, the place where proteins are segregated into different transport packages and dispatched to their next destinations.

The oligosaccharide-processing steps occur in an organized sequence in the Golgi apparatus, with each cisterna containing a characteristic mixture of processing enzymes. Proteins are modified in successive stages as they move from cisterna to cisterna across the stack, so that the stack forms a multistage processing unit.

Investigators discovered the functional differences between the cis, medial, and trans subdivisions of the Golgi apparatus by localizing the enzymes involved in processing N-linked oligosaccharides in distinct regions of the organelle, both by physical fractionation of the organelle and by labeling the enzymes in electron microscope sections with antibodies (Figure 13–29). The removal of mannose and

Figure 13–29 Molecular compartmentalization of the Golgi apparatus. A series of electron micrographs shows the Golgi apparatus (A) unstained, (B) stained with osmium, which preferentially labels the cisternae of the *cis* compartment, and (C and D) stained to reveal the location of specific enzymes. Nucleoside diphosphatase is found in the *trans* Golgi cisternae (C), while acid phosphatase is found in the *trans* Golgi network (D). Note that usually more than one cisterna is stained. The enzymes are therefore thought to be highly enriched rather than precisely localized to a specific cisterna. (Courtesy of Daniel S. Friend, by permission of E.L. Bearer.)

MBOC7_ptr_ch13_749-810.indd 770 08/12/21 11:39 AM

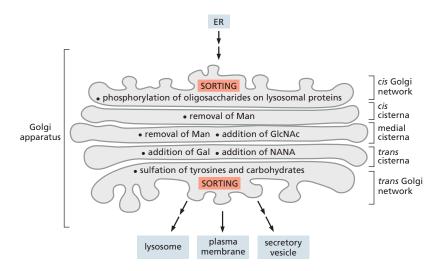

Figure 13–30 Oligosaccharide processing in Golgi compartments.

The localization of each processing step shown was determined by a combination of techniques, including biochemical subfractionation of the Golgi apparatus membranes and electron microscopy after staining with antibodies specific for some of the processing enzymes. Processing enzymes are not restricted to a particular cisterna; instead, their distribution is graded across the stack, such that early-acting enzymes are present mostly in the cis Golgi cisternae and later-acting enzymes are mostly in the trans Golgi cisternae. Man, mannose; GlcNAc, N-acetylglucosamine; Gal, galactose; NANA, N-acetylneuraminic acid (sialic acid).

the addition of *N*-acetylglucosamine, for example, occur in the *cis* and medial cisternae, while the addition of galactose and sialic acid occurs in the *trans* cisterna and *trans* Golgi network. **Figure 13–30** summarizes the functional compartmentalization of the Golgi apparatus.

Oligosaccharide Chains Are Processed in the Golgi Apparatus

Whereas the ER lumen is full of soluble resident proteins and enzymes, the resident proteins in the Golgi apparatus are all membrane bound. All of the Golgi glycosidases and glycosyl transferases, for example, are single-pass transmembrane proteins, many of which are organized in multienzyme complexes.

Two broad classes of N-linked oligosaccharides, the **complex oligosaccharides** and the **high-mannose oligosaccharides**, are attached to mammalian glycoproteins. Sometimes, both types are attached (in different places) to the same polypeptide chain. Complex oligosaccharides are generated when the original N-linked oligosaccharide added in the ER is trimmed and further sugars are added; by contrast, high-mannose oligosaccharides are trimmed but have no new sugars added to them in the Golgi apparatus (**Figure 13–31**). The sialic acids

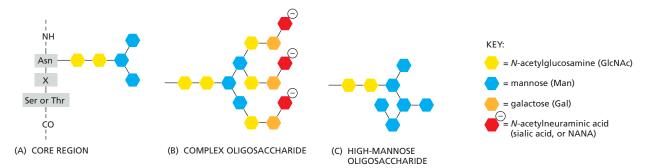

Figure 13–31 The two main classes of asparagine-linked (*N*-linked) oligosaccharides found in mature mammalian glycoproteins.

(A) Both complex oligosaccharides and high-mannose oligosaccharides share a common *core region* derived by trimming the original *N*-linked oligosaccharide added in the ER (see Figure 12–32) and typically containing two *N*-acetylglucosamines (GlcNAc) and three mannoses (Man). The three amino acids constitute the sequence recognized by the oligosaccharyl transferase enzyme that adds the initial oligosaccharide to the protein. Asn, asparagine; Ser, serine; Thr, threonine; X, any amino acid, except proline. (B) Each complex oligosaccharide consists of a *core region*, together with a *terminal region* that contains a variable number of copies of a special trisaccharide unit (*N*-acetylglucosamine–galactose–sialic acid) linked to the three core mannoses. Frequently, the terminal region is truncated and contains only GlcNAc and galactose (Gal) or just GlcNAc. In addition, a fucose may be added, usually to the core GlcNAc attached to the asparagine (Asn). Thus, although the steps of processing and subsequent sugar addition are rigidly ordered, complex oligosaccharides can be heterogeneous. Moreover, although the complex oligosaccharide shown has three terminal branches, two and four branches are also common, depending on the glycoprotein and the cell in which it is made (Movie 13.4). (C) Highmannose oligosaccharides are not trimmed back all the way to the core region and contain additional mannoses. Hybrid oligosaccharides with one Man branch and one GlcNAc and Gal branch are also found (not shown).

MBOC7_ptr_ch13_749-810.indd 771 08/12/21 11:39 AM

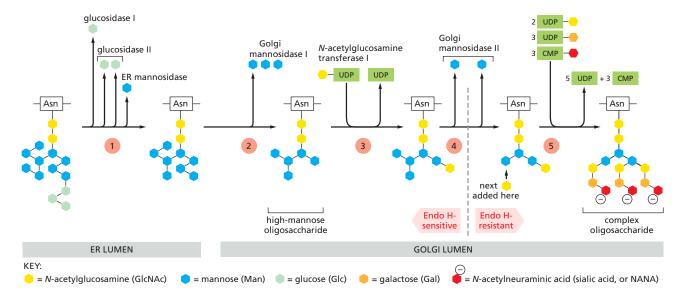

Figure 13–32 Oligosaccharide processing in the ER and the Golgi apparatus. The processing pathway is highly ordered, so that each step shown depends on the previous one. Step 1: Processing begins in the ER with the removal of the glucoses from the oligosaccharide initially transferred to the protein. Then a mannosidase in the ER membrane removes a specific mannose. The remaining steps occur in the Golgi stack. Step 2: Golgi mannosidase I removes three more mannoses. Step 3: N-acetylglucosamine transferase I then adds an N-acetylglucosamine. Step 4: Golgi mannosidase II then removes two additional mannoses. This yields the final core of three mannoses that is present in a complex oligosaccharide. At this stage, the bond between the two N-acetylglucosamines in the core becomes resistant to attack by a highly specific endoglycosidase (Endo H). Because all later structures in the pathway are also Endo H-resistant, treatment with this enzyme is widely used to distinguish complex from high-mannose oligosaccharides. Step 5: Finally, as shown in Figure 13–31, additional N-acetylglucosamines, galactoses, and sialic acids are added. These final steps in the synthesis of a complex oligosaccharide occur in the cisternal compartments of the Golgi apparatus: three types of glycosyl transferase enzymes act sequentially, using sugar substrates that have been activated by linkage to the indicated nucleotide; the membranes of the Golgi cisternae contain specific carrier proteins that allow each sugar nucleotide to enter in exchange for the nucleoside phosphates that are released after the sugar is attached to the protein on the lumenal face.

Note that, as a biosynthetic organelle, the Golgi apparatus differs from the ER: all sugars in the Golgi are assembled inside the lumen from sugar nucleotides, whereas in the ER, the *N*-linked precursor oligosaccharide is assembled partly in the cytosol and partly in the lumen, and most lumenal reactions use dolichol-linked sugars as their substrates (see Figure 12–33).

in the complex oligosaccharides are of special importance because they bear a negative charge. Whether a given oligosaccharide remains high-mannose or is processed depends largely on its position in the protein. If the oligosaccharide is accessible to the processing enzymes in the Golgi apparatus, it is likely to be converted to a complex form; if it is inaccessible because its sugars are tightly held to the protein's surface, it is likely to remain in a high-mannose form. The processing that generates complex oligosaccharide chains follows the highly ordered pathway shown in Figure 13–32.

Beyond these commonalities in oligosaccharide processing that are shared among most cells, the products of the carbohydrate modifications carried out in the Golgi apparatus are highly complex and have given rise to a field of study called glycobiology. The human genome, for example, encodes hundreds of different Golgi glycosyl transferases and many glycosidases. These enzymes are expressed differently from one cell type to another and at different times during development, resulting in a variety of glycosylated forms of a given protein or lipid in different cell types and at varying stages of differentiation. The complexity of modifications is not limited to *N*-linked oligosaccharides but also occurs on *O-linked sugars*, as we discuss next.

Proteoglycans Are Assembled in the Golgi Apparatus

In addition to the *N*-linked oligosaccharide alterations, many proteins are modified in the Golgi apparatus in other ways as they pass through the Golgi cisternae *en route* from the ER to their final destinations. Some proteins have sugars added

MBOC7_ptr_ch13_749-810.indd 772 08/12/21 11:39 AM

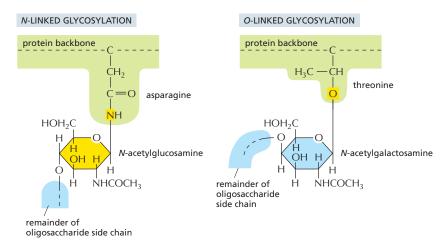

Figure 13–33 N- and O-linked glycosylation. In each case, only the single sugar group that is directly attached to the protein chain is shown.

to the hydroxyl groups of selected serines or threonines or, in some cases (such as collagens), to hydroxylated proline and lysine side chains. This *O*-linked glycosylation (Figure 13–33), like the extension of *N*-linked oligosaccharide chains, is catalyzed by a series of glycosyl transferase enzymes that use the sugar nucleotides in the lumen of the Golgi apparatus to add sugars to a protein one at a time. Usually, *N*-acetylgalactosamine is added first, followed by a variable number of additional sugars, ranging from just a few to 10 or more.

The Golgi apparatus confers the heaviest *O*-linked glycosylation of all on *mucins*, the glycoproteins in mucus secretions, and on *proteoglycan core proteins*, which it modifies to produce **proteoglycans**. As discussed in Chapter 19, this process involves the polymerization of one or more *glycosaminoglycan chains* (long, unbranched polymers composed of repeating disaccharide units; see Figure 19–35) onto serines on a core protein. Many proteoglycans are secreted and become components of the extracellular matrix, while others remain anchored to the extracellular face of the plasma membrane. Still others form a major component of slimy materials, such as the mucus that is secreted to form a protective coating on the surface of many epithelia.

The sugars incorporated into glycosaminoglycans are heavily sulfated in the Golgi apparatus immediately after these polymers are made, thus adding a significant portion of their characteristically large negative charge. Some tyrosines in proteins also become sulfated shortly before they exit from the Golgi apparatus. In both cases, the sulfation depends on the sulfate donor 3'-phosphoadenosine-5'-phosphosulfate (PAPS) (Figure 13–34), which is transported from the cytosol into the lumen of the *trans* Golgi network.

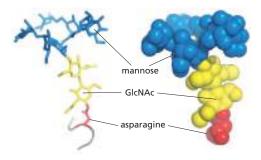

What Is the Purpose of Glycosylation?

There is an important difference between the construction of an oligosaccharide and the synthesis of other macromolecules such as DNA, RNA, and protein. Whereas nucleic acids and proteins are copied from a template in a repeated series of identical steps using the same enzyme or set of enzymes, complex carbohydrates require a different enzyme at each step. The product of each enzyme is recognized as the exclusive substrate for the next enzyme in the series. The vast abundance of glycoproteins and the complicated pathways that have evolved to synthesize them emphasize that the oligosaccharides on glycoproteins and glycosphingolipids have very important functions. A large family of genetic human diseases known as congenital disorders of glycosylation is caused by inherited mutations in individual enzymes involved in glycan modification of proteins and lipids.

MBOC7_ptr_ch13_749-810.indd 773 08/12/21 11:39 AM

N-linked glycosylation, for example, is prevalent in all eukaryotes, including yeasts. N-linked oligosaccharides also occur in a very similar form in archaeal cell-wall proteins, suggesting that the whole machinery required for their synthesis is evolutionarily ancient. N-linked glycosylation promotes protein folding in two ways. First, it has a direct role in making folding intermediates more soluble, thereby preventing their aggregation. Second, the sequential modifications of the N-linked oligosaccharide establish a "glyco-code" that marks the progression of protein folding. This glyco-code is used by chaperones and lectins in the ER to guide protein folding and degradation (discussed in Chapter 12) and by other lectins that guide ER-to-Golgi transport. As we discuss later, oligosaccharides also participate in protein sorting in the trans Golgi network.

Because chains of sugars have limited flexibility, even a small N-linked oligosaccharide protruding from the surface of a glycoprotein (Figure 13–35) can limit the approach of other macromolecules to the protein surface. In this way, for example, the presence of oligosaccharides tends to make a glycoprotein more resistant to digestion by proteolytic enzymes. It may be that the oligosaccharides on cell-surface proteins originally provided an ancestral cell with a protective coat; compared to the rigid bacterial cell wall, such a sugar coat has the advantage that it leaves the cell with the freedom to change shape and move.

The sugar chains have since been adapted to serve other purposes as well. The mucus coat of lung and intestinal cells, for example, protects against many pathogens. The recognition of sugar chains by *lectins* in the extracellular space is important in many developmental processes and in cell-cell recognition: *selectins*, for example, are transmembrane lectins that function in cell-cell adhesion during blood-cell migration, as discussed in Chapter 19. The presence of oligo-saccharides may modify a protein's antigenic and functional properties, making glycosylation an important factor in the production of proteins for pharmaceutical purposes.

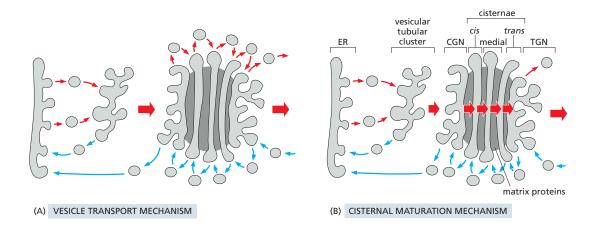

Glycosylation can also have important regulatory roles. Signaling through the cell-surface signaling receptor Notch, for example, is an important factor in determining the cell's fate in development (discussed in Chapter 21). Notch is a transmembrane protein that is *O*-glycosylated by addition of a single fucose to some serines, threonines, and hydroxylysines. Some cell types express an additional glycosyl transferase that adds an *N*-acetylglucosamine to each of these fucoses in the Golgi apparatus. This addition changes the specificity of Notch for the cell-surface signal proteins that activate it.

Transport Through the Golgi Apparatus Occurs by Multiple Mechanisms

In order to function, the Golgi apparatus must maintain its polarized multicisternal structure while facilitating the transit of a large number of diverse molecules. It is likely that multiple mechanisms are used to transport cargo molecules through the Golgi cisternae while efficiently retaining Golgi resident proteins. One mechanism involves the movement of cargo in transport vesicles from one compartment to the next while retrieving any escaped resident

Figure 13–35 The three-dimensional structure of a high-mannose *N*-linked oligosaccharide. The structure was determined by x-ray crystallographic analysis of a glycoprotein. This oligosaccharide contains only 9 sugars, whereas there are 14 sugars in the *N*-linked oligosaccharide that is initially transferred to proteins in the ER (see Figure 12–32). *Left:* a backbone model showing all atoms except hydrogens; only the asparagine side chain of the protein is shown. *Right:* a space-filling model, with the asparagine and sugars indicated using the same color scheme as at left. (PDB code: 5KZC.)

MBOC7_ptr_ch13_749-810.indd 774 08/12/21 11:39 AM

proteins using different transport vesicles (**Figure 13–36A**). This *vesicle transport mechanism* is conceptually similar to how proteins and lipids are transported from the ER to the Golgi, except that only COPI-coated vesicles are used. Although both forward- and backward-moving vesicles would likely be COPI-coated, the coats may contain different adaptor proteins that confer selectivity on the packaging of cargo molecules.

A different way for cargo to move through the Golgi apparatus involves the **cisternal maturation mechanism**. According to this view, new *cis* cisternae continually form as vesicular tubular clusters arrive from the ER and fuse with transport vesicles containing Golgi resident proteins and enzymes. As the cargo within a *cis* cisterna is modified, the enzymes leave in transport vesicles that will fuse with newly arriving vesicular tubular clusters. At the same time, the cisterna accepts transport vesicles containing enzymes from later Golgi cisternae, converting it into a medial cisterna. In this way, a cisterna full of cargo moves through the Golgi stack while different subsets of Golgi resident proteins transit backwards in COPI-coated vesicles from later to earlier cisternae (**Figure 13–36B**). When a cisterna finally moves forward to become part of the *trans* Golgi network, various types of coated vesicles bud off it until this network disappears, to be replaced by a maturing cisterna just behind. At the same time, other transport vesicles are continually retrieving membrane from post-Golgi compartments and returning it to the *trans* Golgi network.

It is likely that aspects of both mechanisms are used to varying degrees depending on the type of cell and the nature of cargo molecules that need to be transported. A stable core of long-lasting cisternae might exist in the center of each Golgi cisterna, while regions at the rim may undergo continual maturation, perhaps utilizing Rab cascades that change their identity. As matured pieces of the cisternae are formed, they might break off and fuse with downstream cisternae by homotypic fusion mechanisms, taking large cargo molecules such as procollagen rods and lipoprotein particles with them. In addition, COPI-coated vesicles might transport small cargo in the forward direction and retrieve escaped Golgi enzymes to their appropriate upstream cisternae.

Golgi Matrix Proteins Help Organize the Stack

The unique architecture of the Golgi apparatus depends on both the microtubule cytoskeleton, as already mentioned, and cytoplasmic Golgi matrix proteins. The Golgi reassembly and stacking proteins (called GRASPs) form a scaffold between adjacent cisternae and give the Golgi stack its structural integrity. Other matrix proteins, called *golgins*, form long tethers composed of stiff coiled-coil domains with interspersed hinge regions. Golgins form a forest of tentacles that can extend 100–400 nm from the surface of the Golgi stack. Different members of the golgin family are found in different regions of the Golgi stack and contain binding

Figure 13-36 Two mechanisms explaining the organization of the Golgi apparatus and how proteins move through it. It is likely that transport of cargo molecules through the Golgi apparatus in the forward direction (red arrows) involves elements of both mechanisms. (A) In the vesicle transport mechanism, Golgi cisternae are static compartments, which contain a characteristic complement of resident enzymes. The passing of molecules from cis to trans through the Golgi is accomplished by forward-moving transport vesicles, which bud from one cisterna and fuse with the next in a cisto-trans direction. (B) In the cisternal maturation mechanism, each Golgi cisterna matures as it migrates outward through the stack. At each stage, the Golgi resident proteins that are carried forward in a maturing cisterna are moved backwards (blue arrows) to an earlier compartment in COPI-coated vesicles When a newly formed cisterna moves to a medial position, for example, "leftover" cis Golgi enzymes would be extracted and transported retrogradely to a new cis cisterna behind. Likewise, the medial enzymes would be received by retrograde transport from the cisternae just ahead. In this way, a cis cisterna would mature to a medial and then trans cisterna as it moves outward.

MBOC7_ptr_ch13_749-810.indd 775 08/12/21 11:39 AM

sites for different Rab proteins. Because transport vesicles arriving from different locations have their characteristic Rab proteins on them, golgins are thought to function as tethers that initially select which part of the Golgi stack a transport vesicle engages (Figure 13–37).

When the cell prepares to divide, mitotic protein kinases phosphorylate the Golgi matrix proteins, causing the Golgi apparatus to fragment and disperse throughout the cytosol. The Golgi fragments are then distributed evenly to the two daughter cells, where the matrix proteins are dephosphorylated, leading to the reassembly of the Golgi stack. Similarly, during apoptosis, proteolytic cleavage of golgins by caspases (discussed in Chapter 18) leads to fragmentation of the Golgi apparatus as the cell self-destructs.

Summary

Correctly folded and assembled proteins in the ER are packaged into COPII-coated transport vesicles that pinch off from the ER membrane. Shortly thereafter, the vesicles shed their coat and fuse with one another to form vesicular tubular clusters. In animal cells, the clusters then move on microtubule tracks to the Golgi apparatus, where they fuse with one another to form the cis Golgi network. Any resident ER proteins that escape from the ER are returned there from the vesicular tubular clusters and Golgi apparatus by retrograde transport in COPI-coated vesicles.

The Golgi apparatus, unlike the ER, contains many sugar nucleotides, which glycosyl transferase enzymes use to glycosylate lipid and protein molecules as they pass through the Golgi apparatus. The mannoses on the N-linked oligosaccharides that are added to proteins in the ER are often initially removed, and further sugars are added. Moreover, the Golgi apparatus is the site where O-linked glycosylation occurs and where glycosaminoglycan chains are added to core proteins to form proteoglycans. Sulfation of the sugars in proteoglycans and of selected tyrosines on proteins also occurs in a late Golgi compartment.

The Golgi apparatus modifies the many proteins and lipids that it receives from the ER and then distributes them to the plasma membrane, endosomes, and secretory vesicles. The Golgi apparatus is a polarized organelle, consisting of one or more stacks of disc-shaped cisternae. Each stack is organized as a series of at least three functionally distinct compartments, termed cis, medial, and trans cisternae. The cis and trans cisternae are each connected to special sorting stations, called the cis Golgi network and the trans Golgi network, respectively. Proteins and lipids move through the Golgi stack in the cis-to-trans direction. This movement may occur by vesicle transport, by progressive maturation of the cis cisternae as they migrate continuously through the stack, or by a combination of these two mechanisms. Continual retrograde vesicle transport from later to earlier cisternae keeps the enzymes concentrated in the cisternae where they are needed. The finished new proteins end up in the trans Golgi network, which packages them in transport vesicles and dispatches them to their specific destinations in the cell.

TRANSPORT FROM THE *TRANS* GOLGI NETWORK TO THE CELL EXTERIOR AND ENDOSOMES

After transiting the Golgi cisternae, cargo molecules that arrive at the *trans* Golgi network (TGN) are sorted and packaged into transport vesicles that depart for different destinations. Transport vesicles destined for the *cell surface* normally leave the TGN in a steady stream as irregularly shaped tubules. The membrane proteins and the lipids in these vesicles provide new components for the cell's plasma membrane, while the soluble proteins inside the vesicles are secreted to the extracellular space. The fusion of the vesicles with the plasma membrane is called **exocytosis**. This is the route, for example, by which cells secrete most of the proteoglycans and glycoproteins of the extracellular matrix, as discussed in Chapter 19.

All cells require this **constitutive secretory pathway**, which operates continually (Movie 13.5). Specialized secretory cells, however, have a second secretory pathway in which soluble proteins and other substances are destined to be

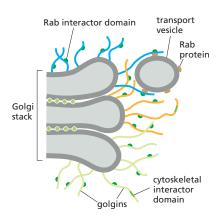

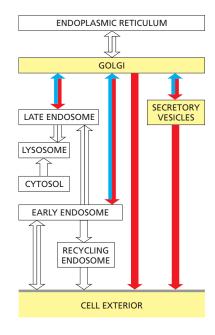

Figure 13–37 A model of golgin function. Filamentous golgins anchored to Golgi membranes capture transport vesicles by binding to Rab proteins on the vesicle surface. Different members of the golgin family of proteins are localized to different regions of the Golgi apparatus. GRASPs are shown tethering adjacent cisternae to each other.

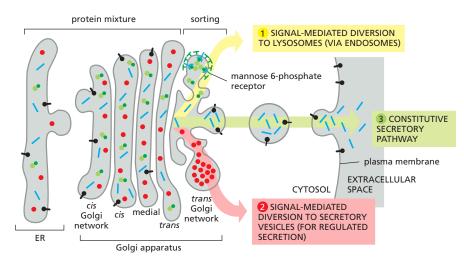

Figure 13-38 The three best-understood pathways of protein sorting in the trans Golgi network. (1) Proteins with the mannose 6-phosphate (M6P) marker (see Figure 13-40) are diverted to lysosomes (via endosomes) in clathrin-coated transport vesicles. (2) Proteins with signals directing them to secretory vesicles are concentrated in such vesicles as part of a regulated secretory pathway that is present only in specialized secretory cells. (3) In unpolarized cells, a constitutive secretory pathway delivers proteins with no special features to the cell surface. In polarized cells, such as epithelial cells, however, secreted and plasma membrane proteins are selectively directed to either the apical or the basolateral plasma membrane domain, so a specific signal must mediate at least one of these two pathways, as we discuss later.

initially stored in *secretory vesicles* for later release by exocytosis. This is the **regulated secretory pathway**, found mainly in cells specialized for secreting products rapidly on demand—such as hormones, neurotransmitters, or digestive enzymes.

The third major destination from the TGN is *endosomes*. Hydrolases that function in the lumen of lysosomes use this pathway to first arrive at endosomes, which progressively mature into lysosomes (discussed later). The sorting mechanism at the TGN for lysosomal hydrolase proteins is especially well understood and provides an example of how cargo molecules in the TGN are segregated among different types of transport vesicles. In this section, we consider the role of the Golgi apparatus in sorting proteins between these three pathways and compare the mechanisms of constitutive and regulated secretion.

Many Proteins and Lipids Are Carried Automatically from the *Trans* Golgi Network to the Cell Surface

A cell capable of regulated secretion must separate at least three classes of proteins before they leave the TGN—those destined for lysosomes (via endosomes), those destined for secretory vesicles, and those destined for immediate delivery to the cell surface (Figure 13–38). Specific signals are needed to direct secretory proteins into secretory vesicles and lysosomal proteins into different specialized transport vesicles. The nonselective constitutive secretory pathway transports most other proteins directly to the cell surface. Because entry into this pathway does not require a particular signal, it is also called the default pathway. Thus, in an unpolarized cell such as a white blood cell or a fibroblast, it seems that any protein in the lumen of the Golgi apparatus is automatically carried by the constitutive pathway to the cell surface unless it is specifically returned to the ER, retained as a resident protein in the Golgi apparatus itself, or selected for the pathways that lead to regulated secretion or to endosomes. In polarized cells, where different products have to be delivered to different domains of the cell surface, we shall see that the options are more complex.

A Mannose 6-Phosphate Receptor Sorts Lysosomal Hydrolases in the *Trans* Golgi Network

The best-understood mechanism for sorting of cargo molecules at the TGN operates on lysosomal hydrolases. Lysosomes are membrane-enclosed organelles filled with about 40 hydrolytic enzymes responsible for digesting all the macromolecules delivered there. Lysosomes are therefore a major site for degradation and recycling of proteins, nucleic acids, lipids, and even whole organelles. The function of lysosomes and the various transport routes leading to this organelle are considered later. For now, we address the pathway that selectively packages

MBOC7_ptr_ch13_749-810.indd 777 08/12/21 11:39 AM

lysosomal hydrolases at the TGN into transport vesicles destined for endosomes. The vesicles that leave the TGN for endosomes incorporate the lysosomal proteins and exclude the many other proteins being packaged into different transport vesicles for delivery elsewhere.

How are lysosomal hydrolases recognized and selected in the TGN with the required accuracy? In animal cells they carry a unique marker in the form of *mannose* 6-phosphate (M6P) groups, which are added exclusively to the N-linked oligosaccharides of these soluble lysosomal enzymes as they pass through the lumen of the *cis* Golgi network (Figure 13–39). Transmembrane M6P receptor proteins, which are present in the TGN, recognize the M6P groups and bind to the lysosomal hydrolases on the lumenal side of the membrane and to adaptor proteins in assembling clathrin coats on the cytosolic side. In this way, the receptors help package the hydrolases into clathrin-coated vesicles that bud from the TGN and deliver their contents to early endosomes.

The M6P receptor protein binds to M6P at pH 6.5–6.7 in the TGN lumen and releases it at pH 6, which is the pH in the lumen of endosomes. Thus, after the receptor is delivered, the lysosomal hydrolases dissociate from the M6P receptors, which are retrieved into transport vesicles that bud from endosomes. These vesicles are coated with retromer, a coat protein complex specialized for endosome-to-TGN transport, which returns the receptors to the TGN for reuse (Figure 13–40).

Transport in either direction requires signals in the cytoplasmic tail of the M6P receptor that direct this protein to the endosome or back to the TGN. An adaptor protein of the clathrin coat recognizes the tail at the TGN, while retromer recognizes it at the endosome. The assembly of different coats at different membranes for the same receptor is ensured by organelle-specific markers, such as Rab7 and PI(3)P at the endosome. The recycling of the M6P receptor resembles the recycling of the KDEL receptor discussed earlier, although it differs in the type of coated vesicles that mediate the transport.

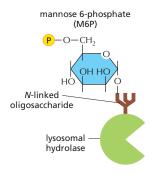

Figure 13–39 The structure of mannose 6-phosphate on a lysosomal hydrolase.

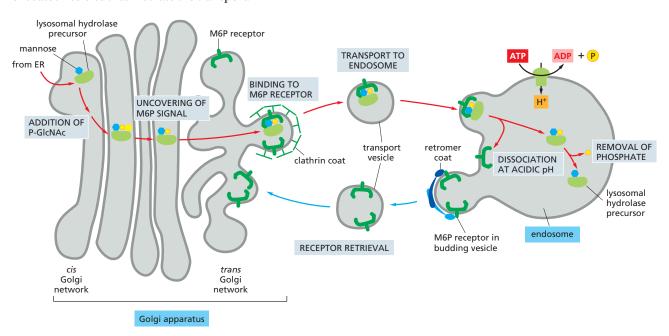

Figure 13–40 The transport of newly synthesized lysosomal hydrolases to endosomes. The sequential action of two enzymes in the *cis* and *trans* Golgi network adds mannose 6-phosphate (M6P) groups to the precursors of lysosomal enzymes (see Figure 13–41). The M6P-tagged hydrolases then segregate from all other types of proteins in the TGN because adaptor proteins (not shown) in the clathrin coat bind the M6P receptors, which, in turn, bind the M6P-modified lysosomal hydrolases. The clathrin-coated vesicles bud off from the TGN, shed their coat, and fuse with early endosomes. At the lower pH of the endosome, the hydrolases dissociate from the M6P receptors, and the empty receptors are retrieved in retromer-coated vesicles to the TGN for further rounds of transport. In the endosomes, the phosphate is removed from the M6P attached to the hydrolases, which may further ensure that the hydrolases do not return to the TGN with the receptor.

MBOC7_ptr_ch13_749-810.indd 778 08/12/21 11:39 AM

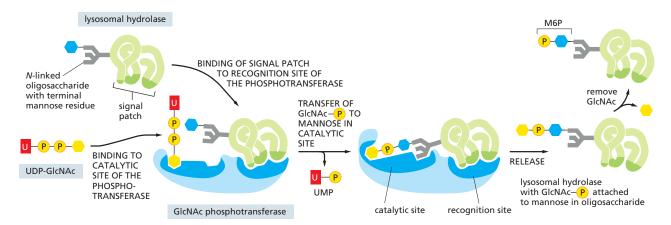

Figure 13–41 The recognition of a lysosomal hydrolase. A GlcNAc phosphotransferase recognizes lysosomal hydrolases in the Golgi apparatus. The enzyme has separate catalytic and recognition sites. The catalytic site binds both high-mannose *N*-linked oligosaccharides and UDP-GlcNAc. The recognition site binds to a signal patch that is present only on the surface of lysosomal hydrolases. A second enzyme cleaves off the GlcNAc, leaving the mannose 6-phosphate exposed.

Not all the hydrolase molecules that are tagged with M6P get to lysosomes. Some escape the normal packaging process in the *trans* Golgi network and are transported by the constitutive secretory pathway to the cell surface, where they are secreted into the extracellular fluid. Some M6P receptors, however, also take a detour to the plasma membrane, where they recapture the escaped lysosomal hydrolases and return them by *receptor-mediated endocytosis* (discussed later) to lysosomes via early and late endosomes. As lysosomal hydrolases require an acidic milieu to work, they can do little harm in the extracellular fluid, which usually has a neutral pH of 7.4.

For the sorting system that segregates lysosomal hydrolases and dispatches them to endosomes to work, the M6P groups must be added only to the appropriate glycoproteins in the Golgi apparatus. This requires specific recognition of the hydrolases by the Golgi enzymes responsible for adding M6P. Because all glycoproteins leave the ER with identical *N*-linked oligosaccharide chains, the signal for adding the M6P units to oligosaccharides must reside somewhere in the polypeptide chain of each hydrolase. Genetic engineering experiments have revealed that the recognition signal is a cluster of neighboring amino acids on each protein's surface, known as a *signal patch* (Figure 13–41). Because most lysosomal hydrolases contain multiple oligosaccharides, they acquire many M6P groups, providing a high-affinity signal for the M6P receptor.

Defects in the GlcNAc Phosphotransferase Cause a Lysosomal Storage Disease in Humans

Genetic defects that affect one or more of the lysosomal hydrolases cause a number of human lysosomal storage diseases. The defects result in an accumulation of undigested substrates in lysosomes, with severe pathological consequences, most often in the nervous system. In most cases, there is a mutation in a structural gene that codes for an individual lysosomal hydrolase. This occurs in *Hurler's disease*, for example, in which the enzyme required for the breakdown of certain types of glycosaminoglycan chains is defective or missing. The most severe form of lysosomal storage disease, however, is a very rare inherited metabolic disorder called *inclusion-cell disease* (*I-cell disease*). In this condition, almost all of the hydrolytic enzymes are missing from the lysosomes of many cell types, and their undigested substrates accumulate in these lysosomes, which consequently form large *inclusions* in the cells. The consequent pathology is complex, affecting all organ systems, skeletal integrity, and mental development; individuals rarely live beyond 6 or 7 years.

MBOC7_ptr_ch13_749-810.indd 779 08/12/21 11:39 AM

I-cell disease is due to a single gene defect and, like most genetic enzyme deficiencies, it is recessive; that is, it occurs only in individuals having two copies of the defective gene. In individuals with I-cell disease, all the hydrolases missing from lysosomes are found in the blood: because they fail to sort properly in the Golgi apparatus, they are secreted rather than transported to lysosomes. The mis-sorting has been traced to a defective or missing GlcNAc phosphotransferase. Because lysosomal enzymes are not phosphorylated in the *cis* Golgi network, the M6P receptors do not segregate them into the appropriate transport vesicles in the TGN. Instead, the lysosomal hydrolases are carried to the cell surface and secreted.

In I-cell disease, the lysosomes in some cell types, such as hepatocytes, contain a normal complement of lysosomal enzymes, implying that there is another pathway for directing hydrolases to lysosomes that is used by some cell types but not others. Alternative sorting receptors function in these M6P-independent pathways. Similarly, an M6P-independent pathway in all cells sorts the membrane proteins of lysosomes from the TGN for transport to late endosomes, and those proteins are therefore normal in I-cell disease.

Secretory Vesicles Bud from the Trans Golgi Network

Cells that are specialized for secreting some of their products rapidly on demand concentrate and store these products in **secretory vesicles** (often called *dense-core secretory granules* because they have dense cores when viewed in the electron microscope). As we discussed (see Figure 13–38), secretory vesicles form from the TGN, and they release their contents to the cell exterior by exocytosis in response to specific signals. The secreted product can be either a small molecule (such as histamine or a neuropeptide) or a protein (such as a hormone or digestive enzyme).

Proteins destined for secretory vesicles (called *secretory proteins*) are packaged into appropriate vesicles in the TGN by a mechanism that involves the selective aggregation of the secretory proteins. Clumps of aggregated, electrondense material can be detected by electron microscopy in the lumen of the TGN. The signals that direct secretory proteins into such aggregates are not well defined and may be quite diverse. When a gene encoding a secretory protein is artificially expressed in a secretory cell that normally does not make the protein, the foreign protein is appropriately packaged into secretory vesicles. This observation shows that, although the proteins that an individual cell expresses and packages in secretory vesicles differ, they contain common sorting signals, which function properly even when the proteins are expressed in cells that do not normally make them.

It is unclear how the aggregates of secretory proteins are segregated into secretory vesicles. Secretory vesicles have unique proteins in their membrane, some of which might serve as receptors for aggregated protein in the TGN. The aggregates are much too big, however, for each molecule of the secreted protein to be bound by its own cargo receptor, as occurs for transport of the lysosomal enzymes. Instead, the aggregate might cause the membrane region containing the cargo receptor to zipper up around the aggregate, thereby enclosing it within the budding vesicle.

Initially, the membrane of the secretory vesicles that leave the TGN is only loosely wrapped around the clusters of aggregated secretory proteins. Morphologically, these *immature secretory vesicles* resemble dilated *trans* Golgi cisternae that have pinched off from the Golgi stack. As immature secretory vesicles mature, clathrin-coated transport vesicles bud from them and go back to the TGN (Figure 13–42). This recycling process not only returns Golgi components to the Golgi apparatus, but also serves to concentrate the contents of secretory vesicles. The sum of all the retrieval pathways during the transit of a secretory protein from the ER through the Golgi cisternae to a mature secretory vesicle results in a 200- to 400-fold increase in net concentration.

MBOC7_ptr_ch13_749-810.indd 780 08/12/21 11:39 AM

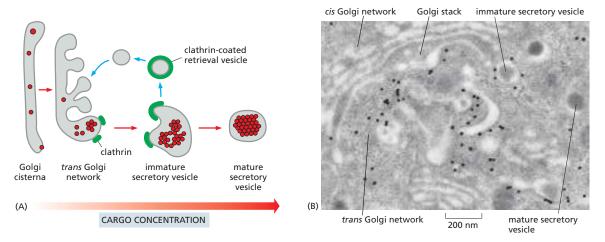

Figure 13–42 The formation of secretory vesicles. (A) Secretory proteins become segregated and highly concentrated in secretory vesicles by two mechanisms. First, they aggregate in the ionic environment of the TGN; often, the aggregates become more condensed as a secretory vesicle matures and its lumen becomes more acidic. Second, clathrin-coated vesicles retrieve excess membrane and lumenal content present in immature secretory vesicles as the secretory vesicles mature. (B) This electron micrograph shows secretory vesicles forming from the TGN in an insulin-secreting β cell of the pancreas. Anti-clathrin antibodies conjugated to gold spheres (black dots) have been used to locate clathrin molecules. The immature secretory vesicles, which contain insulin precursor protein (proinsulin), contain clathrin patches, which are no longer seen on the mature secretory vesicle. (B, courtesy of Lelio Orci.)

Immature secretory vesicles also fuse with one another, and the lumens become progressively more acidic from the increasing concentration of V-type ATPases in the vesicle membrane. Acidification of the lumen further condenses the secretory protein aggregate within a vesicle whose excess membrane has now been retrieved back to the TGN. Because the final mature secretory vesicles are so densely filled with contents, the secretory cell can disgorge large amounts of material promptly by exocytosis when triggered to do so (Figure 13–43).

Precursors of Secretory Proteins Are Proteolytically Processed During the Formation of Secretory Vesicles

Concentration is not the only process to which secretory proteins are subjected as the secretory vesicles mature. Many protein hormones and small neuropeptides, as well as many secreted hydrolytic enzymes, are synthesized as inactive precursors. Proteolysis is necessary to liberate the active molecules from these precursor proteins. The cleavages occur in the secretory vesicles and sometimes in the extracellular fluid after secretion. Additionally, many of the precursor proteins exit the ER with an N-terminal propeptide that is cleaved off only later in the secretory pathway to yield the mature protein. These proteins are initially synthesized as pre-pro-proteins, with the ER signal peptide (sometimes referred to as a pre-peptide) cleaved off earlier as the protein enters the rough ER (see Figure 12-18). In other cases, peptide signaling molecules are made as polyproteins that contain multiple copies of the same amino acid sequence. In still more complex cases, a variety of peptide signaling molecules are synthesized as parts of a single polyprotein that acts as a precursor for multiple end products, which are individually cleaved from the initial polypeptide chain. The same polyprotein may be processed in various ways to produce different peptides in different cell types (Figure 13-44).

Why is proteolytic processing so common in the secretory pathway? Some of the peptides produced in this way, such as the *enkephalins* (five-aminoacid neuropeptides with morphine-like activity), are undoubtedly too short in their mature forms to be co-translationally transported into the ER lumen or to

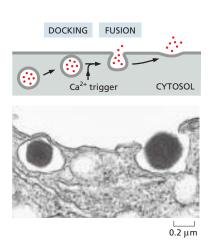

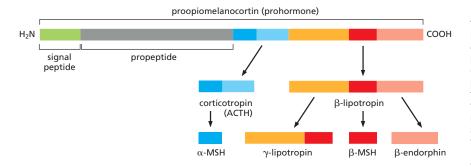

Figure 13–43 Exocytosis of secretory vesicles. The process is illustrated schematically (top) and in an electron micrograph that shows the release of insulin from a secretory vesicle of a pancreatic β cell. (Courtesy of Lelio Orci, from L. Orci et al., Sci. Am. 259:85–94, 1988.)

MBOC7_ptr_ch13_749-810.indd 781 08/12/21 11:39 AM

include the necessary signal for packaging into secretory vesicles. In addition, for secreted hydrolytic enzymes—or any other protein whose activity could be harmful inside the cell that makes it—delaying activation of the protein until it reaches a secretory vesicle or until after it has been secreted has a clear advantage: the delay prevents the protein from acting prematurely inside the cell in which it is synthesized.

Secretory Vesicles Wait Near the Plasma Membrane Until Signaled to Release Their Contents

Once loaded, a secretory vesicle has to reach the site of secretion, which in some cells is far away from the TGN. Nerve cells are the most extreme example. Secretory proteins, such as peptide neurotransmitters (neuropeptides), which will be released from nerve terminals at the end of the axon, are made and packaged into secretory vesicles in the cell body. They then travel along the axon to the nerve terminals, which can be a meter or more away. As discussed in Chapter 16, motor proteins propel the vesicles along axonal microtubules, whose uniform orientation guides the vesicles in the proper direction. Microtubules also guide transport vesicles to the cell surface for constitutive exocytosis.

Whereas transport vesicles containing materials for constitutive release fuse with the plasma membrane once they arrive there, secretory vesicles in the regulated pathway wait at the membrane until the cell receives a signal for the vesicles to secrete their cargo. The signal can be an electrical nerve impulse (an action potential) or an extracellular signal molecule, such as a hormone. In either case, it leads to a transient increase in the concentration of free Ca²⁺ in the cytosol, which is the trigger for secretory vesicle fusion.

For Rapid Exocytosis, Synaptic Vesicles Are Primed at the Presynaptic Plasma Membrane

Nerve cells (and some endocrine cells) contain two types of secretory vesicles. As for all secretory cells, these cells package proteins and neuropeptides in densecored secretory vesicles in the standard way for release by the regulated secretory pathway. In addition, however, they use another specialized class of tiny (\sim 50 nm diameter) secretory vesicles called **synaptic vesicles**. These vesicles store small *neurotransmitter molecules*, such as acetylcholine, glutamate, glycine, and γ -aminobutyric acid (GABA), which mediate rapid signaling from a nerve cell to its target cell at chemical synapses as we discussed in Chapter 11. When an action potential arrives at a nerve terminal, it causes an influx of Ca²⁺ through voltage-gated Ca²⁺ channels, which triggers the synaptic vesicles to fuse with the plasma membrane and release their contents to the extracellular space (see Figure 11–38). Some neurons fire more than 1000 times per second, releasing neurotransmitters each time.

The speed of transmitter release (taking only milliseconds) indicates that the proteins mediating the fusion reaction do not undergo complex, multistep

Figure 13-44 Processing pathways for the prohormone polyprotein proopiomelanocortin. The initial cleavages are made by proteases that cut next to pairs of positively charged amino acids (Lys-Arg, Lys-Lys, Arg-Lys, or Arg-Arg pairs). Trimming reactions then produce the final secreted products. Different cell types produce different concentrations of individual processing enzymes, so that the same prohormone precursor is cleaved to produce different peptide hormones. In the anterior lobe of the pituitary gland, for example, only corticotropin (ACTH) and β-lipotropin are produced from proopiomelanocortin, whereas in the intermediate lobe of the pituitary gland, mainly α -melanocyte stimulating hormone $(\alpha\text{-MSH})$, $\gamma\text{-lipotropin}$, $\beta\text{-MSH}$, and β -endorphin are produced— α -MSH from ACTH and the other three from β-lipotropin, as shown.

MBOC7_ptr_ch13_749-810.indd 782 08/12/21 11:39 AM

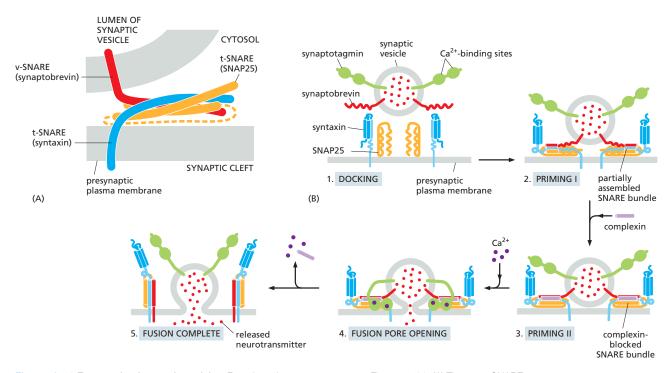

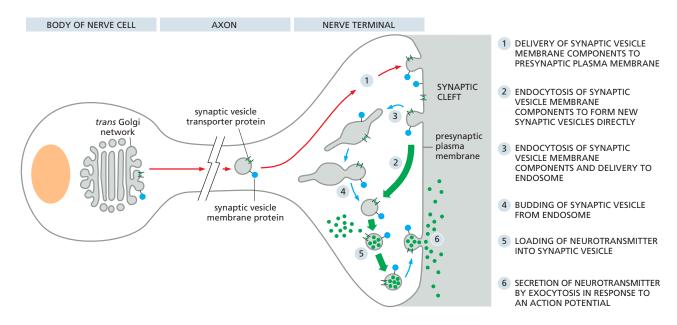

Figure 13–45 Exocytosis of synaptic vesicles. For orientation at a synapse, see Figure 11–38. (A) The trans-SNARE complex responsible for docking synaptic vesicles at the plasma membrane of nerve terminals consists of three proteins. The v-SNARE synaptobrevin and the t-SNARE syntaxin are both transmembrane proteins, and each contributes one α helix to the complex. By contrast to other SNAREs discussed earlier, the t-SNARE SNAP25 is a peripheral membrane protein that contributes two α helices to the four-helix bundle; the two helices are connected by a loop (dashed line) that lies parallel to the membrane and has fatty acyl chains (not shown) attached to anchor it there. The four α helices are shown as rods for simplicity. (B) At the synapse, the basic SNARE machinery is modulated by the Ca^{2+} sensor synaptotagmin and an additional protein called complexin. Synaptic vesicles first dock at the membrane (step 1), and the SNARE bundle partially assembles (step 2), resulting in a "primed vesicle" that is already drawn close to the membrane. The SNARE bundle assembles further, but the additional binding of complexin prevents fusion (step 3). Upon arrival of an action potential, Ca^{2+} enters the cell and binds to synaptotagmin, which releases the block and opens a fusion pore (step 4). Further rearrangements complete the fusion reaction (step 5) and release the fusion machinery, which now can be reused. This elaborate arrangement allows the fusion machinery to respond on the millisecond time scale essential for rapid and repetitive synaptic signaling. (A, adapted from R.B. Sutton et al., Nature 395:347–353, 1998; B, adapted from J. Tang et al., Cell 126:1175–1187, 2006. With permission from Elsevier.)

rearrangements. Rather, after vesicles have been docked at the presynaptic plasma membrane, they undergo a priming step, which prepares them for rapid fusion. In the primed state, the SNAREs are partly paired but their helices are not fully wound into the final four-helix bundle required for fusion (Figure 13–45). Proteins called *complexins* freeze the SNARE complexes in this metastable state. The brake imposed by the complexins is released by another synaptic vesicle protein, synaptotagmin, which contains Ca²⁺-binding domains. A rise in cytosolic Ca²⁺ triggers binding of synaptotagmin to the SNAREs, displacing the complexins. As the SNARE bundle zippers up completely, a fusion pore opens and the neurotransmitters are released. At a typical synapse, only a small number of the docked vesicles are primed and ready for exocytosis. The use of only a small fraction of primed vesicles at a time allows each synapse to fire over and over again in quick succession. With each firing, new synaptic vesicles dock and become primed to replace those that have fused and released their contents.

Synaptic Vesicles Can Be Recycled Locally After Exocytosis

For the nerve terminal to respond rapidly and repeatedly, synaptic vesicles need to be replenished very quickly after they discharge. This is achieved by local recycling of synaptic vesicles from the presynaptic plasma membrane in the

MBOC7_ptr_ch13_749-810.indd 783 08/12/21 11:39 AM

nerve terminals (Figure 13–46). In this process, membrane components of synaptic vesicles are removed from the surface by endocytosis almost as fast as they are added by exocytosis. Similarly, newly made membrane components of the synaptic vesicles are initially delivered to the plasma membrane by the constitutive secretory pathway and then retrieved by endocytosis. The membrane components of a synaptic vesicle include transporters specialized for the uptake of neurotransmitter from the cytosol, where the small-molecule neurotransmitters that mediate fast synaptic signaling are synthesized (Figure 13–47). Most of the endocytic vesicles immediately fill with neurotransmitter to become synaptic vesicles. Once filled with neurotransmitter, the synaptic vesicles can be used again (see Figure 13–46).

Secretory Vesicle Membrane Components Are Quickly Removed from the Plasma Membrane

When a secretory vesicle fuses with the plasma membrane, its contents are discharged from the cell by exocytosis and its membrane becomes part of the plasma membrane. Although this should increase the surface area of the plasma membrane, it does so only transiently, because an equivalent amount of membrane is removed from the surface by endocytosis almost as fast as it is added by exocytosis, a process reminiscent of the endocytic–exocytic cycle discussed later. The proteins of the secretory vesicle membrane that are endocytosed from the plasma membrane are either recycled or shuttled to lysosomes for degradation through mechanisms discussed later. The amount of secretory vesicle membrane that is temporarily added to the plasma membrane can be enormous: in a pancreatic acinar cell discharging digestive enzymes for delivery to the gut lumen, about 900 μm^2 of vesicle membrane is inserted into the apical plasma membrane (whose area is only 30 μm^2) when the cell is stimulated to secrete.

Control of membrane traffic thus has a major role in maintaining the composition of the various membranes of the cell. To maintain each membrane-enclosed compartment in the secretory and endocytic pathways at a constant size, the balance between the outward and inward flows of membrane needs to be precisely regulated. For cells to grow, however, the forward flow needs to be greater than the retrograde flow, so that the membrane can increase in area. For cells to maintain a constant size, the forward and retrograde flows must be equal. We still know very little about the mechanisms that coordinate these flows.

Figure 13–46 The formation of synaptic vesicles in a nerve cell. These tiny uniform vesicles are found only in nerve cells and in some endocrine cells, where they store and secrete small-molecule neurotransmitters. The import of neurotransmitter directly into the small endocytic vesicles that form from the plasma membrane is mediated by membrane transporters that function as antiports and are driven by an H⁺ gradient maintained by V-type ATPase H⁺ pumps in the vesicle membrane (discussed in Chapter 11).

MBOC7_ptr_ch13_749-810.indd 784 08/12/21 11:39 AM

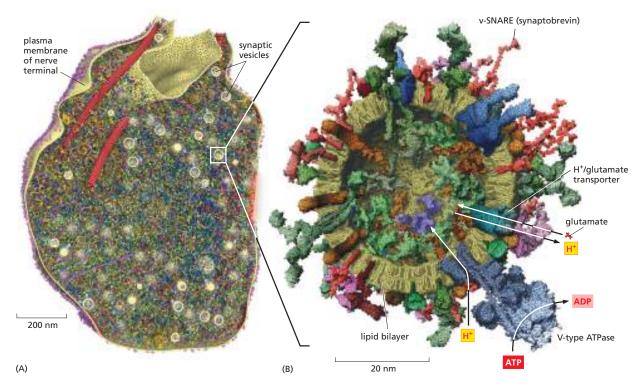

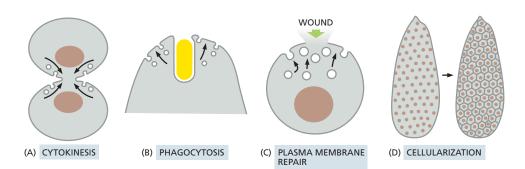

Figure 13–47 Scale models of a brain presynaptic terminal and a synaptic vesicle. The illustrations show sections through a presynaptic terminal (A) and a synaptic vesicle (B) in which proteins and lipids are drawn to scale on the basis of their known stoichiometry and either known or approximated structures. The relative localization of protein molecules in different regions of the presynaptic terminal was inferred from superresolution imaging and electron microscopy. The model in A contains 300,000 proteins of 60 different kinds that vary in abundance from 150 copies to 20,000 copies. In the model in B, only 70% of the membrane proteins present in the membrane are shown; a complete model would therefore show a membrane that is even more crowded than this picture suggests (Movie 13.6). Each synaptic vesicle membrane contains 7000 phospholipid molecules and 5700 cholesterol molecules. Each also contains close to 50 different integral membrane protein molecules, which vary widely in their relative abundance and together contribute about 600 transmembrane α helices. The transmembrane v-SNARE synaptobrevin is the most abundant protein in the vesicle (\sim 70 copies per vesicle). By contrast, the V-type ATPase, which uses ATP hydrolysis to pump H+ into the vesicle lumen, is present in 1–2 copies per vesicle. The H+ gradient provides the energy for neurotransmitter import by an H+/neurotransmitter antiport, which loads each vesicle with 1800 neurotransmitter molecules, such as glutamate, one of which is shown to scale. (A, from B.G. Wilhelm et al., *Science* 344:1023–1028, 2014. With permission from AAAS; B, adapted from S. Takamori et al., *Cell* 127:831–846, 2006. With permission from Elsevier.)

Some Regulated Exocytosis Events Serve to Enlarge the Plasma Membrane

An important task of regulated exocytosis is to deliver more membrane to enlarge the surface area of a cell's plasma membrane when such a need arises. A spectacular example is the plasma membrane expansion that occurs during the cellularization process in a fly embryo, which initially is a syncytium—a single cell containing about 6000 nuclei surrounded by a single plasma membrane (see Figure 21–14). Within tens of minutes, the embryo is converted into the same number of cells. This process of *cellularization* requires a vast amount of new plasma membrane, which is added by a carefully orchestrated fusion of cytoplasmic vesicles, eventually forming the plasma membranes that enclose the separate cells. Similar vesicle fusion events are required to enlarge the plasma membrane when other animal cells or plant cells divide during *cytokinesis* (discussed in Chapter 17).

Many animal cells, especially those subjected to mechanical stresses, frequently experience small ruptures in their plasma membrane. In a remarkable process thought to involve both homotypic vesicle-vesicle fusion and exocytosis, a temporary cell-surface patch is quickly fashioned from locally available

MBOC7_ptr_ch13_749-810.indd 785 08/12/21 11:39 AM

internal-membrane sources, such as lysosomes. In addition to providing an emergency barrier against leaks, the patch reduces membrane tension over the wounded area, allowing the bilayer to flow back together to restore continuity and seal the puncture. The fusion and exocytosis of vesicles that mediated membrane repair is triggered by the sudden increase of ${\rm Ca^{2^+}}$, which is abundant in the extracellular space and rushes into the cell as soon as the plasma membrane is punctured. Figure 13–48 shows four examples in which regulated exocytosis leads to plasma membrane expansion.

Polarized Cells Direct Proteins from the *Trans* Golgi Network to the Appropriate Domain of the Plasma Membrane

Most cells in tissues are *polarized*, with two or more molecularly and functionally distinct plasma membrane domains. This raises the general problem of how the delivery of membrane from the Golgi apparatus is organized so as to maintain the differences between one cell-surface domain and another. A typical epithelial cell, for example, has an *apical domain*, which faces either an internal cavity or the outside world and often has specialized features such as cilia or a brush border of microvilli. It also has a *basolateral domain*, which covers the rest of the cell. The two domains are separated by a ring of *tight junctions* (see Figure 19–20), which prevents proteins and lipids from diffusing between the two domains, so that the differences between the two domains are maintained.

Different subsets of proteins are secreted from the apical and basolateral surfaces of the cell. Epithelial cells lining the gut, for example, secrete digestive enzymes and mucus at their apical surface and components of the basal lamina at their basolateral surface. Such cells must have ways of directing vesicles carrying different cargoes to different plasma membrane domains. Proteins destined for different domains travel together from the ER until they reach the TGN, where they are separated and dispatched in secretory or transport vesicles to the appropriate plasma membrane domain (Figure 13–49). These routes are known as the *direct pathways* for polarized secretion because cargo destined for the apical and basolateral domains is delivered there directly.

The apical plasma membrane of most epithelial cells is greatly enriched in glycosphingolipids, which help protect this exposed surface from damage; for example, from the digestive enzymes and low pH in sites such as the gut or stomach, respectively. Similarly, plasma membrane proteins that are linked to the lipid bilayer by a glycosylphosphatidylinositol (GPI) anchor (see Figure 12–30) are found predominantly in the apical plasma membrane. If recombinant DNA techniques are used to attach a GPI anchor to a protein that would normally be delivered to the basolateral surface, the protein is delivered to the apical surface instead. GPI-anchored proteins are thought to be directed to the apical membrane because they associate with glycosphingolipids in lipid rafts that form in the membrane of the TGN. As discussed in Chapter 10, lipid rafts form in the TGN and plasma membrane when glycosphingolipids and cholesterol molecules self-associate (see Figure 10–13). Having selected a unique set of cargo molecules, the rafts then bud from the TGN into transport vesicles destined for the apical plasma membrane.

Figure 13–48 Four examples of regulated exocytosis leading to plasma membrane enlargement. The vesicles fusing with the plasma membrane during cytokinesis (A) (discussed in Chapter 17) and phagocytosis (B) (discussed later in this chapter) are thought to be derived from endosomes, whereas those involved in wound repair (C) may be derived from plasma membranes and lysosomes. The vast amount of new plasma membrane inserted during cellularization in a fly embryo occurs by the fusion of cytoplasmic vesicles (D).

MBOC7_ptr_ch13_749-810.indd 786 08/12/21 11:39 AM

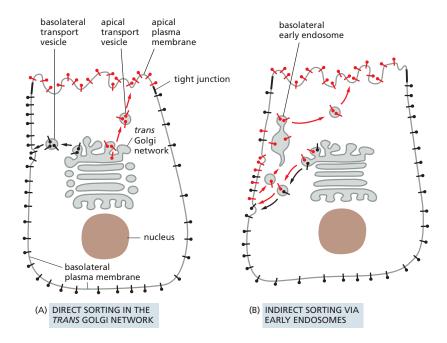

Figure 13-49 Two ways of sorting plasma membrane proteins in a polarized epithelial cell. (A) In the direct pathway, proteins destined for different plasma membrane domains are sorted and packaged into different transport vesicles. The lipid raft-dependent delivery system to the apical domain described in the text is an example of the direct pathway. (B) In the indirect pathway, a protein is retrieved from the inappropriate plasma membrane domain by endocytosis and then transported to the correct domain via early endosomes; that is, by transcytosis. The indirect pathway, for example, is used in liver hepatocytes to deliver proteins to the apical domain that lines bile ducts.

While secretory and GPI-anchored proteins rely on the direct pathways, membrane proteins can sometimes use an indirect route to arrive at the appropriate membrane surface (see Figure 13–49B). In this route, both apical and basolateral cargo travel together in transport vesicles from the TGN to the basolateral membrane. Membrane proteins that do not belong in that region of the plasma membrane are retrieved by endocytosis and are transported via early endosomes to the correct region. Membrane proteins destined for delivery to the basolateral membrane contain sorting signals in their cytosolic tail. When present in an appropriate structural context, these signals are recognized by coat proteins that package them into appropriate transport vesicles in the TGN. The same basolateral signals that are recognized in the TGN also function in early endosomes to redirect the proteins back to the basolateral plasma membrane after they have been endocytosed. A combination of direct and indirect deliveries ensures that the apical and basolateral membranes retain their distinct identities.

Summary

Transport vesicles departing the TGN carry their contents to one of two major destinations: the plasma membrane for exocytosis or endosomes for eventual delivery to lysosomes. Vesicle transport from the TGN to the plasma membrane is further divided into a constitutive pathway or regulated pathways. Proteins follow the constitutive pathway unless they are diverted into other pathways or retained in the Golgi apparatus. In polarized cells, the transport pathways from the TGN to the plasma membrane operate selectively to ensure that different sets of membrane proteins, secreted proteins, and lipids are delivered to the different domains of the plasma membrane.

The regulated pathways operate only in specialized secretory cells and neurons. The molecules for regulated secretion are stored either in secretory vesicles or in synaptic vesicles, which do not fuse with the plasma membrane to release their contents until they receive an appropriate signal. Secretory vesicles containing proteins for secretion bud from the TGN. The secretory proteins become concentrated during the formation and maturation of the secretory vesicles. Synaptic vesicles, which are confined to nerve cells and some endocrine cells, form from both endocytic vesicles and from endosomes, and they mediate the regulated secretion of small-molecule neurotransmitters at the axon terminals of nerve cells.

Newly synthesized lysosomal proteins are carried from the TGN to endosomes by means of clathrin-coated transport vesicles before moving on to lysosomes.

MBOC7_ptr_ch13_749-810.indd 787 08/12/21 11:39 AM

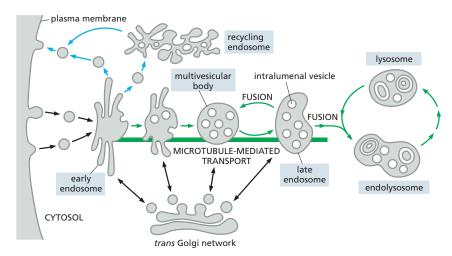

The lysosomal hydrolases contain N-linked oligosaccharides that are covalently modified in a unique way in the cis Golgi network so that their mannoses are phosphorylated. These mannose 6-phosphate (M6P) groups are recognized by an M6P receptor protein in the trans Golgi network that segregates the hydrolases and helps package them into budding transport vesicles that deliver their contents to endosomes. The M6P receptors shuttle back and forth between the trans Golgi network and the endosomes. The low pH in endosomes and the removal of the phosphate from the M6P group cause the lysosomal hydrolases to dissociate from these receptors, making the transport of the hydrolases unidirectional. A separate transport system uses clathrin-coated vesicles to deliver resident lysosomal membrane proteins from the trans Golgi network to endosomes.

TRANSPORT INTO THE CELL FROM THE PLASMA MEMBRANE: ENDOCYTOSIS

The routes that lead inward from the cell surface start with the process of **endocytosis**, by which cells take up plasma membrane components, fluid, solutes, macromolecules, and particulate substances. Endocytosed cargo includes receptor-ligand complexes, a spectrum of nutrients and their carriers, extracellular matrix components, cell debris, bacteria, viruses, and, in specialized cases, even other cells. Through endocytosis, the cell regulates the composition of its plasma membrane in response to changing extracellular conditions.

In endocytosis, the material to be ingested is progressively enclosed by a small portion of the plasma membrane, which first invaginates and then pinches off to form an **endocytic vesicle** containing the ingested substance or particle. Most eukaryotic cells constantly form endocytic vesicles, a process called *pinocytosis* ("cell drinking"); in addition, some specialized cells contain dedicated pathways that take up large particles on demand, a process called *phagocytosis* ("cell eating"). Endocytic vesicles form at the plasma membrane by multiple mechanisms that differ in both the molecular machinery used and how that machinery is regulated.

Once generated at the plasma membrane, most endocytic vesicles fuse with a common receiving compartment, the *early endosome*, where internalized cargo is sorted: some cargo molecules are returned to the plasma membrane, either directly or via a *recycling endosome*, and others remain as the early endosome changes into a *late endosome* by a process termed *endosome maturation* (Figure 13–50). This conversion process changes the protein composition of the endosome membrane, patches of which invaginate and become incorporated within the organelles as *intralumenal vesicles*, while the endosome itself moves from the cell periphery to a location close to the nucleus. As an endosome matures, it ceases to recycle material to the plasma membrane. Instead, late

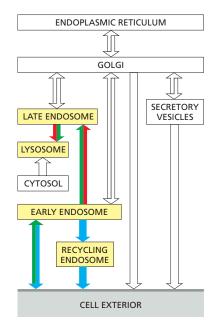

Figure 13-50 Endosome maturation: the endocytic pathway from the plasma membrane to lysosomes. Near the cell periphery, endocytic vesicles fuse with an early endosome, which is the primary sorting station. Tubular portions of the early endosome bud off vesicles that recycle endocytosed cargo back to the plasma membrane-either directly or indirectly via recycling endosomes. Recycling endosomes can store proteins until they are needed. Conversion of early endosomes to late endosomes is accompanied by loss of the tubular projections. Membrane proteins destined for degradation are internalized in intralumenal vesicles. The developing late endosome, or multivesicular body, moves on microtubules to the cell interior. Fully matured late endosomes no longer send vesicles to the plasma membrane. and they fuse with one another and with endolysosomes and lysosomes to degrade their contents. Each stage of endosome maturation is connected to the TGN via transport vesicles, providing a continual supply of newly synthesized lysosomal proteins.

MBOC7_ptr_ch13_749-810.indd 788 08/12/21 11:39 AM

endosomes fuse with one another and with lysosomes to form endolysosomes, which degrade their contents.

Each of the stages of endosome maturation—from the early endosome to the endolysosome—is connected to the TGN through bidirectional vesicle transport pathways. These pathways allow insertion of newly synthesized materials, such as lysosomal enzymes arriving from the ER, and the retrieval of components, such as the M6P receptor, back into the early parts of the secretory pathway. We later discuss how the cell uses and controls the various features of endocytic trafficking.

Pinocytic Vesicles Form from Coated Pits in the Plasma Membrane

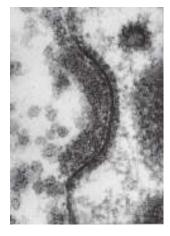

Virtually all eukaryotic cells continually ingest portions of their plasma membrane in the form of small pinocytic (endocytic) vesicles. The rate at which plasma membrane is internalized in this process of **pinocytosis** varies between cell types, but it is usually surprisingly high. A macrophage, for example, ingests 25% of its own volume of fluid each hour. This means it must ingest 3% of its plasma membrane each minute, or 100% in about half an hour. Fibroblasts endocytose at a somewhat lower rate (1% of their plasma membrane per minute), whereas some amoebae ingest their plasma membrane even more rapidly. Because a cell's surface area and volume remain unchanged during this process, it is clear that the same amount of membrane being removed by endocytosis is being added to the cell surface by the converse process of *exocytosis*. In this sense, endocytosis and exocytosis are linked processes that can be considered to constitute an *endocytic-exocytic cycle*. The coupling between exocytosis and endocytosis is particularly strict in specialized structures characterized by high membrane turnover, such as a nerve terminal.

The endocytic part of the cycle often begins at **clathrin-coated pits**. These specialized regions typically occupy about 2% of the total plasma membrane area. The lifetime of a clathrin-coated pit is short: within a minute or so of being formed, it invaginates into the cell and pinches off to form a clathrin-coated vesicle (**Figure 13–51**). About 2500 clathrin-coated vesicles pinch off from the plasma membrane of a cultured fibroblast every minute. The coated vesicles are even more transient than the coated pits: within seconds of being formed, they shed their coat and fuse with early endosomes.

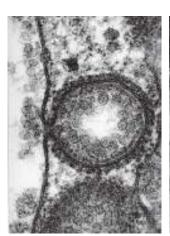

Not All Membrane Invaginations and Pinocytic Vesicles Are Clathrin Coated

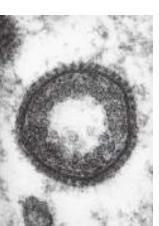

In addition to clathrin-coated pits and vesicles, cells can form other types of pinocytic vesicles and membrane invaginations. Most of these clathrin-independent membrane invaginations are poorly understood, and the molecules that mediate

Figure 13-51 The formation of clathrincoated vesicles from the plasma membrane. These electron micrographs illustrate the probable sequence of events in the formation of a clathrin-coated vesicle from a clathrin-coated pit. The clathrincoated pits and vesicles shown are larger than those seen in normal-sized cells: they are from a very large hen oocyte, and they take up lipoprotein particles to form yolk. The lipoprotein particles bound to their membrane-bound receptors appear as a dense, fuzzy layer on the extracellular surface of the plasma membrane-which is the inside surface of the coated pit and vesicle. MBOC7_ptr_ch13_749-810.indd 789 08/12/21 11:39 AM

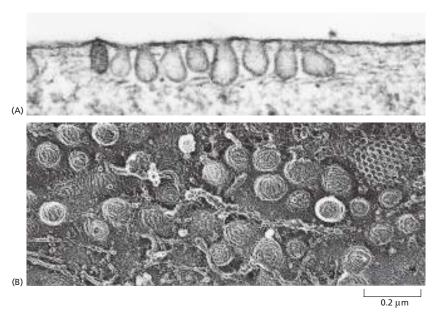

Figure 13–52 Caveolae in the plasma membrane of a fibroblast. (A) This electron micrograph shows a plasma membrane with a very high density of caveolae. (B) This rapid-freeze deep-etch image demonstrates the characteristic "cauliflower" texture of the cytosolic face of the caveolae membrane. The characteristic texture is thought to result from aggregates of caveolins and cavins. A clathrin-coated pit is also seen at the upper right. (From K.G. Rothberg et al., *Cell* 68:673–682, 1992. With permission from Elsevier.)

membrane bending and vesicle formation are often not defined fully. The best-understood clathrin-independent invaginations are called **caveolae** (from the Latin for "little cavities"), originally observed as a prominent feature of the endothelial cells that form the inner lining of blood vessels.

Caveolae, sometimes seen in the electron microscope as deeply invaginated flasks, are present in the plasma membrane of most vertebrate cell types (Figure 13–52). The major structural proteins in caveolae are caveolins, a family of unusual integral membrane proteins that each insert a hydrophobic loop into the membrane from the cytosolic side but do not extend across the membrane. On their cytosolic side, caveolins are bound to large protein complexes of cavin proteins, which are thought to stabilize the membrane curvature. Caveolae are especially rich in cholesterol, glycosphingolipids, and glycosylphosphatidylinositol (GPI)-anchored membrane proteins and might represent a type of *lipid raft* in the plasma membrane (see Figure 10–13).

In contrast to clathrin-coated and COPI-coated or COPII-coated vesicles, caveolae are usually static structures that can serve as a reservoir of additional plasma membrane. It is thought that cells subjected to dynamic changes in shear forces, such as the endothelial cells of arteries, exploit this reservoir to provide their plasma membranes greater resilience to stretch. This is accomplished by the rapid disassembly of the cavin protein scaffold in response to mechanical force, thereby allowing the underlying membrane to temporarily increase the surface area of the cell. The ability to rapidly change membrane surface area is thought to be important for accommodating dynamic changes in blood flow to different parts of the brain.

Two other endocytosis pathways are known, neither of which uses clathrin. **Macropinocytosis** is a process whereby the plasma membrane protrudes from the cell and engulfs a portion of the surrounding extracellular fluid into a *macropinosome*. This is a nonselective process for bringing fluid into the cell under certain conditions. In *phagocytosis*, the plasma membrane is directed to wrap around the particle to be engulfed until it fuses with itself, resulting in an enclosed *phagosome* inside the cell. Both processes utilize actin polymerization underneath the

MBOC7_ptr_ch13_749-810.indd 790 08/12/21 11:39 AM

plasma membrane to mediate the large-scale membrane deformations required to engulf a large particle or a high volume of fluid. Both macropinosomes and phagosomes are destined to fuse with lysosomes so their internal contents can be degraded. These routes of degradation will be discussed later when we consider the function of lysosomes.

Cells Use Receptor-mediated Endocytosis to Import Selected Extracellular Macromolecules

In most animal cells, clathrin-coated pits and vesicles provide an efficient pathway for taking up specific macromolecules from the extracellular fluid. In this process, called **receptor-mediated endocytosis**, the macromolecules bind to complementary transmembrane receptor proteins, which accumulate in coated pits, and then enter the cell as receptor-macromolecule complexes in clathrin-coated vesicles (see Figure 13–51). Because ligands are selectively captured by receptors, receptor-mediated endocytosis provides a selective concentrating mechanism that increases the efficiency of internalization of particular ligands more than a hundredfold. In this way, even minor components of the extracellular fluid can be efficiently taken up in large amounts. A particularly well-understood and physiologically important example is the process that mammalian cells use to import cholesterol.

Many animal cells take up cholesterol through receptor-mediated endocytosis and, in this way, acquire most of the cholesterol they require to make new membrane. If the uptake is blocked, cholesterol accumulates in the blood and can contribute to the formation in blood vessel (artery) walls of *atherosclerotic plaques*, deposits of lipid and fibrous tissue that can cause strokes and heart attacks by blocking arterial blood flow. In fact, it was a study of humans with a strong genetic predisposition for *atherosclerosis* that first revealed the mechanism of receptor-mediated endocytosis.

Most cholesterol is transported in the blood as cholesterol esters in the form of lipid–protein particles known as **low-density lipoproteins (LDLs)** that, architecturally, resemble lipid droplets bearing a core of triacylglycerol, free cholesterol, and cholesterol esters. The droplet is stabilized by a single molecule of apolipoprotein B, a very large protein that wraps around the LDL particle (Figure 13–53). When a cell needs cholesterol for membrane synthesis, it makes transmembrane receptor proteins for LDL at the ER and transports them to the plasma membrane. Once in the plasma membrane, the *LDL receptor* diffuses until an endocytosis signal in its cytoplasmic tail binds the adaptor protein AP2 after AP2's conformation has been locally unlocked by binding to $PI(4,5)P_2$ on the plasma membrane. This

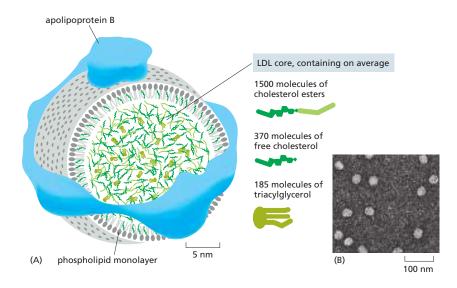

Figure 13-53 A low-density lipoprotein (LDL) particle. (A) Each roughly spherical particle has a mass of 3×10^6 daltons. It contains a core of about 1500 cholesterol molecules esterified to long-chain fatty acids and smaller amounts of free cholesterol and triacylglycerol molecules. A lipid monolayer composed of about 800 phospholipid and 500 unesterified cholesterol molecules surrounds the core of cholesterol esters. A single molecule of apolipoprotein B. a 500.000-dalton beltlike protein, organizes the particle and mediates the specific binding of LDL to cell-surface LDL receptors. (B) Purified LDL particles seen by negative staining in the electron microscope. (B, from L. Zhang et al., J. Lipid Res. 52:175-184, 2011. With permission from Elsevier.)

MBOC7_ptr_ch13_749-810.indd 791 08/12/21 11:39 AM

two-step mechanism of AP2 binding to an endocytosis signal (see Figure 13-9) imparts both efficiency and selectivity to the process. AP2 then recruits clathrin to initiate endocytosis.

Because coated pits constantly pinch off to form coated vesicles, any LDL particles bound to LDL receptors in the coated pits are rapidly internalized in coated vesicles. After shedding their clathrin coats, the vesicles deliver their contents to early endosomes. Once the LDL and LDL receptors encounter the low pH in early endosomes, LDL is released from its receptor and is delivered via late endosomes to lysosomes. There, the cholesterol esters in the LDL particles are hydrolyzed to free cholesterol, which is now available to the cell for new membrane synthesis (Movie 13.7). If too much free cholesterol accumulates in a cell, the cell simultaneously shuts off endogenous cholesterol synthesis (Figure 12–64) and reduces exogenous cholesterol intake by shutting off the synthesis of LDL receptors.

This regulated pathway for cholesterol uptake is disrupted in individuals who inherit defective genes encoding LDL receptors. The resulting high levels of blood cholesterol predispose these individuals to develop atherosclerosis prematurely, and many would die at an early age of heart attacks resulting from coronary artery disease if they were not treated with drugs such as statins that lower the level of blood cholesterol. In some cases, the receptor is lacking altogether. In others, the receptors are defective—in either the extracellular binding site for LDL or the intracellular binding site for the AP2 adaptor protein in clathrin-coated pits. In the latter case, normal numbers of LDL receptors are present, but they fail to become localized in clathrin-coated pits. Although LDL binds to the surface of these mutant cells, it is not internalized, directly demonstrating the importance of clathrin-coated pits for the receptor-mediated endocytosis of cholesterol.

More than 25 distinct receptors are known to participate in receptor-mediated endocytosis of different types of molecules. They all apparently use clathrin-dependent internalization routes and are guided into clathrin-coated pits by signals in their cytoplasmic tails that bind to adaptor proteins in the clathrin coat. Many of these receptors, like the LDL receptor, enter coated pits irrespective of whether they have bound their specific ligands. Others enter preferentially when bound to a specific ligand, suggesting that a ligand-induced conformational change is required for them to activate the signal sequence that guides them into the pits. Because most plasma membrane proteins fail to become concentrated in clathrin-coated pits, the pits serve as molecular filters, preferentially collecting certain plasma membrane proteins (receptors) over others.

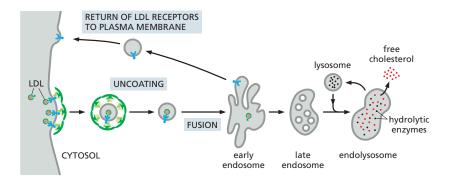

Electron microscopy of cultured cells exposed simultaneously to different labeled ligands demonstrates that many kinds of receptors can cluster in the same clathrin-coated pit, whereas some other receptors cluster in different clathrin-coated pits. The plasma membrane of one clathrin-coated pit can accommodate more than 100 receptors of assorted varieties.

Specific Proteins Are Retrieved from Early Endosomes and Returned to the Plasma Membrane

Early endosomes are the main sorting stations in the endocytic pathway, just as the *cis* and *trans* Golgi networks serve this function in the secretory pathway. In the mildly acidic environment of the early endosome, many internalized receptor proteins change their conformation and release their ligand, as already discussed for the M6P receptors. Those endocytosed ligands that dissociate from their receptors in the early endosome are usually destined for delivery to lysosomes, where they are either degraded and recycled into building blocks or utilized directly by the cell (such as the cholesterol just discussed). Some other endocytosed ligands, however, remain bound to their receptors and thereby share the fate of the receptors.

In the early endosome, the LDL receptor dissociates from its ligand, LDL, and is recycled back to the plasma membrane for reuse, leaving the discharged LDL

MBOC7_ptr_ch13_749-810.indd 792 08/12/21 11:39 AM

to be carried to lysosomes (Figure 13–54). The recycling transport vesicles bud from long, narrow tubules that extend from the early endosomes (Figure 13–55). It is likely that the geometry of these tubules helps the sorting process: because tubules have a large membrane area enclosing a small volume, membrane proteins become enriched over soluble proteins. The transport vesicles return the LDL receptor directly to the plasma membrane.

The **transferrin receptor** follows a similar recycling pathway as the LDL receptor, but unlike the LDL receptor it also recycles its ligand. Transferrin is a soluble protein that carries iron in the blood. Cell-surface transferrin receptors deliver transferrin with its bound iron to early endosomes by receptor-mediated endocytosis. The low pH in the endosome induces transferrin to release its bound iron, but the iron-free transferrin itself (called apotransferrin) remains bound to its receptor. The receptor-apotransferrin complex enters the tubular extensions of the early endosome and from there is recycled back to the plasma membrane. When the apotransferrin returns to the neutral pH of the extracellular fluid, it dissociates from the receptor and is thereby freed to pick up more iron and begin the cycle again. Thus, transferrin shuttles back and forth between the extracellular fluid and early endosomes, avoiding lysosomes and delivering iron to the cell interior, as needed for cells to grow and proliferate.

Recycling Endosomes Regulate Plasma Membrane Composition

The fates of endocytosed receptors—and of any ligands remaining bound to them—vary according to the specific type of receptor. As we discussed, most receptors are recycled and returned to the same plasma membrane domain from which they came; some proceed to a different domain of the plasma membrane, thereby mediating **transcytosis**; and some remain in the endosomal system and progress to lysosomes, where they are degraded, as we discuss next.

Receptors on the surface of polarized epithelial cells can transfer specific macromolecules from one extracellular space to another by transcytosis. A newborn, for example, obtains antibodies from its mother's milk (which help protect it against infection) by transporting them across the epithelium of its gut. The lumen of the gut is acidic, and, at this low pH, the antibodies in the milk bind to specific receptors on the apical (absorptive) surface of the gut epithelial cells. The receptor–antibody complexes are internalized via clathrin-coated pits and vesicles and are delivered to early endosomes. The complexes remain intact and are retrieved in transport vesicles that bud from the early endosome and subsequently fuse with the basolateral domain of the plasma membrane. On exposure to the neutral pH of the extracellular fluid that bathes the basolateral surface of the cells, the antibodies dissociate from their receptors and eventually enter the baby's bloodstream.

The transcytotic pathway from the early endosome back to the plasma membrane is not direct. The receptors first move from the early endosome to the **recycling endosome**. The variety of pathways that different receptors follow from early endosomes implies that, in addition to binding sites for their ligands and

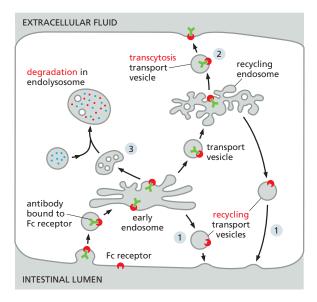

Figure 13-54 The receptor-mediated endocytosis of LDL. Note that the LDL dissociates from its receptors in the acidic environment of the early endosome. After a number of steps, the LDL ends up in endolysosomes and lysosomes, where it is degraded to release free cholesterol. In contrast, the LDL receptors are returned to the plasma membrane via transport vesicles that bud off from the tubular region of the early endosome, as shown For simplicity, only one LDL receptor is shown entering the cell and returning to the plasma membrane. Whether it is occupied or not, an LDL receptor typically makes one round trip into the cell and back to the plasma membrane every 10 minutes, making up to several hundred trips in its 20-hour life span.

0.5 μm

Figure 13-55 Electron micrograph of an early endosome. The endosomal compartments can be made visible in the electron microscope by adding a readily detectable tracer molecule. such as the enzyme peroxidase, to the extracellular medium and allowing the cell to endocytose the tracer. Within a minute or so after adding the tracer, it starts to appear in early endosomes, just beneath the plasma membrane. The image shows an electron-dense reaction product of peroxidase in the early endosome that has been visualized in the electron microscope Many tubular extensions protrude from the central vacuolar space of the early endosome, which will later mature to give rise to a late endosome. (© 1992 J. Tooze and M. Hollinshead. Originally published in J. Cell Biol. 118:813-830, 1992, doi.org/10.1083/jcb.118.4.813. With permission from Rockefeller University Press.)

MBOC7_ptr_ch13_749-810.indd 793 08/12/21 11:39 AM

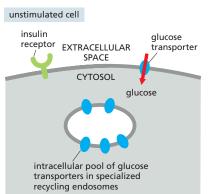

binding sites for coated pits, many receptors also possess sorting signals that guide them into the appropriate transport pathway (Figure 13-56).

Cells can regulate the release of membrane proteins from recycling endosomes, thus adjusting the flux of proteins through the transcytotic pathway according to need. This regulation, the mechanism of which is uncertain, allows recycling endosomes to play an important part in adjusting the concentration of specific plasma membrane proteins. Fat cells and muscle cells, for example, contain large intracelular pools of the glucose transporters that are responsible for the uptake of glucose across the plasma membrane. These membrane transport proteins are stored in specialized recycling endosomes until the hormone *insulin* stimulates the cell to increase its rate of glucose uptake. In response to the insulin signal, transport vesicles rapidly bud from the recycling endosome and deliver large numbers of glucose transporters to the plasma membrane, thereby greatly increasing the rate of glucose uptake into the cell (Figure 13–57). Similarly, kidney cells regulate the insertion of aquaporins and V-type ATPase into the plasma membrane to increase water reabsorption and acid excretion, respectively, both in response to hormones.

Plasma Membrane Signaling Receptors Are Down-regulated by Degradation in Lysosomes

The final potential fate for endocytosed receptors is to remain in the endosome as it matures and eventually fuses with lysosomes, where the receptor is degraded. Many signaling receptors, including opioid receptors and the receptor that binds

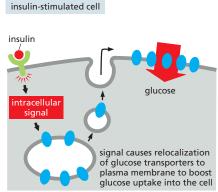

Figure 13-56 Possible fates for transmembrane receptor proteins that have been endocytosed. Three pathways from the early endosomal compartment in an epithelial cell are shown. Retrieved receptors are returned (1) to the same plasma membrane domain from which they came (recycling) or (2) via a recycling endosome to a different domain of the plasma membrane (transcytosis). (3) Receptors that are not specifically retrieved from early or recycling endosomes follow the pathway from the endosomal compartment to lysosomes, where they are degraded (degradation). If the ligand that is endocytosed with its receptor stays bound to the receptor in the acidic environment of the endosome, it shares the same fate as the receptor: otherwise, it is delivered to lysosomes. Recycling endosomes are a way station on the transcytotic pathway. In the transcytosis example shown here, an antibody Fc receptor on a gut epithelial cell binds antibody and is endocytosed, eventually carrying the antibody to the basolateral plasma membrane. The receptor is called an Fc receptor because it binds the Fc part of the antibody (discussed in Chapter 24).

Figure 13–57 Storage of plasma membrane proteins in recycling endosomes. Recycling endosomes can serve as an intracellular storage site for specialized plasma membrane proteins that can be mobilized when needed. In the example shown, insulin binding to the insulin receptor triggers an intracellular signaling pathway that causes the rapid insertion of glucose transporters into the plasma membrane of a fat or muscle cell, greatly increasing its glucose intake.

MBOC7_ptr_ch13_749-810.indd 794 08/12/21 11:39 AM

epidermal growth factor (EGF), follow this route. EGF is a small, extracellular signal protein that stimulates epidermal and various other cells to divide. Unlike LDL receptors, EGF receptors accumulate in clathrin-coated pits only after binding their ligand, and most do not recycle but are degraded in lysosomes, along with the ingested EGF. EGF binding therefore first activates intracellular signaling pathways and then leads to a decrease in the concentration of EGF receptors on the cell surface, a process called *receptor down-regulation*, that reduces the cell's subsequent sensitivity to EGF (see Figure 15–21).

Receptor down-regulation is highly regulated. The activated receptors are first covalently modified on the cytosolic face with the small protein ubiquitin. Unlike polyubiquitylation, which adds a chain of ubiquitins that typically targets a protein for degradation in proteasomes (discussed in Chapter 6), ubiquitin tagging for sorting into the clathrin-dependent endocytic pathway adds just one or a few single ubiquitin molecules to the protein—a process called *monoubiquitylation* or multiubiquitylation, respectively. Ubiquitin-binding proteins recognize the attached ubiquitin and help direct the modified receptors into clathrin-coated pits. The ubiquitylated receptor does not get recycled back to the plasma membrane from the early endosome. Instead, it remains there as the endosome matures. During the maturation process, which we discuss next, the ubiquitin tag is used to selectively sort the receptor and its bound ligand into intralumenal vesicles. Receptor signaling is terminated when the receptor is sequestered into intralumenal vesicles, which ultimately are degraded in lysosomes. In this way, addition of ubiquitin blocks receptor recycling to the plasma membrane and directs the receptors into the degradation pathway.

Early Endosomes Mature into Late Endosomes

Early endosomes are mainly derived from incoming endocytic vesicles that fuse with one another (Movie 13.8). Typically, an early endosome receives incoming vesicles for about 10 minutes before beginning its maturation into a late endosome. Early endosomes have tubular and vacuolar domains (see Figure 13–55). Most of the membrane surface is in the tubules, and most of the volume is in the vacuolar domain.

Many changes occur during the maturation process. (1) The endosome changes shape and location as the tubular domains are mostly recycled back to the plasma membrane, the vacuolar domains are thoroughly modified, and the endosome is moved by motors along microtubules toward the nucleus. (2) Rab proteins drive changes in phosphoinositide lipids and fusion machinery (SNAREs and tethers) on the cytosolic face of the endosome membrane to change the functional characteristics of the organelle. (3) Lysosome proteins, including lumenal hydrolases and a membrane-embedded V-type ATPase, are delivered from the TGN to the maturing endosome. (4) The V-type ATPase pumps H⁺ from the cytosol into the endosome lumen and further acidifies the organelle. Crucially, the increasing acidity that accompanies maturation renders lysosomal hydrolases increasingly more active, influencing many receptor-ligand interactions, thereby controlling receptor loading and unloading. (5) Intralumenal vesicles sequester endocytosed signaling receptors inside the endosome, thus halting the receptor signaling activity. Most of these events occur gradually but eventually lead to a complete transformation of the endosome into an early endolysosome.

In addition to committing selected cargo for degradation, the maturation process is important for lysosome maintenance. The continual delivery of lysosome components from the TGN to maturing endosomes ensures a steady supply of new lysosome proteins. The endocytosed materials mix in early endosomes with newly arrived acid hydrolases. Although mild digestion may start here, many hydrolases are synthesized and delivered as proenzymes, called *zymogens*, which contain extra inhibitory domains that keep the hydrolases inactive until these domains are proteolytically removed at later stages of **endosome maturation**. Moreover, the pH in early endosomes is not low enough to activate lysosomal

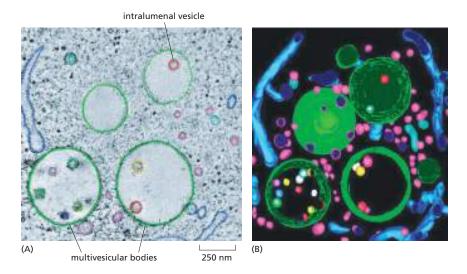

Figure 13–58 Cryo-electron microscopy (cryo-EM) tomogram of multivesicular bodies in cultured human lymphocytes. The tracing of membranes in single sections (A) allowed reconstruction of the three-dimensional arrangement of the organelles (B). The enclosing membranes of the multivesicular bodies are traced in green. (From J.L.A.N. Murk et al., *Proc. Natl. Acad. Sci. USA* 100:13332–13337, 2003.)

hydrolases optimally. By these means, cells can retrieve membrane proteins intact from early endosomes and recycle them back to the plasma membrane.

ESCRT Protein Complexes Mediate the Formation of Intralumenal Vesicles in Multivesicular Bodies

As endosomes mature, patches of their membrane invaginate into the endosome lumen and pinch off to form intralumenal vesicles. Because of their appearance in the electron microscope, such maturing endosomes are also called multivesicular bodies (Figure 13–58).

The multivesicular bodies carry endocytosed membrane proteins that are to be degraded. As part of the protein-sorting process, receptors destined for degradation, such as the occupied EGF receptors described previously, selectively partition into the invaginating membrane of the multivesicular bodies. In this way, both the receptors and any signaling proteins strongly bound to them are sequestered away from the cytosol where they might otherwise continue signaling. They also are made fully accessible to the digestive enzymes that eventually will degrade them (Figure 13–59). In addition to endocytosed membrane proteins, multivesicular bodies include the soluble content of early endosomes destined for late endosomes and digestion in lysosomes.

As discussed earlier, sorting into intralumenal vesicles requires one or multiple ubiquitin tags, which are added to the cytosolic domains of membrane proteins. These tags initially help guide the proteins into clathrin-coated vesicles in the plasma membrane. Once delivered to the endosomal membrane, the ubiquitin tags are recognized again, this time by a series of cytosolic **ESCRT protein complexes** (ESCRT-0, -I, -II, and -III), which bind sequentially and ultimately mediate

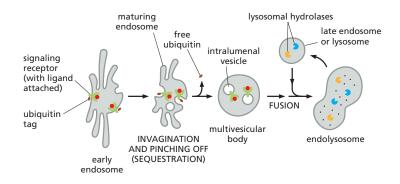

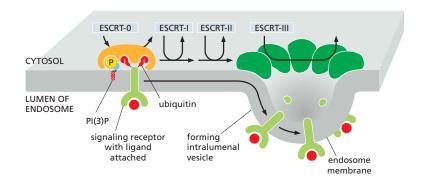

Figure 13-59 The sequestration of endocytosed proteins into intralumenal vesicles of multivesicular bodies. Ubiquitylated membrane proteins are sorted into domains on the endosome membrane, which invaginate and pinch off to form intralumenal vesicles. The ubiquitin marker is removed and returned to the cytosol for reuse before the intralumenal vesicle closes. Eventually, lysosomal hydrolases (such as proteases and lipases) in lysosomes digest all of the internal membranes. The invagination processes are essential for complete digestion of endocytosed membrane proteins. Because the outer membrane of the multivesicular body becomes continuous with the lysosomal membrane, the hydrolases only digest the cytosolic domains of endocytosed transmembrane proteins when the protein becomes localized in intralumenal vesicles.

MBOC7_ptr_ch13_749-810.indd 796 08/12/21 11:39 AM

the sorting process into the intralumenal vesicles. Membrane invagination into multivesicular bodies also depends on a lipid kinase that phosphorylates phosphatidylinositol to produce PI(3)P, which serves as an additional docking site for the ESCRT complexes. For docking and vesicle invagination, ESCRT complexes require both PI(3)P and the presence of ubiquitylated cargo proteins to bind to the endosomal membrane. ESCRT-III forms large multimeric assemblies on the membrane that bend the membrane (Figure 13–60).

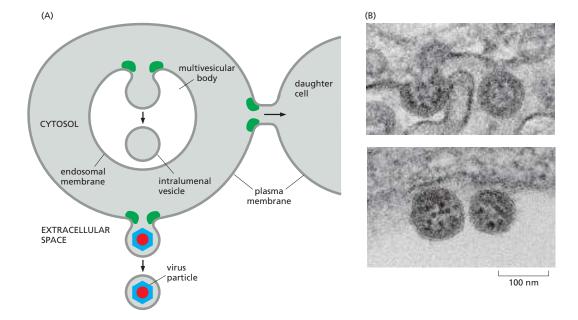

Mutant cells compromised in ESCRT function display signaling defects. In such cells, activated receptors cannot be down-regulated by endocytosis and packaging into multivesicular bodies. The still-active receptors therefore mediate prolonged signaling, which can lead to uncontrolled cell proliferation and cancer.

The ESCRT machinery that drives the internal budding from the endosome membrane to form intralumenal vesicles is also used in animal-cell cytokinesis and virus budding, which are topologically equivalent. In all three processes, budding occurs in a direction away from the cytosolic surface of the membrane (Figure 13–61A). ESCRT complexes are thought to have originated from similar components that mediate cell-membrane deformation during cytokinesis in archaea.

Although some viruses such as HIV hijack the host ESCRT machinery to bud directly out of the cell, other viruses escape using different mechanisms. For example, SARS-CoV-2, the virus that causes COVID-19, buds into the vesicular tubular clusters between the ER and Golgi apparatus, then uses the secretory pathway to exit the cell (Figure 13–61B). This budding reaction deforms membranes away

Figure 13-60 Sorting of endocytosed membrane proteins into the intralumenal vesicles of a multivesicular body. A series of complex binding events passes ubiquitylated membrane proteins, such as the signaling receptor with its ligand shown here, sequentially from one ESCRT complex (ESCRT-0) to the next, eventually concentrating them in membrane areas that bud into the lumen of the endosome to form intralumenal vesicles. ESCRT-III assembles into expansive multimeric structures and mediates invagination. The mechanisms of how cargo molecules are shepherded into the vesicles and how the vesicles are formed without including the ESCRT complexes themselves remain unknown. ESCRT complexes are soluble in the cytosol, are recruited to the membrane sequentially as needed, and are then released back into the cytosol as the vesicle pinches off

Figure 13-61 Conserved mechanism in multivesicular body formation, virus budding, and cytokinesis. (A) In the three topologically equivalent processes indicated by the arrows, ESCRT complexes (green) shape membranes into buds that bulge away from the cytosol. (B) Electron micrographs of a cultured cell infected with SARS-CoV-2. The top panel shows virus particles budding away from the cytosol into vesicular tubular clusters between the ER and the Golgi apparatus. The virus particles are carried through the secretory pathway until they are released to the outside of the cell by exocytosis (bottom panel). (B, from N.S. Ogando et al., J. Gen. Virol. 101:925-940, 2020.)

MBOC7_ptr_ch13_749-810.indd 797 08/12/21 11:39 AM

from the cytosol but does not seem to use ESCRT machinery. Instead, viral proteins are thought to facilitate budding by a mechanism that is not well understood.

Summary

Cells ingest fluid, molecules, and particles by endocytosis, in which localized regions of the plasma membrane invaginate and pinch off to form endocytic vesicles. In most cells, endocytosis internalizes a large fraction of the plasma membrane every hour. The cells remain the same size because most of the plasma membrane components (proteins and lipids) that are endocytosed are continually returned to the cell surface by exocytosis. This large-scale endocytic-exocytic cycle is mediated largely by clathrin-coated pits and vesicles, but clathrin-independent endocytic pathways also contribute.

While many of the endocytosed molecules are quickly recycled to the plasma membrane, others eventually end up in lysosomes, where they are degraded. Most of the ligands that are endocytosed with their receptors dissociate from their receptors in the acidic environment of the endosome and eventually end up in lysosomes, while most of the receptors are recycled via transport vesicles back to the cell surface for reuse. Many cell-surface signaling receptors become tagged with ubiquitin when activated by binding their extracellular ligands. Ubiquitylation guides activated receptors into clathrin-coated pits, and they and their ligands are efficiently internalized and delivered to early endosomes.

Early endosomes rapidly mature into late endosomes. During maturation, patches of the endosomal membrane containing ubiquitylated receptors invaginate and pinch off to form intralumenal vesicles. This process is mediated by ESCRT complexes and sequesters the receptors away from the cytosol, which terminates their signaling activity. Late endosomes migrate along microtubules toward the interior of the cell where they fuse with one another and with lysosomes to form endolysosomes, where degradation occurs.

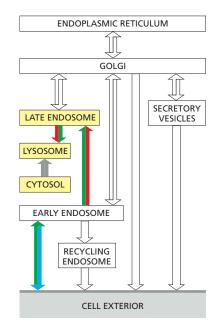

In some cases, both receptor and ligand are transferred to a different plasma membrane domain, causing the ligand to be released at a different surface from where it originated, a process called transcytosis. In some cells, endocytosed plasma membrane proteins and lipids can be stored in recycling endosomes for as long as necessary until they are needed.

THE DEGRADATION AND RECYCLING OF MACROMOLECULES IN LYSOSOMES

Having discussed how molecules are trafficked forward through the secretory pathway and how material enters the cell through the endocytic pathway, we now consider lysosomes. The lysosome is a terminal destination for the degradation of proteins, microorganisms, dead cells, and other materials ingested by endocytosis and phagocytosis. In addition, proteins, old organelles, and other components in the cytosol can also be degraded in lysosomes through a process termed autophagy. In this section, we begin with a brief account of lysosome structure and function, then discuss how material for degradation is delivered to lysosomes.

Lysosomes Are the Principal Sites of Intracellular Digestion

Lysosomes are membrane-enclosed organelles filled with soluble hydrolytic enzymes that digest macromolecules. Lysosomes contain about 40 types of hydrolytic enzymes, including proteases, nucleases, glycosidases, lipases, phospholipases, phosphatases, and sulfatases. All are acid hydrolases; that is, hydrolases that work best at acidic pH. For optimal activity, they need to be activated by proteolytic cleavage, which also requires an acid environment. The lysosome provides this acidity, maintaining an interior pH of about 4.5–5.0. By this arrangement, the contents of the cytosol are doubly protected against attack by the cell's own digestive system: the membrane of the lysosome keeps the

MBOC7_ptr_ch13_749-810.indd 798 08/12/21 11:39 AM

digestive enzymes out of the cytosol, but, even if they leak out, they can do little damage at the cytosolic pH of about 7.2.

Like all other membrane-enclosed organelles, the lysosome not only contains a unique collection of enzymes but also has a unique surrounding membrane. Most of the lysosome membrane proteins, for example, are highly glycosylated, which helps to protect them from the lysosome proteases in the lumen. Transport proteins in the lysosome membrane carry the final products of the digestion of macromolecules—such as amino acids, sugars, and nucleotides—to the cytosol, where the cell can either reuse or excrete them.

A *vacuolar H*⁺ *ATPase* in the lysosome membrane uses the energy of ATP hydrolysis to pump H⁺ into the lysosome, thereby maintaining the lumen at its acidic pH (**Figure 13–62**). The lysosome H⁺ pump belongs to the family of *V-type ATPases* and has a similar architecture to the mitochondrial and chloroplast ATP synthases (F-type ATPases), which convert the energy stored in H⁺ gradients into ATP (see Figure 11–12). By contrast to these enzymes, however, the vacuolar H⁺ ATPase exclusively works in reverse, pumping H⁺ into the organelle. Similar or identical V-type ATPases acidify all endocytic and exocytic organelles, including lysosomes, endosomes, some compartments of the Golgi apparatus, and many transport and secretory vesicles. In addition to providing a low-pH environment that is suitable for reactions occurring in the organelle lumen, the H⁺ gradient provides a source of energy that drives the transport of small metabolites across the organelle membrane.

Lysosomes Are Heterogeneous

Lysosomes are found in all eukaryotic cells. They were initially discovered by the biochemical fractionation of cell extracts; only later were they seen clearly in the electron microscope. Although extraordinarily diverse in shape and size, staining them with specific antibodies shows they are members of a single family of organelles. They can also be identified by histochemical techniques that reveal which organelles contain acid hydrolase (Figure 13–63).

The heterogeneous morphology of lysosomes contrasts with the relatively uniform structures of many other cell organelles. The diversity reflects the wide variety of digestive functions that acid hydrolases mediate, including the breakdown of intracellular and extracellular debris, the destruction of phagocytosed microorganisms, and the production of nutrients for the cell. Their morphological diversity, however, also reflects the way lysosomes form. Late endosomes containing material received from the plasma membrane by endocytosis and containing newly synthesized lysosomal hydrolases fuse with preexisting lysosomes to form structures that are referred to as endolysosomes, which then fuse with one another (Figure 13-64). When the majority of the endocytosed material within an endolysosome has been digested so that only resistant or slowly digestible residues remain, these organelles become "classical" lysosomes. These are relatively dense, round, and small, but they can enter the cycle again by fusing with late endosomes or endolysosomes. Thus, there is no real distinction between endolysosomes and lysosomes: they are the same except that they are in different stages of a maturation cycle. For this reason, lysosomes are sometimes viewed as a heterogeneous collection of distinct organelles, the common feature of which is a high content of hydrolytic enzymes. It is especially hard to apply a narrower definition than this in plant cells, as we discuss next.

Figure 13–63 Histochemical visualization of lysosomes. These electron micrographs show two sections of a cell stained to reveal the location of acid phosphatase, a marker enzyme for lysosomes. The larger membrane-enclosed organelles, containing dense precipitates of lead phosphate, are lysosomes. Their diverse morphology reflects variations in the amount and nature of the material they are digesting. The precipitates are produced when tissue fixed with glutaraldehyde (to fix the enzyme in place) is incubated with a phosphatase substrate in the presence of lead ions. Red arrows in the top panel indicate two small vesicles thought to be carrying acid hydrolases from the Golgi apparatus. (Courtesy of Daniel S. Friend, and by permission of E.L. Bearer.)

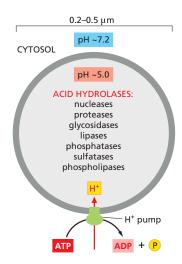

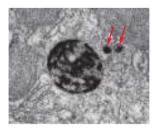

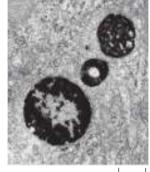

Figure 13–62 Lysosomes. The acid hydrolases are hydrolytic enzymes that are active under acidic conditions. An H⁺ ATPase in the membrane pumps H⁺ into the lysosome, maintaining its lumen at an acidic pH.

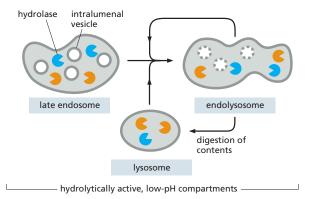

Figure 13–64 A model for lysosome maturation. Late endosomes fuse with preexisting lysosomes (bottom) or preexisting endolysosomes (top right). Endolysosomes eventually mature into lysosomes as hydrolases complete the digestion of their contents, which can include intralumenal vesicles. Lysosomes also fuse with phagosomes, as we discuss later.

Plant and Fungal Vacuoles Are Remarkably Versatile Lysosomes

Most plant and fungal cells (including yeasts) contain one or several very large, fluid-filled vesicles called **vacuoles**. They typically occupy more than 30% of the cell volume and as much as 90% in some cell types (**Figure 13–65**). Vacuoles are related to animal-cell lysosomes and contain a variety of hydrolytic enzymes, but their functions are remarkably diverse. The plant vacuole can act as a storage organelle for both nutrients and waste products, as a degradative compartment, as an economical way of increasing cell size, and as a controller of *turgor pressure* (the osmotic pressure that pushes outward on the cell wall and keeps the plant from wilting) (**Figure 13–66**). The same cell may have different vacuoles with distinct functions, such as digestion and storage.

The vacuole is important as a homeostatic device, enabling plant cells to withstand wide variations in their environment. When the pH in the environment drops, for example, the flux of H^+ into the cytosol is balanced, at least in part, by an increased transport of H^+ into the vacuole, which tends to keep the pH in the cytosol constant. Similarly, many plant cells maintain an almost constant turgor pressure despite large changes in the tonicity of the fluid in their immediate environment. They do so by changing the osmotic pressure of the cytosol and vacuole—in part by the controlled breakdown and resynthesis of polymers such as polyphosphate in the vacuole, and in part by altering the transport rates of sugars, amino acids, and other metabolites across the plasma membrane and the vacuolar membrane. The turgor pressure regulates the activities of distinct transporters in each membrane to control these fluxes.

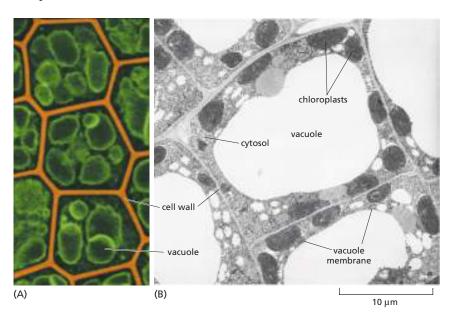

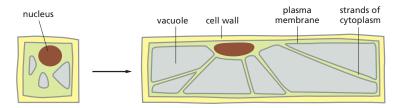

Figure 13-65 The plant-cell vacuole. (A) A confocal image of cells from an Arabidopsis embryo that is expressing an aquaporin-YFP (yellow fluorescent protein) fusion protein in its vacuole membrane YFP fluorescence and the cell walls have been false colored green and orange, respectively. Each cell contains several large vacuoles. (B) This electron micrograph of cells in a young tobacco leaf shows the cytosol as a thin layer, containing chloroplasts, pressed against the cell wall by the enormous vacuole. (A, courtesy of C. Carroll and L. Frigerio, based on S. Gattolin et al., Mol. Plant 4:180-189, 2011; B, courtesy of J. Burgess.)

MBOC7_ptr_ch13_749-810.indd 800 08/12/21 11:39 AM

Humans often harvest substances stored in plant vacuoles—from rubber to opium to the flavoring of garlic. Many stored products have a metabolic function. Proteins, for example, can be preserved for years in the vacuoles of the storage cells of many seeds, such as those of peas and beans. When the seeds germinate, these proteins are hydrolyzed, and the resulting amino acids provide a food supply for the developing embryo. Anthocyanin pigments stored in vacuoles color the petals of many flowers so as to attract pollinating insects, while noxious molecules released from vacuoles when a plant is eaten or damaged provide a defense against predators.

Multiple Pathways Deliver Materials to Lysosomes

Lysosomes are meeting places where several streams of intracellular traffic converge. A route that leads outward from the ER via the Golgi apparatus delivers most of the lysosome's digestive enzymes, as we discussed earlier. In addition, at least three paths from the cell surface and extracellular space feed substances into lysosomes for digestion, while a fourth route called *autophagy* originates in the cytoplasm and is used to digest intracellular macromolecules and organelles.

We have already discussed how macromolecules taken up from plasma membrane and extracellular fluid by endocytosis can reside in endosomes until they mature and fuse with lysosomes. A second pathway called *macropinocytosis* specializes in the nonspecific uptake of fluids, membrane, and particles attached to the plasma membrane. A third pathway found in phagocytic cells, such as macrophages and neutrophils in vertebrates, is dedicated to the engulfment, or *phagocytosis*, of large particles and microorganisms to form *phagosomes*. In contrast to these routes originating from the plasma membrane, autophagy is used to digest cytosol, worn-out organelles, and microbes that invade the cytosol. The four paths to degradation in lysosomes are illustrated in Figure 13–67.

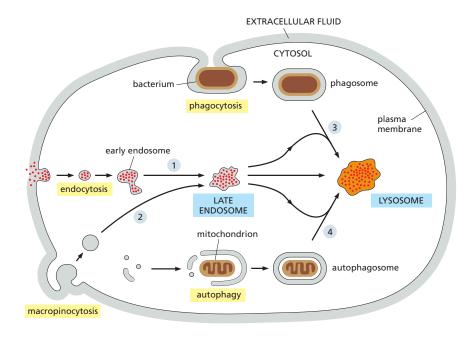

Figure 13–66 The role of the vacuole in controlling the size of plant cells. A plant cell can achieve a large increase in volume without increasing the volume of the cytosol. Localized weakening of the cell wall orients a turgor-driven cell enlargement that accompanies the uptake of water into an expanding vacuole. The cytosol is eventually confined to a thin peripheral layer, which is connected to the nuclear region by strands of cytosol stabilized by bundles of actin filaments (not shown).

Figure 13–67 Four pathways to degradation in lysosomes. Materials in each pathway are derived from a different source. Note that the autophagosome has a double membrane, as we explain later in this chapter. In all cases, the final step is the fusion with lysosomes.

MBOC7_ptr_ch13_749-810.indd 801 08/12/21 11:39 AM

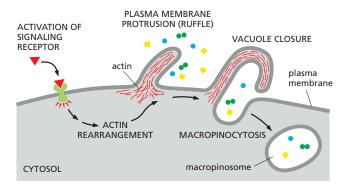

Figure 13–68 Schematic representation of macropinocytosis. Cell signaling events lead to a reprogramming of actin dynamics, which in turn triggers the formation of cell-surface ruffles. As the ruffles collapse back onto the cell surface, they nonspecifically trap extracellular fluid and macromolecules and particles contained in it, forming large vacuoles, or macropinosomes, as shown.

As we have seen, the endocytic pathway not only routes macromolecules for degradation but is also used to regulate the location and trafficking of macromolecules. By contrast, phagocytosis, macropinocytosis, and autophagy are pathways dedicated to degradation. We consider each of the latter three pathways in turn, highlighting the materials each one is responsible for degrading and the mechanisms used to deliver these materials to lysosomes.

Cells Can Acquire Nutrients from the Extracellular Fluid by Macropinocytosis

Macropinocytosis was among the first types of endocytosis to be described because it is visible by light microscopy, where cells can be seen taking up the surrounding fluid into large vesicles called *macropinosomes* (Figure 13–68). In most cell types, macropinocytosis does not operate continually but rather is induced for a limited time in response to cell-surface receptor activation by specific cargoes, including growth factors, integrin ligands, apoptotic-cell remnants, and some viruses. These ligands activate a complex signaling pathway, resulting in a change in actin dynamics and the formation of cell-surface protrusions, called *ruffles* (discussed in Chapter 16). Macropinosomes form when the protruding ends of ruffles fuse with each other or the cell membrane, thereby trapping a portion of extracellular content.

Macropinocytosis is a dedicated degradative pathway: macropinosomes acidify and then fuse with late endosomes or endolysosomes, without recycling their cargo back to the plasma membrane. Micropinocytosis is stimulated by activation of the oncogene *Ras*. Induction of macropinocytosis can increase the bulk fluid uptake of a cell by up to tenfold. Cancer cells that contain constitutively active Ras (see Chapter 15) use enhanced micropinocytosis to obtain increased nutrients from the surrounding environment in order to support their rapid growth and division.

Specialized Phagocytic Cells Can Ingest Large Particles

Phagocytosis is a special form of endocytosis in which a cell uses large endocytic vesicles called **phagosomes** to ingest large particles such as microorganisms and dead cells. Phagocytosis is distinct, both in purpose and mechanism, from macropinocytosis, which we discussed earlier. In protozoa, phagocytosis is a form of feeding: large particles taken up into phagosomes end up in lysosomes, and the products of the subsequent digestive processes pass into the cytosol to be used as food. However, few cells in multicellular organisms are able to ingest such large particles efficiently. In the gut of animals, for example, extracellular processes break down food particles, and cells import the small products of hydrolysis.

Phagocytosis is important in most animals for purposes other than nutrition, and it is carried out mainly by specialized cells—so-called *professional*

MBOC7_ptr_ch13_749-810.indd 802 08/12/21 11:39 AM

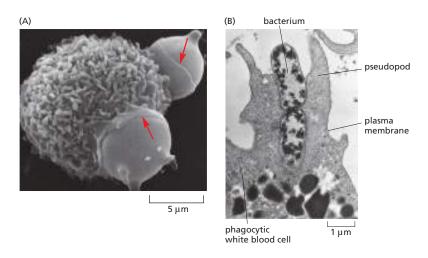

Figure 13–69 Phagocytosis by a macrophage. (A) Scanning electron micrograph of a mouse macrophage phagocytosing two chemically altered red blood cells. The *red arrows* point to edges of thin processes (pseudopods) of the macrophage that are extending as collars to engulf the red cells. (B) An electron micrograph of a neutrophil phagocytosing a bacterium, which is in the process of dividing. (A, courtesy of Jean Paul Revel; B, courtesy of Dorothy F. Bainton, Phagocytic Mechanisms in Health and Disease. New York: Intercontinental Medical Book Corporation, 1971.)

phagocytes. In mammals, two important classes of white blood cells that act as professional phagocytes are **macrophages** and **neutrophils** (Movie 13.9). These cells develop from hemopoietic stem cells (discussed in Chapter 22), and they ingest invading microorganisms to defend us against infection. Macrophages also have an important role in scavenging senescent cells and cells that have died by apoptosis (discussed in Chapter 18). In quantitative terms, the clearance of senescent and dead cells is by far the most important: our macrophages, for example, phagocytose more than 10^{11} senescent red blood cells in each of us every day.

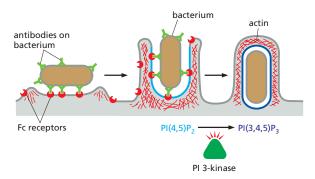

The diameter of a phagosome is determined by the size of its ingested particles, and those particles can be almost as large as the phagocytic cell itself (Figure 13–69). Phagosomes fuse with lysosomes, and the ingested material is then degraded. Indigestible substances remain in the lysosomes, forming *residual bodies* that can be excreted from cells by exocytosis Some of the internalized plasma membrane components never reach the lysosome, because they are retrieved from the phagosome in transport vesicles and returned to the plasma membrane.

Some pathogenic bacteria have evolved elaborate mechanisms to prevent phagosome–lysosome fusion. The bacterium *Legionella pneumophila*, for example, which causes Legionnaires' disease (discussed in Chapter 23), injects into its unfortunate host a Rab-modifying enzyme that causes certain Rab proteins to misdirect membrane traffic, thereby preventing phagosome–lysosome fusion. The bacterium, thus spared from lysosomal degradation, remains in the modified phagosome, growing and dividing as an intracellular pathogen, protected from the host's adaptive immune system.

Cargo Recognition by Cell-surface Receptors Initiates Phagocytosis

Phagocytosis is a cargo-triggered process. That is, it requires the activation of cell-surface receptors that transmit signals to the cell interior. Thus, to be phagocytosed, particles must first bind to the surface of the phagocyte (although not all particles that bind are ingested). Phagocytes have a variety of cell-surface receptors that are functionally linked to the phagocytic machinery of the cell. The best-characterized triggers of phagocytosis are antibodies, which protect us by binding to the surface of infectious microorganisms (pathogens) and initiating a series of events that culminate in the invader being phagocytosed. When antibodies initially attack a pathogen, they coat it with antibody molecules that bind to *Fc receptors* on the surface of macrophages and neutrophils, activating the receptors to induce the phagocytic cell to extend pseudopods, which engulf

MBOC7_ptr_ch13_749-810.indd 803 08/12/21 11:39 AM

the particle and fuse at their tips to form a phagosome (Figure 13–70). Localized actin polymerization, initiated by Rho family GTPases and their activating Rho GEFs (discussed in Chapters 15 and 16), shapes the pseudopods. The activated Rho GTPases switch on the kinase activity of local PI kinases to produce PI(4,5)P₂ in the membrane (see Figure 13–11), which stimulates actin polymerization. To seal off the phagosome and complete the engulfment, actin is depolymerized by a PI 3-kinase that converts the PI(4,5)P₂ to PI(3,4,5)P₃, which is required for closure of the phagosome and may also contribute to reshaping the actin network to help drive the invagination of the forming phagosome (Figure 13–70). In this way, the ordered generation and consumption of specific phosphoinositides guides sequential steps in phagosome formation.

Several other classes of receptors that promote phagocytosis have been characterized. Some recognize *complement* components, which collaborate with antibodies in targeting microbes for destruction (discussed in Chapter 24). Others directly recognize oligosaccharides on the surface of certain pathogens. Still others recognize cells that have died by apoptosis. Apoptotic cells lose the asymmetric distribution of phospholipids in their plasma membrane. As a consequence, negatively charged phosphatidylserine, which is normally confined to the cytosolic leaflet of the lipid bilayer, is now exposed on the outside of the cell, where it helps to trigger the phagocytosis of the dead cell.

Remarkably, macrophages will also phagocytose a variety of inanimate particles—such as glass or latex beads and asbestos fibers—yet they do not phagocytose live cells in their own body. The living cells display "don't-eat-me" signals in the form of cell-surface proteins that bind to inhibitory receptors on the surface of macrophages. The inhibitory receptors recruit tyrosine phosphatases that antagonize the intracellular signaling events required to initiate phagocytosis, thereby locally inhibiting the phagocytic process. Thus phagocytosis, like many other cell processes, depends on a balance between positive signals that activate the process and negative signals that inhibit it. Apoptotic cells are thought both to gain "eat-me" signals (such as extracellularly exposed phosphatidylserine) and to lose their "don't-eat-me" signals, causing them to be very rapidly phagocytosed by macrophages.

Autophagy Degrades Unwanted Proteins and Organelles

All eukaryotic cells can carry out a process called **autophagy**, or "self-eating." During autophagy, a portion of the cytoplasm is engulfed into a membrane structure called the **autophagosome** that subsequently fuses with the lysosome where the autophagosome's contents are degraded (**Figure 13–71**). Autophagy can be either nonselective or selective. In *nonselective autophagy*, a bulk portion of cytoplasm is sequestered in autophagosomes. In *selective autophagy*, autophagosomes tightly enclose specific cargo and mostly exclude the surrounding cytosol.

Autophagy serves several important roles in the cell. During normal cell growth and in development, autophagy helps restructure differentiating cells by removing unwanted organelles or other cellular contents. When cells experience stress or starvation, nonselective autophagy is used to recycle existing

Figure 13-70 Membrane interactions and dynamics during phagocytosis. A bacterium in the body is recognized by antibodies that coat its surface. The Fc receptor on the surface of phagocytic cells recognizes the antibody, recruiting the bacterium to the plasma membrane. This initiates phagocytosis by triggering the formation of pseudopods that begin to surround the bacterium. Pseudopod extension and phagosome formation are driven by actin polymerization and reorganization, which respond to the accumulation of specific phosphoinositides in the membrane of the forming phagosome: PI(4,5)P2 stimulates actin polymerization, which promotes pseudopod formation, and then PI(3,4,5)P₃ depolymerizes actin filaments at the base.

MBOC7_ptr_ch13_749-810.indd 804 08/12/21 11:39 AM

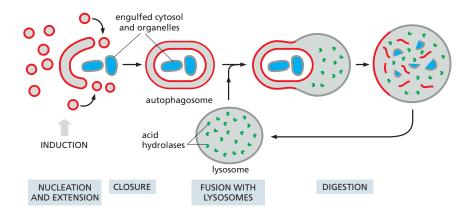

Figure 13–71 A model of autophagy.
Activation of a signaling pathway initiates a nucleation event in the cytoplasm.
A crescent of autophagosomal membrane grows by fusion of vesicles of unknown origin and eventually fuses to form a double-membrane-enclosed autophagosome, which sequesters a portion of the cytoplasm. The autophagosome then fuses with lysosomes containing acid hydrolases that digest its content.

proteins and macromolecules into building blocks that are used for other priorities. Selective autophagy can be used to degrade bacteria and viruses that invade the cytosol, as well as damaged proteins, protein aggregates, and damaged whole organelles. The range of cargoes degraded by autophagy explains why dysregulated autophagy contributes to diseases ranging from infectious disorders to neurodegeneration and cancer.

The autophagosome assembles by the fusion of small vesicles of unknown origin. The process begins when a phosphoinositide lipid kinase complex (termed the ATG1 complex) locally produces PI(3)P (see Figure 13–10) to mark a potential membrane site for the recruitment of several autophagy-related factors. These factors catalyze the covalent attachment of the membrane lipid phosphatidylethanolamine to a ubiquitin-like protein called ATG8. The ATG8-marked vesicles undergo homotypic fusion with each other and heterotypic fusion with vesicles containing ATG9. This results in expansion of a membrane whose identity is provided by ATG8 and other autophagy-related proteins.

For reasons that are not known, the growing membrane structure formed by vesicle fusion is not spherical. Instead, it is a flattened disc (similar to a Golgi apparatus cisterna) that curls into a cup-shaped structure. Fusion of the lips of this cup encloses the contents inside a compartment that is now surrounded by two membranes. The outer membrane of this newly formed autophagosome then fuses with the lysosome in a SNARE-mediated process. The inner membrane and its enclosed cargo are released into the lysosome where they are degraded by the acid hydrolases.

The Rate of Nonselective Autophagy Is Regulated by Nutrient Availability

The activity of the ATG1 kinase complex that initiates autophagosome formation is tightly regulated. Most of the time, it is kept inactive because of phosphorylation by another protein kinase called the mTOR complex 1 (discussed in Chapter 15). The activity of mTOR complex 1 is dependent on the availability of certain amino acids generated by the recycling of proteins in the lysosome. When these amino acids become limiting, mTOR complex 1 activity is reduced, relieving its inhibition of the ATG1 complex. Activation of the ATG1 complex initiates nonselective autophagy to degrade bulk cytosol in lysosomes, thereby generating amino acids that activate the mTOR complex 1. Through this feedback loop, the rate of nonselective autophagy is dynamically regulated by the nutrient status of the cell.

Starvation-induced nonselective autophagy is particularly important in mammals in the hours immediately after birth. During this transition period, the constant nutrient supply from the womb is abruptly lost, and feeding by mouth has not yet started. Rapid acquisition of amino acids via autophagy is used to sustain critical cellular functions until a steady source of food from the mother

MBOC7_ptr_ch13_749-810.indd 805 08/12/21 11:39 AM

is established. In mammals, the rate of autophagy is controlled by several other signaling pathways in addition to the mTOR complex 1. This regulation allows the cell to integrate multiple external and internal cues, such as growth factor signaling and ATP levels, into a decision about the rate of recycling of macromolecules in the cytosol.

A Family of Cargo-specific Receptors Mediates Selective Autophagy

Selective autophagy mediates the degradation of invading microbes, damaged or otherwise unwanted organelles, and protein complexes or aggregates that are too large for degradation by the proteasome. The steps of autophagosome formation and its fusion with lysosomes are the same as in nonselective autophagy. Selective autophagy differs only at the very early stages when the cargo destined for degradation is recruited to the concave surface of the forming autophagosome membrane. This recruitment is mediated by specialized receptor proteins that recognize the cargo and have a binding site for the autophagosome-specific protein ATG8.

To accommodate the large range of potential cargoes, cells have evolved numerous cargo-specific autophagy receptors. In most cases, autophagy receptors recognize their cargo via a mark that is acquired only when the cargo is destined for degradation. The most commonly used mark is ubiquitin. For example, bacteria that escape from phagosomes and invade the cytosol are recognized by cytosolic proteins that ubiquitylate proteins on the bacterial surface. Several cargo receptors recognize the ubiquitin and other bacteria-specific proteins and recruit ATG8-containing vesicles. These vesicles fuse together, and the forming autophagosome effectively zippers around the cargo to engulf it without trapping bulk cytosol in the process (Figure 13–72A). This is why the shape of an autophagosome during selective autophagy typically reflects the shape of its cargo (Figure 13–72B).

The selective autophagy of worn out or damaged mitochondria is called *mitophagy*. As discussed in Chapters 12 and 14, when mitochondria function normally, the inner mitochondrial membrane is energized by an electrochemical H⁺ gradient that drives ATP synthesis and the import of mitochondrial precursor proteins and metabolites. Damaged mitochondria cannot maintain the gradient, so protein import is blocked. As a consequence, a protein kinase called Pink1, which is normally imported into mitochondria, is instead retained on the mitochondrial surface where it recruits the ubiquitin ligase Parkin from the cytosol. Parkin ubiquitylates mitochondrial outer membrane proteins, which serves as a mark for a ubiquitin-dependent cargo receptor for autophagy. Mutations in Pink1 or Parkin cause a form of early-onset Parkinson's disease, a degenerative disorder of the central nervous system. It is not known why the neurons that die prematurely in this disease are particularly reliant on mitophagy.

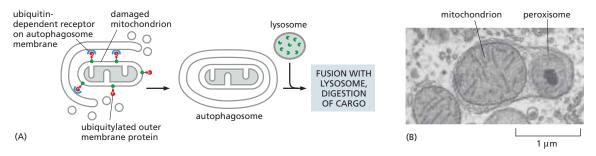

Figure 13–72 Selective autophagy is mediated by receptors that recruit cargo to the autophagosome membrane. MBOC7_ptr_ch13_749-810.indd 806 08/12/21 11:39 AM

Some Lysosomes and Multivesicular Bodies Undergo Exocytosis

Targeting of material to lysosomes is not necessarily the end of the pathway. Lysosomal secretion of undigested content enables cells to eliminate indigestible debris. For most cells, this seems to be a minor pathway, used only when the cells are stressed. Some cell types, however, contain specialized lysosomes that have acquired the necessary machinery for fusion with the plasma membrane. Melanocytes in the skin, for example, produce and store pigments in their lysosomes. These pigment-containing melanosomes release their pigment into the extracellular space of the epidermis by exocytosis. The melanosomes are then taken up by keratinocytes, leading to normal skin pigmentation. In some genetic disorders, defects in melanosome exocytosis block this transfer process, leading to forms of hypopigmentation (albinism). Under certain conditions, multivesicular bodies can also fuse with the plasma membrane. If that occurs, their intralumenal vesicles are released from cells. Circulating small vesicles, also called exosomes, have been observed in the blood and may be used to transport components between cells, although the importance of such a mechanism of potential communication between distant cells is unknown. Some exosomes may derive from direct vesicle budding events at the plasma membrane similar to how some viruses bud and are released from the cell (see Figure 13-61).

Summary

Lysosomes are specialized for the intracellular digestion of macromolecules. They contain unique membrane proteins and a wide variety of soluble hydrolytic enzymes that operate best at pH 5, which is the internal pH of lysosomes. An ATP-driven H⁺ pump in the lysosomal membrane maintains this low pH. In plants and fungi, lysosome-related compartments called vacuoles are adapted for other functions including storage, regulation of cell volume, and maintenance of turgor pressure. Lysosomes are the end product of endosome maturation. Cell-surface proteins that are endocytosed into endosomes are degraded in lysosomes unless they are retrieved back to the plasma membrane. Extracellular contents internalized by micropinocytosis are also delivered via endosomes to lysosomes and provide a source of nutrients under some conditions.

Lysosomes can receive content from two other routes. In phagocytosis, cells can engulf large particles including bacteria and even other cells into phagosomes that fuse with lysosomes. Phagocytosis is usually a receptor-mediated process and is especially prominent in some specialized cell types such as macrophages. In autophagy, cells engulf parts of their own cytoplasm into a double-membrane structure called an autophagosome. The autophagosome can engulf random parts of cytosol nonselectively or specific cargoes identified by selective receptors. Nonselective autophagy is used to recycle macromolecules into their building blocks during nutrient starvation. Selective autophagy is used to destroy invading microbes, protein aggregates, and damaged or unwanted organelles.

MBOC7_ptr_ch13_749-810.indd 807 08/12/21 11:39 AM

PROBLEMS

Which statements are true? Explain why or why not.

- **13–1** In all events involving fusion of a vesicle to a target membrane, the cytosolic leaflets of the vesicle and target bilayers always fuse together, as do the leaflets that are not in contact with the cytosol.
- **13–2** In order for a protein to exit from the ER, it must be correctly folded and, if part of a multiprotein complex, properly assembled.
- **13–3** When a foreign gene encoding a secretory protein is introduced into a secretory cell that normally does not make the protein, the alien secretory protein is not packaged into secretory vesicles.
- **13–4** More than 25 different receptors, including the low-density lipoprotein (LDL) receptor, participate in receptor-mediated endocytosis. In all cases, they enter coated pits only after they have bound their specific ligands.
- 13–5 Lysosomal membranes contain a proton pump that utilizes the energy of ATP hydrolysis to pump protons out of the lysosome, thereby maintaining the lumen at a low pH.

Discuss the following problems.

- 13–6 In a nondividing cell such as a liver cell, why must the flow of membrane between compartments be balanced, so that the retrieval pathways match the outward flow? Would you expect the same balanced flow in a gut epithelial cell, which is actively dividing?
- 13–7 For fusion of a vesicle with its target membrane to occur, the membranes have to be brought to within 1.5 nm so that the two bilayers can join (Figure Q13–1). Assuming that the relevant portions of the two membranes at the fusion site are circular regions 1.5 nm in diameter, calculate the number of water molecules that would remain between the membranes. (Water is 55.5 M and the volume of a cylinder is $\pi r^2 h$.) Given that an average phospholipid occupies a membrane surface area of 0.2 nm², how many phospholipids would be present in each of the opposing monolayers at the fusion site? Are there sufficient water molecules to bind to the hydrophilic head groups of this number of phospholipids? (It is estimated that 10–12 water molecules are normally associated with each phospholipid head group at the exposed surface of a membrane.)

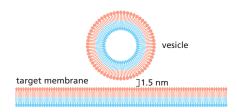

Figure Q13–1 Close approach of a vesicle and its target membrane in preparation for fusion (Problem 13–7).

13–8 SNAREs exist as complementary partners that carry out membrane fusions between appropriate vesicles and their target membranes. In this way, a vesicle with a particular variety of v-SNARE will fuse only with a membrane that carries the complementary t-SNARE. In some instances, however, fusions of identical membranes (homotypic fusions) are known to occur. For example, when a yeast cell forms a bud, vesicles derived from the mother cell's vacuole move into the bud where they fuse with one another to form a new vacuole. These vesicles carry both v-SNAREs and t-SNAREs. Are both types of SNAREs essential for this homotypic fusion event?

To test this point, you have developed an ingenious assay for fusion of vacuolar vesicles. You prepare vesicles from two different mutant strains of yeast: strain B has a defective gene for vacuolar alkaline phosphatase (Pase); strain A is defective for the protease that converts the precursor of alkaline phosphatase (pro-Pase) into its active form (Pase) (Figure Q13-2A). Neither strain has

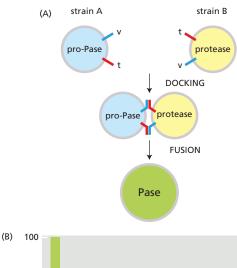

Figure Q13–2 SNARE requirements for vesicle fusion (Problem 13–8). (A) Scheme for measuring the fusion of vacuolar vesicles. (B) Results of fusions of vesicles with different combinations of v-SNAREs and t-SNAREs. The SNAREs present on the vesicles of the two strains are indicated as v (v-SNARE) and t (t-SNARE). (Adapted from B.J. Nichols et al., *Nature* 387:199-202, 1997.)

MBOC7_ptr_ch13_749-810.indd 808 08/12/21 11:39 AM

PROBLEMS 809

active alkaline phosphatase, but when extracts of the strains are mixed, vesicle fusion generates active alkaline phosphatase, which can be easily measured.

Now you delete the genes for the vacuolar v-SNARE, t-SNARE, or both, in each of the two yeast strains. You prepare vacuolar vesicles from each and test them for their ability to fuse, as measured by the alkaline phosphatase assay (Figure Q13-2B).

What do these data say about the requirements for v-SNAREs and t-SNAREs in the fusion of vacuolar vesicles?

Does it matter which kind of SNARE is on which vesicle?

13–9 Enveloped viruses, which have a membrane coat, gain access to the cytosol by fusing with a cell membrane. Why do you suppose that these viruses carry their own special fusion protein, rather than making use of a cell's SNAREs?

13–10 If you were to remove the ER retrieval signal from protein disulfide isomerase (PDI), which is normally a soluble resident of the ER lumen, where would you expect the modified PDI to be located?

13–11 The KDEL receptor must shuttle back and forth between the ER and the Golgi apparatus to accomplish its task of ensuring that soluble ER proteins are retained in the ER lumen. In which compartment does the KDEL receptor bind its ligands more tightly? In which compartment does it bind its ligands more weakly? What is thought to be the basis for its different binding affinities in the two compartments? If you were designing the system, in which compartment would you have the highest concentration of KDEL receptor? Would you predict that the KDEL receptor, which is a transmembrane protein, would itself possess an ER retrieval signal?

13–12 Drosophila shibire mutants, which carry a temperature-sensitive mutation in the dynamin gene, are rapidly paralyzed when the temperature is elevated. They recover quickly once the temperature is lowered. The complete paralysis at the elevated temperature suggests that synaptic transmission between nerve and muscle cells is blocked. Electron micrographs of nerve terminals from the paralyzed flies showed a loss of synaptic vesicles and a tremendously increased number of coated pits relative to normal synapses (Figure Q13–3). What step in

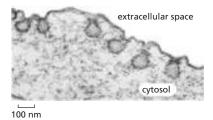

Figure Q13–3 Electron micrograph of a nerve terminal from a *shibire* mutant fly at elevated temperature (Problem 13–12). (From J.H. Koenig and K. Ikeda, *J. Neurosci.* 9:3844–3860, 1989. With permission from the Society of Neuroscience.)

synaptic transmission is defective in *shibire* mutants at high temperature?

13–13 A macrophage ingests the equivalent of 100% of its plasma membrane each half hour by endocytosis. What is the rate at which membrane is returned by exocytosis?

13–14 The recycling of transferrin receptors has been studied by covalently attaching radioactive iodine (^{125}I) to the receptors on the cell surface at 0°C and then following their fate at 0°C and 37°C. If the labeled cells were kept at 0°C and treated with trypsin to digest the receptors on the cell surface, all the labeled transferrin receptors were completely degraded. If the cells were first warmed to 37°C for 1 hour, then cooled back to 0°C and treated with trypsin, about 70% of the labeled receptors were resistant to trypsin. Why did the transferrin receptors respond differently to trypsin digestion depending on whether they were kept at 0°C or first warmed to 37°C before they were returned to 0°C?

13–15 How does the low pH of lysosomes protect the rest of the cell from lysosomal enzymes in case the lysosome breaks?

13–16 Melanosomes are specialized lysosomes that store pigments for eventual release by exocytosis. Various cells such as skin and hair cells then take up the pigment, which accounts for their characteristic pigmentation. Mouse mutants that have defective melanosomes often have pale or unusual coat colors. One such light-colored mouse, the *Mocha* mouse (**Figure Q13–4**), has a defect in the gene for one of the subunits of the adaptor protein complex AP3, which is associated with coated vesicles budding from the *trans* Golgi network. How might the loss of AP3 cause a defect in melanosomes?

Figure Q13–4 A normal mouse and the *Mocha* mouse (Problem 13–16). In addition to its light coat color, the *Mocha* mouse has a poor sense of balance. (Courtesy of Margit Burmeister.)

Energy Conversion and Metabolic Compartmentation: Mitochondria and Chloroplasts

CHAPTER

14

To maintain their high degree of organization in a universe that is constantly drifting toward chaos, cells have a constant need for a plentiful supply of ATP, as explained in Chapter 2. In eukaryotic cells, most of the ATP that powers life processes is produced by specialized, membrane-enclosed, *energy-converting organelles*. These are of two types. **Mitochondria** burn food molecules to produce ATP by *oxidative phosphorylation*, and they are present in virtually all cells of animals, plants, and fungi. In contrast, **chloroplasts** harness solar energy to produce ATP by *photosynthesis*, and they occur only in plants and green algae. In electron micrographs, the most striking features of both mitochondria and chloroplasts are their extensive internal membrane systems. These internal membranes contain sets of membrane protein complexes that work together to harvest energy and then use that energy to catalyze the production of most of the cell's ATP.

Comparisons of DNA sequences suggest that the energy-converting organelles in present-day eukaryotes originated from prokaryotic cells that entered symbiotic relationships during the evolution of eukaryotes (discussed in Chapter 1). This would explain why mitochondria and chloroplasts contain their own DNA, which still encodes a subset of their proteins. Over time, the majority of the genes originally encoded in the prokaryotic genome appear to have been transferred to the nuclear genome. As a result, these organelles have become heavily dependent on those nuclear-encoded proteins being synthesized in the cytosol and then imported into the organelle. And eukaryotic cells rely on these organelles not only for the ATP they need for biosynthesis, solute transport, and movement, but also for many important biosynthetic reactions that occur inside each organelle.

The common evolutionary origin of the energy-converting machinery in mitochondria, chloroplasts, and prokaryotes (archaea and bacteria) is reflected in the fundamental mechanism that they share for harnessing energy. This mechanism is known as **chemiosmotic coupling**, signifying a link between the chemical bond-forming reactions that generate ATP ("chemi") and membrane transport processes ("osmotic"). The chemiosmotic process, which occurs in two linked stages, is performed by protein complexes embedded in the membrane that is colored in the bacterium, mitochondrion, and chloroplast shown in **Figure 14–1**.

Stage 1: High-energy electrons (derived from the oxidation of food molecules, from pigments excited by sunlight, or from other sources described later) are transferred along a series of electron-transport protein complexes that form an *electron-transport chain* embedded in a membrane. Each electron transfer releases a small amount of energy that is used to pump

IN THIS CHAPTER

The Proton Pumps of the Electron-Transport Chain

ATP Production in Mitochondria

Chloroplasts and Photosynthesis

The Genetic Systems of Mitochondria and Chloroplasts

Figure 14-1 The membranes of bacteria, mitochondria, and chloroplasts that carry out chemiosmotic energyconversion processes. Mitochondria and chloroplasts are cell organelles that have originated from bacteria and have retained the bacterial energy-conversion mechanisms as well as other features of their ancestry. Like their bacterial ancestors, mitochondria and chloroplasts have an outer and an inner membrane. For each type of cell or organelle, it is the membrane that is colored in the figure that contains its energy-harvesting electron-transport chains. The deep invaginations of the mitochondrial inner membrane and the internal membrane system of the chloroplast harbor the machinery for cellular respiration and photosynthesis, respectively.

MBOC7_ptr_ch14_811-872.indd 811 02/12/21 2:31 PM

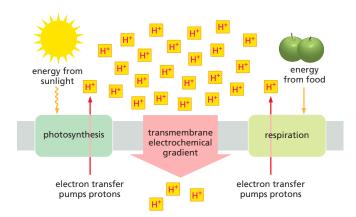

Figure 14–2 Stage 1 of chemiosmotic coupling. Energy from either sunlight or the oxidation of food compounds is captured by special, membrane-embedded protein complexes to generate an electrochemical proton gradient across a membrane. The electrochemical gradient serves as a versatile energy store that drives energy-requiring reactions in mitochondria, chloroplasts, and prokaryotes (bacteria and archaea).

protons (H⁺) and thereby generate a large *electrochemical gradient* across the membrane (**Figure 14–2**). As discussed in Chapter 11, such an electrochemical gradient provides a way of temporarily storing energy, and it can be harnessed to do useful work when ions flow back across the membrane.

Stage 2: The protons flow back down their electrochemical gradient through an elaborate membrane protein machine called *ATP synthase*, which uses this energy to catalyze the production of ATP from ADP and inorganic phosphate. This ubiquitous enzyme works like a turbine in the membrane, driven by a flow of protons, to synthesize ATP (Figure 14–3). In this way, the energy derived from either food or sunlight in stage 1 is converted into the chemical energy of a phosphate bond in ATP.

Electrons can move through protein complexes in biological systems via tightly bound metal ions or other carriers that take up and release electrons easily or by special small molecules that pick electrons up at one location and deliver them to another. For mitochondria, one critical electron carrier is NAD⁺, a water-soluble small molecule that takes up two electrons and one H⁺ derived from food molecules (fats and carbohydrates) to become NADH (see Figure 2-36). NADH transfers these electrons from food-derived molecules to the inner mitochondrial membrane. There, the electrons from the energy-rich NADH are passed from one membrane protein complex to the next, transitioning to a lower-energy state at each step, until they reach a final complex in which they combine with molecular oxygen (O₂) plus protons to produce water. The energy released at each step as the electrons flow down this path from the energy-rich NADH to the low-energy water molecule drives H⁺ pumps that are embedded in three different protein complexes in the inner mitochondrial membrane. Together, these three complexes generate the proton gradient (or proton-motive force) that is harnessed by ATP synthase to produce ATP—the molecule that serves as the universal energy currency throughout the cell.

Figure 14-4 compares the electron-transport processes in mitochondria, which harness energy from food molecules, with those in chloroplasts, which harness energy from sunlight. The energy-conversion systems of mitochondria and chloroplasts can be described in similar terms, and we shall see later in the chapter that two of their key components are closely related. One of these is the ATP synthase, and the other is a proton pump.

Among the crucial constituents that are unique to photosynthetic organisms are the two *photosystems*. These use the green pigment chlorophyll to capture light energy and power the transfer of electrons. The net result of the series of electron transfers in chloroplasts is opposite to the net result in mitochondria. In mitochondria, electrons derived from food are transferred to O_2 , with water and CO_2 being the final products. But in photosynthesis, electrons are taken from water to produce O_2 , and these electrons are used to synthesize carbohydrates from CO_2 and water. These carbohydrates then serve as the source for the other compounds a plant cell needs.

Thus, both mitochondria and chloroplasts make use of an electron-transfer chain to produce an H⁺ gradient that powers reactions that are critical for the cell.

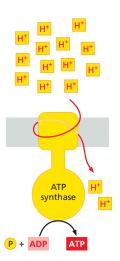

Figure 14–3 Stage 2 of chemiosmotic coupling. An ATP synthase protein machine (yellow) embedded in the lipid bilayer of a membrane harnesses the electrochemical proton gradient across the membrane, using this energy store to drive ATP synthesis. The red arrow shows the direction of proton movement through the ATP synthase.

MBOC7_ptr_ch14_811-872.indd 812 02/12/21 2:31 PM

THE MITOCHONDRION 813

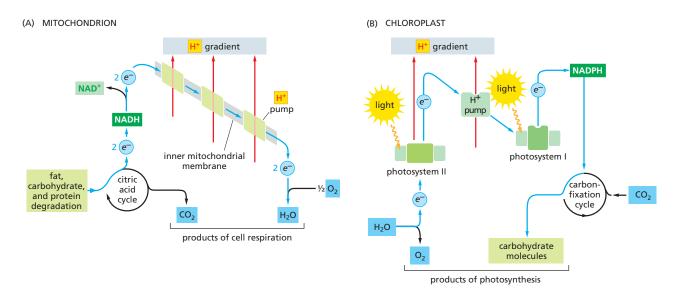

Figure 14–4 A comparison of two electron-conversion processes. The mitochondrion converts energy from chemical fuels, whereas the chloroplast converts energy from sunlight. In both cases, electron flow is indicated by *blue arrows*. As indicated, the electrons pass through a series of protein complexes embedded in a membrane. (A) In the mitochondrion, energy-rich molecules derived from fat, carbohydrate, or protein degradation are fed into the citric acid cycle. This cycle provides electrons to generate the energy-rich compound NADH from NAD⁺. The NADH electrons then flow down an energy gradient as they pass from one protein complex to the next in the mitochondrial electron-transport chain, until they combine with molecular O_2 and H⁺ in the final complex to produce water. The energy released is harnessed by the three protein complexes to pump H⁺ across the membrane. (B) In the chloroplast, by contrast, light-derived energy is used to extract electrons from water in the photosystem II complex, and molecular O_2 is released. The high-energy electrons produced by photosystem II are passed to the next protein complex in the chain, which uses some of the energy derived from electron transfer to pump protons across the membrane, before passing the electrons to photosystem I, where sunlight generates high-energy electrons that combine with NADP⁺ to produce NADPH (NADPH is a small molecule closely related to the NADH used in mitochondria). This NADPH then enters the *carbon-fixation cycle* along with CO₂ to generate the carbohydrates that provide both the carbon and the energy required for cell processes. Note that the products in A are the inputs for B, while the products in B are inputs for A.

However, chloroplasts generate O_2 and take up CO_2 , whereas mitochondria consume O_2 and release CO_2 (see Figure 14–4). Plants provide the food for animals, and the complementary chemistry that is performed by mitochondria and chloroplasts has been fundamental for producing a sustainable ecosystem on Earth—balancing O_2 with CO_2 and carbohydrate production with carbohydrate consumption.

THE MITOCHONDRION

Mitochondria can occupy up to 20% of the cytoplasmic volume of a eukary-otic cell. Although they are often depicted as short, bacterium-like bodies with a diameter of 0.5–1 μm , they are in fact remarkably dynamic and plastic, moving about the cell, constantly changing shape, dividing, and fusing (Movie 14.1). Mitochondria are often associated with the cytoskeleton, which determines their distribution in different cell types. Thus, in highly polarized cells such as neurons, mitochondria can move long distances (up to a meter or more in the extended axons of neurons), being propelled along microtubule tracks from where they are formed in the cell body to sites of energy demand like synapses (Movie 14.2). In other cells, mitochondria remain fixed at points of high energy demand; for example, in skeletal or cardiac muscle cells, they pack between myofibrils, and in sperm cells they wrap tightly around the flagellum (Figure 14–5).

In addition to their directional movement along cytoskeletal filaments, mitochondria undergo highly dynamic interactions with other membrane systems in the cell, most notably the endoplasmic reticulum (ER). Contacts between mitochondria and ER define specialized domains thought to facilitate the exchange of lipids, calcium, and potentially other molecules between the two

MBOC7_ptr_ch14_811-872.indd 813 02/12/21 2:31 PM

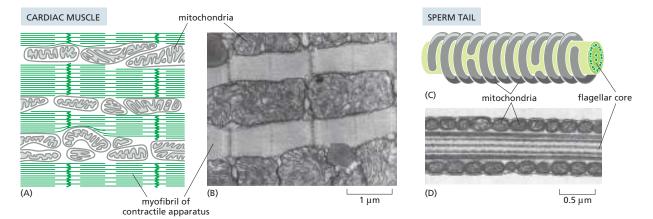

Figure 14–5 Localization of mitochondria near sites of high ATP demand. (A) In a cardiac muscle cell, mitochondria are located close to the contractile apparatus, where ATP hydrolysis provides the energy for contraction. The structure of the contractile apparatus is discussed in Chapter 16. (B) An electron micrograph of cardiac muscle shows a preponderance of mitochondria. (C) In a sperm, mitochondria are located in the tail, wrapped around a portion of the motile flagellum that requires ATP for its movement. The internal structure of the flagellar core is discussed in Chapter 16. (D) Micrograph showing a flagellum that has been thinly sliced to reveal the internal core structure as well as the surrounding mitochondria. (B, Keith Porter papers, Center for Biological Sciences Archives, University of Maryland, Baltimore County; D, from W. Bloom and D.W. Fawcett, A Textbook of Histology, 10th ed. Philadelphia, PA: W.B. Saunders Company, 1975. Reprinted with permission from the Estate of D.W. Fawcett.)

membrane systems. These regions of ER contact appear to be specialized domains that are also the sites of mitochondrial fission, which aids the distribution and partitioning of the mitochondria within cells, as we discuss later.

The acquisition of mitochondria was a prerequisite for the evolution of complex animals. Without mitochondria, present-day animal cells would have had to generate all of their ATP through glycolysis. When glycolysis converts glucose to pyruvate, it releases only a small fraction of the total free energy that is potentially available from glucose oxidation (see Chapter 2). In mitochondria, the metabolism of sugars is complete: pyruvate is imported into the mitochondrion and ultimately oxidized to $\rm CO_2$ and $\rm H_2O$, which allows 15 times more ATP to be made from a sugar than by glycolysis alone. As explained later, this energy source became available only after enough molecular oxygen had accumulated in Earth's atmosphere to allow organisms to take advantage, via respiration, of the energy potentially available from the complete oxidation of organic compounds.

The Mitochondrion Has an Outer Membrane and an Inner Membrane

Like the bacteria from which they likely originated, mitochondria have an outer and an inner membrane. The two membranes have distinct functions and properties, and they delineate separate compartments within the organelle. The inner membrane, which surrounds the internal **mitochondrial matrix** compartment (**Figure 14–6**), is highly folded to form invaginations known as **cristae** (the singular is crista), which contain in their membranes the proteins of the electron-transport chain. Where the inner membrane runs parallel to the outer membrane, between the cristae, it is known as the *inner boundary membrane*. The narrow (20–30 nm) gap between the inner boundary membrane and the outer membrane is known as the **intermembrane space**. The cristae are about 20-nm-wide membrane discs or tubules that protrude deeply into the matrix and enclose the *crista space*. The *crista membrane* is continuous with the inner boundary membrane, and where their membranes join, the membrane forms narrow membrane tubes or slits, known as *crista junctions*.

Like the bacterial outer membrane, the **outer mitochondrial membrane** is freely permeable to ions and to small molecules as large as 5000 daltons. This is because it contains many porin molecules, a special class of β -barrel-type

MBOC7_ptr_ch14_811-872.indd 814 02/12/21 2:31 PM

THE MITOCHONDRION 815

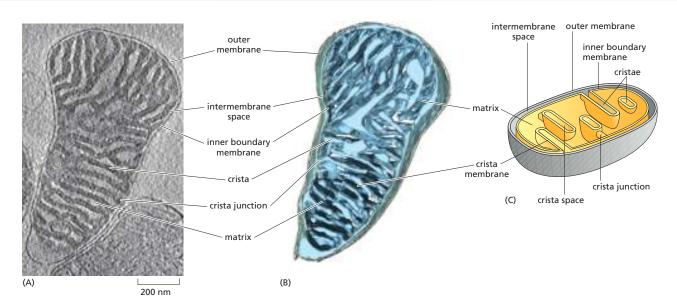

Figure 14–6 Structure of a mitochondrion. (A) Tomographic slice through a three-dimensional map of a mouse heart mitochondrion determined by electron microscope tomography. The outer membrane envelops the inner boundary membrane. The inner membrane is highly folded into tubular or lamellar cristae, which crisscross the matrix. The dense matrix, which contains most of the mitochondrial protein, appears dark in the electron microscope, whereas the intermembrane space and the crista space appear light because of their lower protein content. The inner boundary membrane follows the outer membrane closely at a distance of ~20 nm. The inner membrane turns sharply at the crista junctions, where the cristae join the inner boundary membrane. (B) Tomographic surface-rendered portion of a mouse heart mitochondrion, showing how flattened cristae project into the matrix from the inner membrane (Movie 14.3). (C) Schematic drawing of a mitochondrion showing the outer membrane (gray) and the inner membrane (yellow). Note that the inner membrane is compartmentalized into the inner boundary membrane and the crista membrane. There are three distinct spaces: the intermembrane space, the crista space, and the matrix. (A and B, courtesy of Tobias Brandt.)

membrane protein that creates aqueous pores across the membrane (see Figure 10–21). As a consequence, the intermembrane space between the outer and inner membrane has a pH and ionic composition very similar to that of the cytoplasm, and there is no electrochemical gradient across the outer membrane.

Fission, Fusion, Distribution, and Degradation of Mitochondria

In mammalian cells, mitochondrial DNA makes up less than 1% of the total cellular DNA. In other cells, however, a larger fraction of the cellular DNA may be present in mitochondria or chloroplasts (Table 14–1), and a large fraction of the total RNA and protein synthesis takes place in the organelles.

TABLE 14–1 Quantity of Organelles and Organelle DNA in Some Cells and Tissues					
Organism	Tissue or cell type	DNA molecules per organelle	Organelles per cell	Organelle DNA as percentage of total cellular DNA (%)	
Mitochondrial DNA					
Rat	Liver	5–10	1000	1	
Yeast*	Vegetative	2–50	1–50	15	
Chloroplast DNA					
Chlamydomonas	Vegetative	80	1	7	
Maize	Leaves	0–300**	20–40	0–15**	

^{*}The large variation in the number and size of mitochondria per cell in yeasts is due to mitochondrial fusion and fission.

MBOC7_ptr_ch14_811-872.indd 815 02/12/21 2:31 PM

^{**}In maize, the amount of chloroplast DNA drops precipitously in mature leaves, after cell division ceases: the chloroplast DNA is degraded, and stable mRNAs persist to provide for protein synthesis.

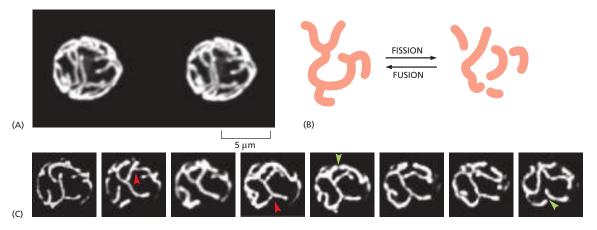

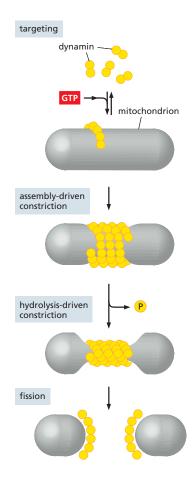

Figure 14–7 The mitochondrial reticulum is dynamic. (A) In yeast cells, mitochondria form a continuous reticulum on the cytoplasmic side of the plasma membrane (stereo pair). (B) A balance between fission and fusion determines the arrangement of the mitochondria in different cells. (C) Time-lapse fluorescence microscopy shows the dynamic behavior of the mitochondrial network in a yeast cell. In addition to shape changes, fission (green arrowheads) and fusion (red arrowheads) constantly remodel the network. These pictures were taken at 3-minute intervals. (A and C, from J. Nunnari et al., Mol. Biol. Cell 8:1233–1242, 1997. With permission from the American Society for Cell Biology.)

Mitochondria and chloroplasts are large enough to be visible by light microscopy in living cells. For example, mitochondria can be visualized by expressing in cells a genetically engineered fusion of a mitochondrial protein linked to green fluorescent protein (GFP), or cells can be incubated with a fluorescent dye that is specifically taken up by mitochondria because of their membrane potential. Such images demonstrate that the mitochondria in living cells are dynamic—frequently dividing by fission, fusing, and changing shape (Figure 14–7 and Movie 14.4). The fission of mitochondria may be necessary so that small parts of the network can pinch off and reach remote regions of the cell; for example, in the thin, extended axon and dendrites of a neuron, for them to be distributed to each of two daughters, or for them to be degraded by mitochondrial autophagy (see Chapter 13).

The fission and fusion of mitochondria are topologically complex processes that must ensure the integrity of the separate mitochondrial compartments defined by the inner and outer membranes. These processes control the number and shape of mitochondria, which can vary dramatically in different cell types, ranging from multiple spherical or wormlike organelles to a highly branched, net-shaped single organelle called a *reticulum*. Each process depends on its own special set of proteins. The mitochondrial fission machine works by assembling dynamin-related GTPases (discussed in Chapter 13) into helical oligomers that cause local constrictions in tubular mitochondria. GTP hydrolysis then generates the mechanical force that severs the inner and outer mitochondrial membranes in one step (Figure 14–8). Mitochondrial fusion requires two separate machineries, one each for the outer and the inner membrane (Figure 14–9).

Mitochondria that have become nonfunctional as assessed by loss of the proton electrochemical gradient typically become overly fragmented because of ongoing fission but loss of fusion. This state is typically coupled to the highly specific and organized degradation of such mitochondria through a

Figure 14–8 A model for mitochondrial division. Dynamin (yellow) exists as dimers in the cytosol, which form larger oligomeric structures in a process that requires GTP hydrolysis. At special sites of ER contact (not shown), dynamin assemblies interact with the outer mitochondrial membrane through special adaptor proteins, forming a spiral of GTP–dynamin around the mitochondrion that causes a constriction. A concerted GTP-hydrolysis event in the dynamin subunits is then thought to produce the conformational changes that result in fission. (Adapted from S. Hoppins et al., Annu. Rev. Biochem. 76:751–780, 2007. With permission from Annual Reviews.)

MBOC7_ptr_ch14_811-872.indd 816 02/12/21 2:31 PM

THE MITOCHONDRION 817

specialized organelle-specific form of autophagy known as mitophagy (see p. 806 in Chapter 13). One mechanism that induces autophagy is based on the fact that mitochondrial protein import becomes inefficient upon loss of the electrochemical gradient, causing the Pink1 protein kinase, which is normally imported into mitochondria, to be retained on the mitochondrial outer membrane. Pink1 then phosphorylates both mitochondria-associated ubiquitin and the mitophagy regulator Parkin to initiate the formation of an autophagosome that engulfs the damaged mitochondrion. The Parkin protein is so-named because mutations in the gene encoding it (as well as the gene encoding Pink1) are associated with Parkinson's disease, which can be characterized by an accumulation of nonfunctional mitochondria.

The Inner Membrane Cristae Contain the Machinery for Electron Transport and ATP Synthesis

Unlike the outer mitochondrial membrane, the **inner mitochondrial membrane** is a diffusion barrier to ions and small molecules, just like the inner membrane of a bacterium. However, selected ions, most notably protons and phosphate, as well as essential metabolites such as ATP, ADP, and pyruvate, can pass through it by means of specific transport proteins.

The inner mitochondrial membrane is highly differentiated into functionally distinct regions with different protein compositions. As discussed in Chapter 10, the lateral segregation of membrane regions with different protein and lipid compositions is a key feature of cells. The boundary membrane region of the inner mitochondrial membrane contains the machinery for protein import, for new membrane protein insertion, and for the assembly of the respiratory-chain complexes. The membranes of the cristae, despite being continuous with the boundary membrane, have a distinct composition. The crista membrane contains the ATP synthase enzyme that produces most of the cell's ATP: this large protein machine is also thought to structurally support the highly curved, crista membrane structure. The crista membrane also contains the large protein complexes of the **respiratory chain**—the name given to the mitochondrion's electron-transport chain. Cristae membranes have one of the highest protein densities of all biological membranes, with a lipid content of 25% and a protein content of 75% by weight.

At the cristae junctions, where the membranes of the cristae join the boundary membrane, specialized protein complexes provide a diffusion barrier that segregates the membrane proteins in the two regions of the inner membrane; these complexes are also thought to anchor the cristae to the outer membrane, thus maintaining the highly folded topology of the inner membrane. The folding of the inner membrane into cristae greatly increases the membrane area available for oxidative phosphorylation. In highly active cardiac muscle cells, for example, the total area of cristae membranes can be up to 20 times larger than the area of the cell's plasma membrane. In total, the surface area of cristae membranes in each human body adds up to roughly the size of a football field.

The Citric Acid Cycle in the Matrix Produces NADH

Together with the cristae that project into it, the matrix is the principal location for the majority of mitochondrial metabolic proteins. Mitochondria can use pyruvate, fatty acids, as well as other substrates as fuel. Pyruvate is derived from glucose and other sugars, whereas fatty acids are derived from fats. Unlike pyruvate and fatty acids, amino acids derived from protein degradation and the ketone bodies that can be produced from fatty acids are typically minor mitochondrial fuels, but they become very important substrates under specific situations such as prolonged fasting. All of these fuel molecules are transported across the inner mitochondrial membrane by specialized transport proteins, and they are then converted to the crucial metabolic intermediate *acetyl CoA* by enzymes located in the mitochondrial matrix (see Chapter 2).

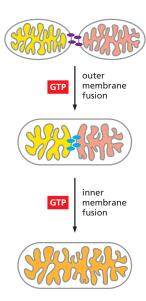

Figure 14-9 A model for mitochondrial fusion. The fusions of the outer and inner mitochondrial membranes are coordinated sequential events, each of which requires a separate set of protein factors. Outermembrane fusion is brought about by an outer-membrane GTPase (purple), which forms an oligomeric complex that includes subunits anchored in each of the two membranes to be fused. Fusion of outer membranes requires GTP and an H⁺ gradient across the inner membrane. For fusion of the inner membrane, a dynamin-related protein forms an oligomeric tethering complex (blue) that includes subunits anchored in the two inner membranes to be fused. Fusion of the inner membranes requires GTP and an electrical potential across the inner membrane. (Adapted from S. Hoppins et al., Annu. Rev. Biochem. 76:751-780, 2007. With permission from Annual Reviews.)

MBOC7_ptr_ch14_811-872.indd 817 02/12/21 2:31 PM

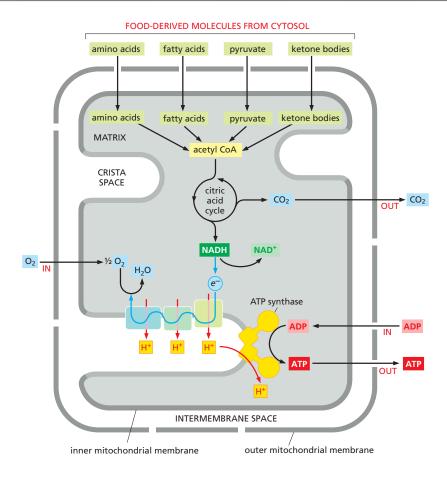

Figure 14-10 A summary of the energyconverting metabolism in mitochondria. Pyruvate, fatty acids, amino acids, and ketone bodies enter the mitochondrion (top of the figure) and are broken down to acetyl CoA. The acetyl CoA is oxidized through a series of steps by the citric acid cycle, passing electrons to NAD+ thereby generating NADH, which then passes its high-energy electrons to the first of three large protein complexes in the electrontransport chain. In the process of oxidative phosphorylation, these electrons pass along the electron-transport chain in the inner membrane cristae to oxygen (O2). This electron transport generates a proton gradient, which drives the production of ATP by the ATP synthase (see Figure 14-3).

The acetyl groups in acetyl CoA are oxidized in the matrix via the *citric acid cycle*, also called the Krebs cycle (see Figure 2–58 and Movie 2.6). The oxidation of these carbon atoms in acetyl CoA produces CO₂, which diffuses out of the mitochondrion to be released to the environment as a waste product. More important, the citric acid cycle saves a great deal of the bond energy released by this oxidation in the form of electrons carried by NADH. These electrons from NADH are transferred from the matrix to the electron-transport chain in the inner mitochondrial membrane, where—through the *chemiosmotic coupling* process described previously (see Figures 14–2 and 14–3)—the energy that was carried by NADH electrons is converted into phosphate-bond energy in ATP. Figure 14–10 outlines this sequence of reactions schematically.

The matrix contains the genetic system of the mitochondrion, including the mitochondrial DNA and the ribosomes. The large number of enzymes required for the maintenance of the mitochondrial genetic system, as well as for many other essential reactions to be outlined next, accounts for the very high protein concentration in the matrix; at more than 500 mg/mL, this concentration is close to that in a protein crystal.

Mitochondria Have Many Essential Roles in Cellular Metabolism

Mitochondria not only generate most of the cell's ATP; they also provide many other essential resources for biosynthesis and cell growth (Table 14–2). Before describing in detail the remarkable machinery of the respiratory chain, we diverge briefly to touch on some of these important roles.

Mitochondria are critical for buffering the redox potential in the cytosol. Cells need a constant supply of the electron acceptor NAD⁺ for the central reaction in glycolysis that converts glyceraldehyde 3-phosphate to 1,3-bisphosphoglycerate

MBOC7_ptr_ch14_811-872.indd 818 02/12/21 2:31 PM

THE MITOCHONDRION 819

TABLE 14–2 Mitochondrial Functions				
Function	Description			
Production of ATP	Oxidative phosphorylation in mitochondria produces most of the ATP used by eukaryotic cells			
Regeneration of NAD ⁺	NAD ⁺ is required for glycolysis and other reactions; under aerobic conditions, this NAD ⁺ is regenerated when NADH donates electrons to oxygen via the respiratory chain (see Chapter 2)			
Provision of precursors for biosynthesis of amino acids, nucleotides, fatty acids	Intermediates produced by the citric acid cycle, which takes place in the mitochondrial matrix, serve as precursors for the synthesis of many macromolecules (see Figure 2–60)			
Participation in synthesis of heme and iron–sulfur clusters	These metal-containing components are synthesized in mitochondria and play a central role in respiration and other cellular processes			
Cell signaling	Mitochondria buffer the concentration of Ca ²⁺ , an ion that plays a role in many signaling processes, including muscle contraction (see Chapters 15 and 16)			
Generation of reactive oxygen species	Although reactive oxygen species can damage macromolecules, they are also involved in signaling			
Regulation of apoptosis	Molecules released from mitochondria trigger a proteolytic cascade that leads to cell death (see Chapter 18)			

(see Figure 2–47). This NAD⁺ is converted to NADH in the process, and the NAD⁺ needs to be regenerated by transferring the high-energy NADH electrons somewhere. The NADH electrons will eventually be used to help drive oxidative phosphorylation inside the mitochondrion. But the inner mitochondrial membrane is impermeable to NADH. The electrons are therefore passed from the NADH to smaller molecules in the cytosol that can move through the inner mitochondrial membrane. Once in the matrix, these smaller molecules transfer their electrons to the NAD⁺ located there to form mitochondrial NADH, after which they are returned to the cytosol for recharging—creating a so-called *shuttle system* for the NADH electrons.

In cells with adequate access to oxygen, this shuttle system and the electron-transport chain provide the cell with a nearly boundless sink for electrons. But under conditions of low oxygen, such as in strenuously exercised muscle or in the center of a poorly vascularized tumor, a cell must change its metabolic program in major ways in order to generate its ATP (see p. 1175 in Chapter 20).

The biosynthesis needed in the cytosol for cell division, cell growth, and normal cell maintenance requires, in addition to ATP, both a constant supply of reducing power and small carbon-rich molecules to serve as the building blocks for the synthesis of nucleotides, amino acids, lipids, and other specialized molecules (discussed in Chapter 2). The reducing power comes from NADPH, a close relative of NADH (see Figure 2-36). Most of this NADPH is produced in the cytosol by a side pathway for the breakdown of sugars (the pentose phosphate pathway, an alternative to glycolysis). The needed carbon-rich molecules are almost completely derived from either intermediates of glycolysis or intermediates of the mitochondrial citric acid cycle (the "carbon skeletons" in Panel 2-1, pp. 94-95). For example, citrate produced in the mitochondrial matrix by the citric acid cycle is transported down its electrochemical gradient to the cytosol, where it is metabolized to produce the acetyl CoA that is required in the cytosol to support the production of the fatty acids and sterols that build new membranes (described in Chapter 10). Rapidly dividing normal cells and cancer cells frequently adapt their metabolism in ways that enhance this and other biosynthetic pathways, as part of their program of cell growth (see Figure 20-30).

While the majority of the reactions involved in nucleotide biosynthesis occur in the cytosol, important steps also occur in the mitochondria. For example, the molecules synthesized there provide the single-carbon units required for both purine and pyrimidine biosynthesis.

MBOC7_ptr_ch14_811-872.indd 819 02/12/21 2:31 PM

Mitochondria also play a particularly important role in the biosynthesis of protein building blocks. Mitochondrial acetyl-CoA, α -ketoglutarate, and oxaloacetate are all required for the *de novo* synthesis of amino acids, and, therefore, mitochondrial perturbations can affect amino acid metabolism. Conversely, perturbations in amino acid metabolism can have profound effects on mitochondrial energetics and function through indirect effects on the production and consumption of citric acid cycle intermediates and on the NADH $^+/NAD$ ratio.

The urea cycle is a central metabolic pathway in mammals that converts the ammonia $(\mathrm{NH_4}^+)$ produced by the breakdown of nitrogen-containing compounds (such as amino acids) to the urea excreted in urine. Two critical steps of the urea cycle are carried out in the mitochondria of liver cells, while the remaining steps occur in the cytosol.

The biosynthesis of *heme groups*—which, as we shall see in the next part of this chapter, play a central role in electron transfer—is another critical process that is shared between the mitochondrion and the cytoplasm. Iron–sulfur clusters, which are essential not only for electron transfer in the respiratory chain (see p. 826) but also for the maintenance and stability of the nuclear genome, are produced in mitochondria (and chloroplasts). Nuclear genome instability, a hallmark of cancer, can sometimes be linked to a decreased function of cellular proteins that contain iron–sulfur clusters. In fact, for those cells that can make sufficient ATP from glycolysis, it has been proposed that iron–sulfur cluster synthesis is the mitochondrial function most essential for viability.

Mitochondria also have a central role in the biosynthesis of membrane lipids. Cardiolipin is a two-headed phospholipid (Figure 14–11) that is confined to the mitochondrial membranes, where it is also produced. But mitochondria are also a major source of phospholipids for the biogenesis of other cell membranes. Phosphatidylethanolamine, phosphatidylglycerol, and phosphatidic acid are synthesized in the mitochondrion, while phosphatidylinositol, phosphatidylcholine, and phosphatidylserine are primarily synthesized in the endoplasmic reticulum (ER). As described in Chapter 12, most of the cell's membranes are assembled in the ER, and a critical exchange of lipids between ER and mitochondria is thought to occur at special sites of close contact.

Finally, mitochondria are important for specialized cellular signaling mechanisms. Mitochondria play a critical regulatory role in the major controlled process of eukaryotic cell death, known as apoptosis, as detailed in Chapter 18. In addition, mitochondria buffer calcium concentrations by taking up calcium from the ER (and the sarcoplasmic reticulum in muscle cells) at special membrane junctions.

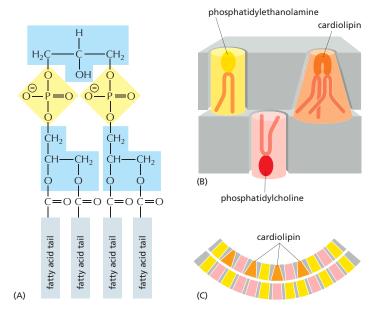

Figure 14-11 The structure of cardiolipin. (A) Cardiolipin consists of two covalently linked phospholipid units, with a total of four rather than the usual two fatty acid chains. (B) Phosphatidylcholine and phosphatidylethanolamine, which are conventional phospholipids and the most abundant lipid species in mitochondria, are shown for comparison. (C) Cardiolipin is produced in the mitochondrial membranes, where it interacts closely with membrane proteins involved in oxidative phosphorylation and ATP transport. In cristae, its unusual structure is thought to support the high curvature of this membrane, as indicated.

MBOC7_ptr_ch14_811-872.indd 820 02/12/21 2:31 PM

THE MITOCHONDRION 821

Intracellular calcium levels not only control muscle contraction (see Chapter 16); alterations of calcium levels are also implicated in neurodegeneration and apoptosis. Mitochondria are also the principal site of production of reactive oxygen species, which—while they can cause damage—also play important signaling roles. And the concentrations of a number of metabolites with regulatory roles are controlled by mitochondrial metabolism and transport. Clearly, cells and organisms depend on mitochondria in many different ways, and the co-housing of diverse functions in this organelle has important implications for cell function and survival.

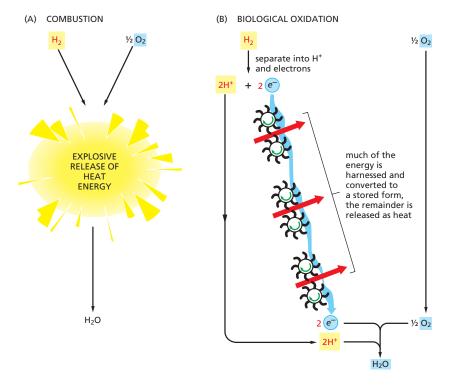

We now return to the central function of the mitochondrion in respiratory ATP generation.

A Chemiosmotic Process Couples Oxidation Energy to ATP Production

Although the citric acid cycle that takes place in the mitochondrial matrix is considered to be part of aerobic metabolism, it does not itself use oxygen. Only the final step of oxidative metabolism consumes molecular oxygen (O_2) directly.

Nearly all the energy available from metabolizing carbohydrates, fats, and other foodstuffs in earlier stages is saved in the form of energy-rich compounds that feed electrons into the respiratory chain in the inner mitochondrial membrane. These electrons, most of which are carried by NADH, finally combine with O_2 at the end of the respiratory chain to form water. The energy released during the complex series of electron transfers from NADH to O_2 is harnessed in the inner membrane to generate an electrochemical gradient that drives the conversion of ADP + phosphate to ATP. For this reason, the term **oxidative phosphorylation** is used to describe this final series of reactions (**Figure 14–12**).

The total amount of energy released by biological oxidation in the respiratory chain is equivalent to that released by the explosive combustion of hydrogen when it combines with oxygen in a single step to form water. But the combustion of hydrogen in a single-step chemical reaction, which has a strongly negative ΔG , releases this large amount of energy unproductively as heat. In the respiratory chain, the same energetically favorable reaction $H_2 + \frac{1}{2}O_2 \rightarrow H_2O$ is divided into small steps (Figure 14–13). This stepwise process allows the cell to capture

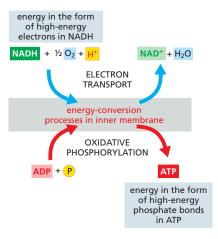

Figure 14–12 The major net energy conversion catalyzed by the mitochondrion. In the process of oxidative phosphorylation, the mitochondrial inner membrane serves as a device that changes one form of chemical-bond energy to another, converting a major part of the energy of NADH oxidation into phosphate-bond energy in ATP.

Figure 14-13 A comparison between the biological oxidation catalyzed by the respiratory chain and combustion. (A) If hydrogen were simply burned, nearly all of the energy would be released in the form of heat. (B) In biological oxidation, about half of the released energy is stored in a form useful to the cell by means of the electrontransport chain (the respiratory chain) in the crista membrane of the mitochondrion. The rest of the energy is released as heat. In the respiratory chain, the protons and electrons, shown here as being derived from H₂, are removed from hydrogen atoms that are covalently linked to NADH molecules.

MBOC7_ptr_ch14_811-872.indd 821 02/12/21 2:31 PM

and store nearly half of the total energy that is released in a useful form. At each step, the electrons, each of which can be thought of as having been removed from a hydrogen atom leaving a proton, pass through a series of electron carriers in the inner mitochondrial membrane. At each of three distinct steps along the way (marked by the three electron-transport complexes of the respiratory chain; see next part of this chapter), much of the energy released by electron transfer is utilized to produce an electrochemical gradient across the membrane (see Figure 14–2). At the end of the electron-transport chain, the electrons and protons recombine with molecular oxygen to produce water, a very low-energy molecule.

The Energy Derived from Oxidation Is Stored as an Electrochemical Gradient

In mitochondria, the process of electron transport begins when two electrons and a proton are removed from NADH (to regenerate NAD⁺). These electrons are passed to the first of about 20 different electron carriers in the respiratory chain. The electrons start at a large *negative* redox potential (see **Panel 14-1**, p. 825)—that is, at a high energy level—which gradually drops as they pass along the chain. Most of the electron carriers are housed in the three large multiprotein *respiratory enzyme complexes*, each composed of protein subunits that sit in the inner mitochondrial membrane. Each complex in the chain has a higher affinity for electrons than its predecessor, and electrons pass sequentially from one complex to the next until they are finally transferred to molecular oxygen, which has the highest electron affinity of all.

The net result is the pumping of H^+ out of the matrix across the inner membrane, driven by the energetically favorable flow of electrons. This transmembrane movement of H^+ has two major consequences:

- 1. It generates a pH gradient across the inner mitochondrial membrane, with a high pH in the matrix (close to 8) and a lower pH in the crista space.
- 2. It generates a voltage gradient across the inner mitochondrial membrane, creating a *membrane potential* with the matrix side negative and the crista space positive.

The pH gradient (Δ pH) reinforces the effect of the membrane potential (ΔV), because the latter acts to attract any positive ion into the matrix and to push any negative ion out. Together, Δ pH and ΔV make up the **electrochemical proton gradient**, which is measured in units of millivolts (mV). This gradient exerts a **proton-motive force**, which tends to drive H⁺ back into the matrix (**Figure 14–14**).

The electrochemical gradient across the inner membrane of a respiring mitochondrion is typically about 180 mV (the inside is electronegative), and it consists of a membrane potential of about 150 mV and a pH gradient of about 0.5 to

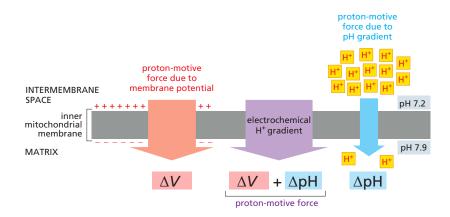

Figure 14–14 The electrochemical proton gradient across the inner mitochondrial membrane. This gradient is composed of a large force due to the membrane potential (ΔV) and a smaller force due to the H+ concentration gradient; that is, the pH gradient (ΔP H). Both forces combine to generate the proton-motive force, which pulls H+ back into the mitochondrial matrix. The exact relationship between these forces is expressed by the Nernst equation (see Panel 11–1, p. 656).

MBOC7_ptr_ch14_811-872.indd 822 02/12/21 2:31 PM

0.6 pH units (each ΔpH of 1 pH unit is equivalent to a membrane potential of about 60 mV). The electrochemical gradient drives not only ATP synthesis but also the energetically unfavorable transport of selected molecules across the inner mitochondrial membrane, including the import of nuclear-encoded proteins from the cytosol (discussed in Chapter 12).

Summary

The mitochondrion performs most cellular oxidations and produces the bulk of an animal cell's ATP. A mitochondrion has two separate membranes: the outer membrane and the inner membrane. The inner membrane surrounds the innermost space (the matrix) of the mitochondrion, and it forms the cristae that project into the matrix and contain the electron-transport chain (the respiratory chain). The mitochondrial matrix and the inner membrane crista are the major sites of mitochondrial metabolism.

The mitochondrial matrix contains a large variety of enzymes, including those that convert pyruvate and fatty acids to acetyl CoA and those that oxidize this acetyl CoA to CO2 through the citric acid cycle. These oxidation reactions produce large amounts of NADH, whose high-energy electrons are passed to the respiratory chain. The respiratory chain then uses the energy derived from transporting electrons from NADH to molecular oxygen to pump H^+ out of the matrix. This produces a large electrochemical proton gradient across the inner mitochondrial membrane, which is composed of contributions from both a membrane potential and a pH difference. This electrochemical gradient exerts a force to drive H^+ back into the matrix. This proton-motive force is harnessed both to produce ATP and to drive the selective transport of metabolites across the inner mitochondrial membrane.

THE PROTON PUMPS OF THE ELECTRON-TRANSPORT CHAIN

Having considered in general terms how a mitochondrion uses electron transport to generate a proton-motive force, we now turn to the molecular mechanisms that underlie this membrane-based energy-conversion process. In describing the respiratory chain of mitochondria, we accomplish the larger purpose of explaining how an electron-transport process can pump protons across a membrane. As stated at the beginning of this chapter, mitochondria, chloroplasts, archaea, and bacteria use very similar chemiosmotic mechanisms. In fact, these mechanisms underlie the function of all living organisms—including anaerobes that derive all their energy from electron transfers between two inorganic molecules, as we shall see later.

We start with some of the basic principles on which all of these processes depend.

The Redox Potential Is a Measure of Electron Affinities

In chemical reactions, any electrons removed from one molecule are always passed to another, so that whenever one molecule is oxidized, another is reduced. As with any other chemical reaction, the tendency of such **redox reactions** to proceed spontaneously depends on the free-energy change (ΔG) for the electron transfer, which in turn depends on the relative affinities of the two molecules for electrons.

Because electron transfers provide most of the energy for life, it is worth taking the time to understand them. As discussed in Chapter 2, acids donate protons and bases accept them (see Panel 2–2, pp. 96–97). Acids and bases exist in conjugate acid-base pairs, in which the acid is readily converted into the base by the loss of a proton. For example, acetic acid (CH₃COOH) is converted into its conjugate base, the acetate ion (CH₃COO $^-$), in the reaction:

 $CH_3COOH \Longrightarrow CH_3COO^- + H^+$

MBOC7_ptr_ch14_811-872.indd 823 02/12/21 2:31 PM

In an exactly analogous way, pairs of compounds such as NADH and NAD⁺ are called redox pairs, as NADH is converted to NAD⁺ by the loss of electrons in the reaction:

$$NADH \Longrightarrow NAD^+ + H^+ + 2e^-$$

NADH is a strong electron donor: because two of its electrons are engaged in a covalent bond, which releases energy when broken, the free-energy change for passing these electrons to many other molecules is favorable. Energy is required to form this bond from NAD^+ , two electrons, and a proton (the same amount of energy that is released when the bond is broken). Therefore NAD^+ , the redox partner of NADH, is of necessity a weak electron acceptor.

We can measure the tendency to transfer electrons from any redox pair experimentally. All that is required is the formation of an electrical circuit linking a 1:1 (equimolar) mixture of the redox pair to a second redox pair that has been arbitrarily selected as a reference standard, so that we can measure the voltage difference between them (see Panel 14–1). This voltage difference is defined as the redox potential; electrons move spontaneously from a redox pair like NADH/NAD+ with a lower redox potential (a lower affinity for electrons) to a redox pair like O_2/H_2O with a higher redox potential (a higher affinity for electrons). Thus, NADH is a good molecule for donating electrons to the respiratory chain, while O_2 is well suited to act as the "sink" for electrons at the end of the chain. As explained in Panel 14–1, the difference in redox potential, $\Delta E'_{0}$, is a direct measure of the standard free-energy change (ΔG°) for the transfer of an electron from one molecule to another.

While the standard redox potential is a useful tool to understand redox reactions, the true redox potential is also influenced by environmental factors in a cell such as pH, temperature, and electrostatic influences, which are often different from standardized conditions in cells. This issue is of particular relevance when the redox pair is embedded within a protein, where the environment is heavily influenced by nearby amino acid residues.

Electron Transfers Release Large Amounts of Energy

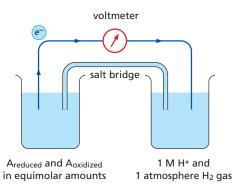

As just discussed, those pairs of compounds that have the most negative redox potentials have the weakest affinity for electrons and therefore are useful as carriers with a strong tendency to donate electrons. Conversely, those pairs that have the most positive redox potentials have the greatest affinity for electrons and therefore are useful as carriers for accepting electrons. A 1:1 mixture of NADH and NAD⁺ has a redox potential of -320 mV, indicating that NADH has a strong tendency to donate electrons; a 1:1 mixture of H_2O and $\frac{1}{2}O_2$ has a redox potential of +820 mV, indicating that O2 has a strong tendency to accept electrons. The difference in redox potential is 1140 mV, which means that the transfer of each electron from NADH to O2 under these standard conditions is enormously favorable, with ΔG° = -109 kJ/mole. Twice this amount of energy is gained for the two electrons transferred per NADH molecule (see Panel 14-1). If we compare this free-energy change with that for the formation of the phosphoanhydride bonds in ATP, where ΔG° = 30.6 kJ/mole (see Figure 2–49), we see that, under standard conditions, the oxidation of one NADH molecule releases more than enough energy to synthesize seven molecules of ATP from ADP and phosphate. (In the cell, the number of ATP molecules generated will be lower because the standard conditions are far from the physiological ones; in addition, energy is inevitably dissipated as heat due to imperfect efficiency in energy transfers.)

Transition Metal Ions and Quinones Accept and Release Electrons Readily

The electron-transport properties of the membrane protein complexes in the respiratory chain depend on electron-carrying *cofactors*, most of which utilize *transition metals* such as Fe, Cu, Ni, and Mn bound to proteins in the complexes.

MBOC7_ptr_ch14_811-872.indd 824 02/12/21 2:31 PM

HOW REDOX POTENTIALS ARE MEASURED

THE STANDARD REDOX POTENTIAL, E'_0

The standard redox potential for a redox pair, defined as E_0 , is measured for a standard state where all of the reactants are at a concentration of 1 M, including H⁺. Since biological reactions occur at pH 7, biologists instead define the standard state as $A_{\rm reduced} = A_{\rm oxidized}$ and H⁺ = 10^{-7} M. This standard redox potential is designated by the symbol E_0' , in place of E_0 .

One beaker (*left*) contains substance A with an equimolar mixture of the reduced ($A_{reduced}$) and oxidized ($A_{oxidized}$) members of its redox pair. The other beaker contains the hydrogen reference standard ($2H^+ + 2e^- \rightleftharpoons H_2$), whose redox potential is arbitrarily assigned as zero by international agreement. (A salt bridge formed from a concentrated KCl solution allows K+ and Cl- to move between the beakers, as required to neutralize the charges when electrons flow between the beakers.) The metal wire (*dark blue*) provides a resistance-free path for electrons, and a voltmeter then measures the redox potential of substance A. If electrons flow from $A_{reduced}$ to H+, as indicated here, the redox pair formed by substance A is said to have a negative redox potential. If they instead flow from H₂ to $A_{oxidized}$, the redox pair is said to have a positive redox potential.

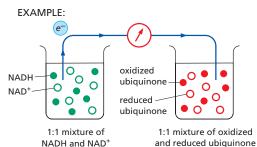

examples of redox reactions	standard redox potential E'_0
$NADH \rightleftharpoons NAD^{+} + H^{+} + 2e^{-}$	–320 mV
$\begin{array}{c} \text{reduced} \\ \text{ubiquinone} \end{array} \rightleftharpoons \begin{array}{c} \text{oxidized} \\ \text{ubiquinone} \end{array} + 2\text{H}^+ + 2e^- \end{array}$	+30 mV
$ \begin{array}{ccc} \text{reduced} & \rightleftharpoons & \text{oxidized} \\ \text{cytochrome c} & \vdash & \text{cytochrome c} & + e^- \end{array} $	+230 mV
$H_2O \rightleftharpoons \frac{1}{2}O_2 + 2H^+ + 2e^-$	+820 mV

CALCULATION OF ΔG° FROM REDOX POTENTIALS

To determine the energy change for an electron transfer, the $\Delta \textit{G}\,^\circ$ of the reaction (kJ/mole) is calculated as follows:

 $\Delta G^{\circ} = -n(0.096)\Delta E'_0$, where n is the number of electrons transferred across a redox potential change of $\Delta E'_0$ millivolts (mV), and

$$\Delta E'_0 = E'_0$$
 (acceptor) $-E'_0$ (donor)

For the transfer of one electron from NADH to ubiquinone:

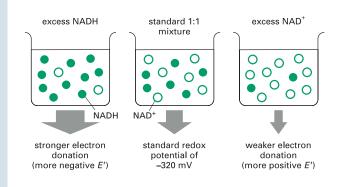

$$\Delta E'_0 = +30 - (-320) = +350 \text{ mV}$$

 $\Delta G^{\circ} = -n(0.096)\Delta E'_{0} = -1(0.096)(350) = -34 \text{ kJ/mole}$

The same calculation reveals that the transfer of one electron from ubiquinone to oxygen has an even more favorable ΔG° of –76 kJ/mole. The ΔG° value for the transfer of one electron from NADH to oxygen is the sum of these two values, –110 kJ/mole.

EFFECT OF CONCENTRATION CHANGES

As explained in Chapter 2, the actual free-energy change for a reaction, ΔG , depends on the concentration of the reactants and generally will be different from the standard free-energy change, ΔG° . The standard redox potentials are for a 1:1 mixture of the redox pair. For example, the standard redox potential of –320 mV is for a 1:1 mixture of NADH and NAD+. But when there is an excess of NADH over NAD+, electron transfer from NADH to an electron acceptor becomes more favorable. This is reflected by a more negative redox potential and a more negative ΔG for electron transfer.

MBOC7_ptr_ch14_811-872.indd 825 02/12/21 2:31 PM

Figure 14–15 The structure of the heme group attached covalently to cytochrome c.

The porphyrin ring of the heme is shown in *light red*. There are six different cytochromes in the respiratory chain. Because the hemes in different cytochromes have slightly different structures and are kept in different local environments by their respective proteins, each has a different affinity for an electron and a slightly different spectroscopic signature. Note that many heme-containing proteins, including others in the electron-transport chain, bind to heme noncovalently unlike the heme in cytochrome *c* shown here. They do so through noncovalent interactions of the protein with the porphyrin ring and the heme iron.

These metals have special properties that allow them to promote both enzyme catalysis and electron-transfer reactions. Most relevant here is the fact that their ions exist in several different oxidation states with closely spaced redox potentials, which enables them to accept or give up electrons readily; this property is exploited by the membrane protein complexes in the respiratory chain to move electrons both within and between complexes.

Unlike the colorless atoms H, C, N, and O that constitute the bulk of biological molecules, transition metal ions are often brightly colored, which makes the proteins that contain them easy to study by spectroscopic methods using visible light. One family of such colored proteins, the **cytochromes**, contains a bound *heme group*, in which an iron atom is tightly held by four nitrogen atoms at the corners of a square in a *porphyrin ring* (**Figure 14–15**). Similar porphyrin rings are responsible both for the red color of blood and for the green color of leaves, binding an iron in hemoglobin or a magnesium in chlorophyll, respectively.

Iron–sulfur proteins contain a second major family of electron-transfer cofactors. In this case, either two or four iron atoms are bound to an equal number of sulfur atoms and to cysteine side chains, forming iron–sulfur clusters in the protein (Figure 14–16). Like the cytochrome hemes, these clusters carry one electron at a time through redox reactions with the iron atoms.

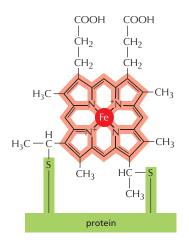

The simplest of the electron-transfer cofactors in the respiratory chain—and the only one that is not always bound to a protein—is a **quinone** (called *ubiquinone*, or *coenzyme Q*). A quinone (Q) is a small hydrophobic molecule that is freely mobile in the lipid bilayer. This *electron carrier* can accept or donate either one or two electrons. Upon reduction (note that reduced quinones are called quinols), it picks up a proton from water along with each electron (**Figure 14–17**).

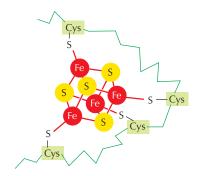

In the mitochondrial electron-transport chain, six different cytochrome hemes, eight iron-sulfur clusters, three copper atoms, a flavin mononucleotide (another electron-transfer cofactor), and ubiquinone work in a defined sequence to carry electrons from NADH to O₂. In total, this pathway involves more than 60 different polypeptides; these are arranged in three large membrane protein complexes, each of which binds several of the above electron-carrying cofactors (Figure 14–18).

As we will discuss later, there is an unusual additional respiratory chain complex that is an important component of the citric acid cycle, where it is known as *succinate dehydrogenase*. This membrane-embedded enzyme captures electrons during the conversion of succinate to fumarate (see Panel 2–9, pp. 110–111). It passes these electrons directly into the electron-transport chain via a flavin electron carrier (flavin adenine dinucleotide; FAD), instead of utilizing NAD⁺, and it does not pump protons (see Figure 14–18).

As we would expect, the electron-transfer cofactors have increasing affinities for electrons (higher redox potentials) as the electrons move along the respiratory chain. The redox potentials have been fine-tuned during evolution by the protein environment of each cofactor, which alters the cofactor's normal affinity for electrons. Because iron-sulfur clusters have a relatively low affinity for electrons,

Figure 14–16 The structure of an iron–sulfur cluster. Iron–sulfur clusters consist either of four iron and four sulfur atoms, as shown here, or of two irons and two sulfurs linked to cysteines in the polypeptide chain via covalent sulfur bridges; alternatively they may be linked to histidines. Although they contain several iron atoms, each iron–sulfur cluster can carry only one electron at a time. Nine different iron–sulfur clusters participate in electron transport in the respiratory chain.

MBOC7_ptr_ch14_811-872.indd 826 02/12/21 2:31 PM

they predominate in the first half of the respiratory chain; in contrast, the heme cytochromes predominate further down the chain, where a higher electron affinity is required.

NADH Transfers Its Electrons to Oxygen Through Three Large Enzyme Complexes Embedded in the Inner Membrane

Membrane proteins are difficult to purify because they are insoluble in aqueous solutions, and they are easily disrupted by the detergents that are required to solubilize them. But by using mild nonionic detergents, such as digitonin or dodecyl maltoside, they can be solubilized and purified in their native form. The three large, detergent-solubilized respiratory complexes can be reinserted into artificial lipid bilayer vesicles, and each protein complex can be shown to pump protons across the membrane as electrons pass through it.

In the mitochondrion, the three complexes are linked in series, serving as electron transport–driven H⁺ pumps that pump protons out of the matrix to acidify the crista space (see Figure 14–18):

- 1. The **NADH dehydrogenase complex** (typically called *Complex I*) is the largest of these respiratory enzyme complexes. It accepts electrons from NADH and passes them through a flavin mononucleotide and eight ironsulfur clusters to ubiquinone. The reduced ubiquinol then transfers its electrons to cytochrome *c* reductase.
- 2. The **cytochrome** c **reductase** (also called the *cytochrome* b- c_1 *complex* and typically called *Complex III*) is a large membrane protein assembly that functions as a dimer. Each monomer contains three cytochrome hemes and an iron–sulfur cluster. The complex accepts electrons from ubiquinol

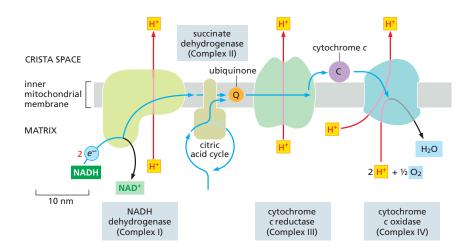

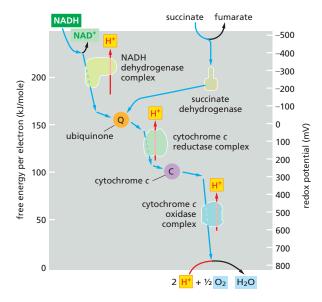

Figure 14-17 Quinone electron

carriers. Ubiquinone in the lipid bilayer picks up one H+ (red) from the aqueous environment for each electron (blue) it accepts from respiratory-chain complexes. The first step in this process involves the acquisition of a proton and an electron and converts the ubiquinone into an unstable ubisemiquinone radical. With the transfer of the second electron, it becomes a fully reduced ubiquinone (called ubiquinol). which is freely mobile as an electron carrier in the lipid bilayer of the membrane. When the ubiquinol donates its electrons to the next complex in the chain, the two protons are released. The long hydrophobic tail (green) that confines ubiquinone to the membrane consists of 6 to 10 five-carbon isoprene units, depending on the organism. The corresponding electron carrier in the photosynthetic membranes of chloroplasts is plastoquinone, which has almost the same structure and works in the same way. For simplicity, we refer to both ubiquinone and plastoquinone in this chapter as quinone (abbreviated as Q).

Figure 14–18 The path of electrons through the three respiratory-chain proton pumps (Movie 14.5). The approximate size and shape of each protein complex are shown. During the transfer of electrons from NADH to oxygen (blue arrows), ubiquinone and cytochrome c serve as mobile carriers that ferry electrons from one complex to the next. During the electron-transfer reactions, protons are pumped across the membrane by each of the respiratory enzyme complexes, as indicated (red arrows).

The three proton pumps in the respiratory chain are typically denoted as Complex I, Complex III, and Complex IV, according to the order in which electrons pass through them from NADH. Electrons from the oxidation of succinate by succinate dehydrogenase (designated as Complex II) are fed into the electron-transport chain in the form of reduced ubiquinone. Although embedded in the crista membrane, succinate dehydrogenase does not pump protons and thus does not contribute to the protonmotive force.

MBOC7 ptr ch14 811-872.indd 827 02/12/21 2:31 PM

and passes them on to the small, soluble protein cytochrome c, which is located in the crista space and carries electrons one at a time to cytochrome c oxidase.

3. The **cytochrome** *c* **oxidase complex** (typically called *Complex IV*) contains two cytochrome hemes and three copper atoms. The complex accepts electrons one at a time from cytochrome *c* and passes them to molecular oxygen. In total, four electrons and four protons are needed to convert one molecule of oxygen to water.

We have previously discussed how the redox potential reflects electron affinities. Figure 14–19 presents an outline of the redox potentials measured along the respiratory chain. These potentials change in three large steps, one across each proton-translocating respiratory complex. The change in redox potential between any two electron carriers is directly proportional to the free energy released when an electron transfers between them. Each complex acts as an energy-conversion device by harnessing some of this free-energy change to pump H⁺ across the inner membrane, thereby creating an electrochemical proton gradient as electrons pass along the chain. In addition to these proton-pumping complexes, the *succinate dehydrogenase* complex, which catalyzes the oxidation of succinate to fumarate in the citric acid cycle, is often also considered to be a component of the electron-transport chain. It is typically called *Complex II* because, like Complex I, it passes electrons to ubiquinone.

The assembly of each of these four protein complexes requires a precisely managed program because of their number of subunits and reactive cofactors. This is accomplished through the function of dedicated assembly factors that chaperone particular steps in the assembly and activation process. Loss of these assembly factors through mutation leads to human diseases; their loss mimics mutations that directly affect the complex subunits themselves.

X-ray crystallography (and, more recently, cryo-electron microscopy, or cryoEM) has elucidated the final structures of each of the respiratory-chain complexes in great detail, and we next examine each of them in turn to see how they work.

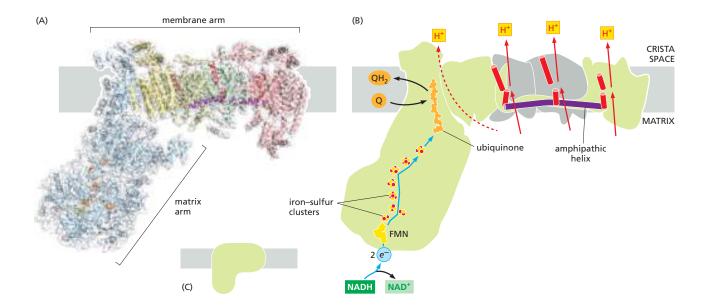

The NADH Dehydrogenase Complex Contains Separate Modules for Electron Transport and Proton Pumping

The NADH dehydrogenase complex is a massive assembly of proteins, some integral to the membrane and others not, that receives electrons from NADH and passes them to ubiquinone. In animal mitochondria, it consists of more than

Figure 14-19 Redox potential changes along the mitochondrial electrontransport chain. The redox potential (designated $\Delta E'_0$) increases as electrons flow down the respiratory chain to oxygen. The standard free-energy change in kilojoules, ΔG° , for the transfer of each of the two electrons donated by an NADH molecule can be obtained from the left-hand ordinate $[\Delta G^{\circ} = -n(0.096)]$ $\Delta E'_{\cap}$, where n is the number of electrons transferred across a redox potential change of $\Delta E'_0$ mV]. Electrons flow through a respiratory enzyme complex by passing in sequence through the multiple electron carriers in each complex (dotted portion of blue arrows). As indicated, part of the favorable free-energy change is harnessed by each enzyme complex to pump H+ across the inner mitochondrial membrane (red arrows). The NADH dehydrogenase pumps up to four H⁺ per electron, the cytochrome c reductase complex pumps two per electron, whereas the cytochrome c oxidase complex pumps one per electron.

Succinate dehydrogenase (Complex II) also passes electrons into the ubiquinone pool by oxidizing succinate and passing those electrons through a stably bound FAD+/FADH₂ redox pair. Fatty acid oxidation (see Figure 2–57) also leads to the generation of FADH₂, which also passes its two electrons directly to ubiquinone, bypassing NADH dehydrogenase. No proton pumping accompanies these electron transfers.

MBOC7_ptr_ch14_811-872.indd 828 02/12/21 2:31 PM

40 different protein subunits, with a molecular mass of nearly a million daltons. The x-ray crystallography and cryoEM structures of the NADH dehydrogenase complex show that it is L-shaped, with both a hydrophobic membrane arm and a hydrophilic arm that projects into the mitochondrial matrix (Figure 14–20).

Electron transfer and proton pumping are physically separated in the NADH dehydrogenase complex, with electron transfer occurring in the matrix arm and proton pumping in the membrane arm. The NADH docks near the tip of the matrix arm, where it transfers its electrons via a bound flavin mononucleotide to a string of iron–sulfur clusters that runs down the arm, acting like a wire to carry electrons to a protein-bound molecule of ubiquinone. Electron transfer to the quinone is thought to trigger proton translocation in a set of proton pumps in the membrane arm, and for this to happen the two processes must be energetically and mechanically linked. One hypothesized mechanism is for this link to be provided by a 6-nm-long, amphipathic α helix that runs parallel to the membrane surface on the matrix side of the membrane arm. This helix may act like the connecting rod in a steam engine to generate a mechanical, energy-transducing power stroke that links the quinone-binding site to the proton-translocating modules in the membrane (see Figure 14–20).

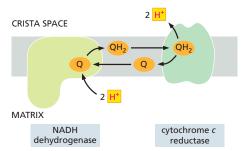

The reduction of each quinone by the transfer of its two electrons, followed by its release from the complex into the membrane, can cause four protons to be pumped out of the matrix into the crista space. In this way, NADH dehydrogenase generates roughly half of the total proton-motive force in mitochondria.

Cytochrome *c* Reductase Takes Up and Releases Protons on Opposite Sides of the Crista Membrane, Thereby Pumping Protons

As described previously, when a quinone molecule (Q) accepts its two electrons, it also takes up two protons to form a quinol (QH₂; see Figure 14–17). In the respiratory chain, ubiquinol transfers electrons to cytochrome c reductase, after picking them up from either NADH dehydrogenase or succinate dehydrogenase. Because the protons in this QH₂ molecule are obtained from the matrix and released on the opposite side of the crista membrane, two protons are transferred from the matrix into the crista space per pair of electrons transferred (Figure 14–21). This simple vectorial transfer of protons supplements the electrochemical proton gradient that is created by the NADH dehydrogenase proton pumping just discussed.

Figure 14-20 The structure of NADH dehydrogenase (also known as Complex I). (A) The structure of Complex I is shown. The matrix arm of NADH dehydrogenase contains one flavin mononucleotide (FMN) and eight iron-sulfur (FeS) clusters that appear to participate in electron transport. The membrane contains more than 70 transmembrane helices, forming three distinct protonpumping modules. (B) Schematic of NADH dehydrogenase electron transport-coupled proton pumping. NADH donates two electrons, via a bound FMN (vellow), to a chain of seven iron-sulfur clusters (red and yellow spheres). From the terminal iron-sulfur cluster, the electrons pass to ubiquinone (orange). Electron transfer results in conformational changes that are thought to be transmitted to a long amphipathic α helix (purple) on the matrix side of the membrane arm, which pulls on discontinuous transmembrane helices (red) in three membrane subunits, each of which resembles an antiporter (see Chapter 11). This movement is thought to change the conformation of charged residues in the three proton channels, resulting in the translocation of three protons out of the matrix. A fourth proton may be translocated at the interface of the two arms (dotted line). (C) This shows the symbol for NADH dehydrogenase used throughout this chapter. (A, adapted from R.G. Efremov et al., Nature 465:441-445, 2010. PDB code: 3M9S.)

MBOC7_ptr_ch14_811-872.indd 829 02/12/21 2:31 PM

Cytochrome c reductase is a large assembly of membrane protein subunits. Three subunits form a catalytic core that passes electrons from ubiquinol to cytochrome c, with a structure that has been highly conserved from bacterial ancestors (**Figure 14–22**). It pumps protons by a vectorial transfer that is more complex than the mechanism in Figure 14–21, thereby doubling the amount of useful energy harvested. This involves a binding site for a second molecule of ubiquinone; the elaborate redox loop mechanism used is called the Q cycle because one of the electrons received from each QH_2 molecule is transferred from

Figure 14–21 How a directional release and uptake of protons by a quinone pumps protons across a membrane.

Two protons are picked up on the matrix side of the inner mitochondrial membrane when the reaction Q + $2e^- + 2H^+ \rightarrow QH_2$ is catalyzed by the NADH dehydrogenase complex. This molecule of ubiquinol (QH₂) then binds to the crista side of cytochrome c reductase. When its oxidation by cytochrome c reductase generates two protons and two electrons (see Figure 14–17), the two protons are released into the crista space. The flow of electrons is not shown in this diagram.

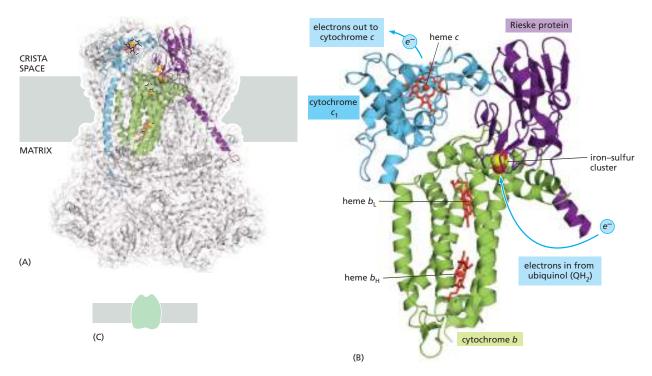

Figure 14–22 The structure of cytochrome c reductase. Cytochrome c reductase (also known as the cytochrome b- c_1 complex) is a dimer of two identical 240,000-dalton halves, each composed of 11 different protein molecules in mammals. (A) A structural model of the entire dimer based on x-ray crystallography, showing in color the three proteins that form the functional core of the enzyme complex: cytochrome b (green) and cytochrome c_1 (blue) are colored in one half, and the Rieske protein (purple) containing an Fe₂S₂ iron–sulfur cluster (red and yellow) is colored in the other. These three protein subunits interact across the two halves. (B) Transfer of electrons through cytochrome c reductase to the small, soluble carrier protein cytochrome c. Electrons entering from ubiquinol near the matrix side of the membrane are captured by the iron–sulfur cluster of the Rieske protein, which moves its iron–sulfur group back and forth to transfer these electrons to heme c (red). Heme c then transfers them to the carrier molecule cytochrome c.

As detailed in Figure 14–23, only one of the two electrons from each ubiquinol is transferred through this path. To increase proton pumping, the second ubiquinol electron is passed to a molecule of ubiquinone bound to cytochrome c reductase on the opposite side of the membrane—near the matrix. (C) This shows the symbol for cytochrome c reductase used throughout this chapter. (A and B, PDB code: 1EZV.)

MBOC7_ptr_ch14_811-872.indd 830 02/12/21 2:31 PM

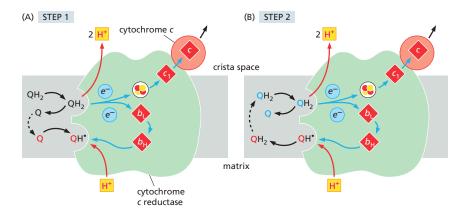

Figure 14–23 The two-step mechanism of the cytochrome c reductase Q cycle. A clear grasp of the processes illustrated here can be obtained from the step-by-step video provided in Movie 14.6. (A) In step 1, ubiquinol reduced by NADH dehydrogenase docks to the cytochrome c reductase complex. Oxidation of the quinol produces two protons and two electrons. The protons are released into the crista space. One electron passes via an iron–sulfur cluster to heme c_1 , and then to the soluble electron carrier protein cytochrome c on the membrane surface. The second electron passes via hemes b_L and b_H to a ubiquinone ($red\ Q$) bound at a separate site near the matrix side of the protein. Uptake of a proton from the matrix produces a ubisemiquinone radical (see Figure 14–17), which remains bound to this site ($red\ QH^{\bullet}$).

(B) In step 2, a second ubiquinol (blue QH_2) docks and releases two protons and two electrons, as described for step 1. One electron is passed to a second molecule of cytochrome c, whereas the other electron is accepted by the ubisemiquinone. The ubisemiquinone then takes up a proton from the matrix and is released into the lipid bilayer as fully reduced ubiquinol (red QH_2), from whence it can subsequently rebind to the complex and donate electrons and protons as in step 1.

On balance, the oxidation of one ubiquinol in the Q cycle pumps two protons through the membrane by a directional release and uptake of protons (see Figure 14–18), while releasing another two into the crista space. In addition, in each of the two steps (A and B), one electron is transferred to a cytochrome c carrier protein.

ubiquinone through the complex to the carrier protein cytochrome c while the other electron is recycled back into the quinone pool. Through the mechanism illustrated in Figure 14–23 and Movie 14.6, the Q cycle increases the total amount of redox energy that can be stored in the electrochemical proton gradient: for every electron that is transferred from NADH dehydrogenase to cytochrome c, two protons are pumped across the crista membrane into the crista space.

The Cytochrome c Oxidase Complex Pumps Protons and Reduces O₂ Using a Catalytic Iron–Copper Center

The final link in the mitochondrial electron-transport chain is cytochrome c oxidase, or Complex IV. The cytochrome c oxidase complex accepts electrons from the soluble electron carrier cytochrome c, and it uses yet a different, third mechanism to pump protons across the inner mitochondrial membrane. The structure of the mammalian complex is illustrated in Figure 14–24.

Because oxygen has a high affinity for electrons, it can release a large amount of free energy when it is reduced to form water. Thus, the evolution of cellular respiration, in which O_2 is converted to water, enabled organisms to harness much more energy than can be derived from anaerobic metabolism. As we discuss later, the availability of the large amount of energy released by the reduction of molecular oxygen to form water is thought to have been essential to the emergence of multicellular life, thereby explaining why all large organisms respire. The ability of biological systems to use O_2 in this way, however, requires sophisticated chemistry. Once a molecule of O_2 has picked up one electron, it forms a superoxide radical anion $(O_2^{\bullet-})$ that is dangerously reactive and rapidly takes up an additional three electrons wherever it can get them, with destructive effects on its immediate environment. We can tolerate oxygen in the air we

MBOC7_ptr_ch14_811-872.indd 831 02/12/21 2:31 PM

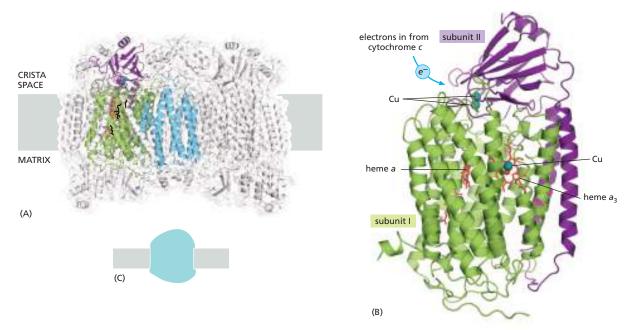

Figure 14–24 The structure of cytochrome c oxidase. The final complex in the human mitochondrial electron-transfer chain consists of \sim 13 different protein subunits, depending on the cell type, with a total mass of approximately 204,000 daltons. (A) The entire dimeric complex is shown, positioned in the crista membrane. The highly conserved subunits I (green), II (purple), and III (blue) are encoded by the mitochondrial genome, and they form the functional core of the enzyme. (B) The functional core of the complex. Electrons pass through this structure from cytochrome c via bound copper ions (blue spheres) and hemes (red) to an O_2 molecule bound between heme a_3 and a copper ion. The four protons needed to reduce O_2 to water are taken up from the matrix; see also Figure 14–25. (C) This shows the symbol for cytochrome c oxidase used throughout this chapter. (A and B, PDB code: 2OCC.)

breathe only because the uptake of the first electron by a free O_2 molecule is slow and inefficient, allowing cells to use enzymes to control electron uptake by oxygen. Thus, cytochrome c oxidase holds on to oxygen at a special bimetallic center, where it remains clamped between a heme-linked iron atom and a copper ion until it has picked up a total of four electrons. Only then are the two oxygen atoms of the oxygen molecule safely released as two molecules of water (Figure 14–25).

The cytochrome c oxidase reaction accounts for about 90% of the total oxygen uptake in most cells. This protein complex is therefore crucial for all aerobic life. Oxygen limitation is life-threatening to obligate aerobic organisms because of an impaired activity of cytochrome c oxidase and these organisms respond rapidly to low oxygen levels to decrease their dependence on mitochondrial respiration. Cyanide is extremely toxic because it binds to the heme iron atoms in cytochrome c oxidase much more tightly than does oxygen, thereby greatly reducing mitochondrial ATP production.

Succinate Dehydrogenase Acts in Both the Electron-Transport Chain and the Citric Acid Cycle

In addition to the three proton pumps just discussed, one of the enzymes in the citric acid cycle, *succinate dehydrogenase* (Figure 14–26), is embedded in the mitochondrial crista membrane. In the course of oxidizing succinate to fumarate in the matrix, this enzyme complex captures electrons in the form of a tightly bound FADH $_2$ molecule (see Panel 2–9, pp. 110–111) and passes them through three iron–sulfur clusters to a molecule of ubiquinone. The reduced ubiquinol then enters the pool of ubiquinol generated by Complex I and passes its two electrons to cytochrome c reductase in the respiratory chain (see Figure 14–18). Succinate dehydrogenase is not a proton pump, and

MBOC7_ptr_ch14_811-872.indd 832 02/12/21 2:31 PM

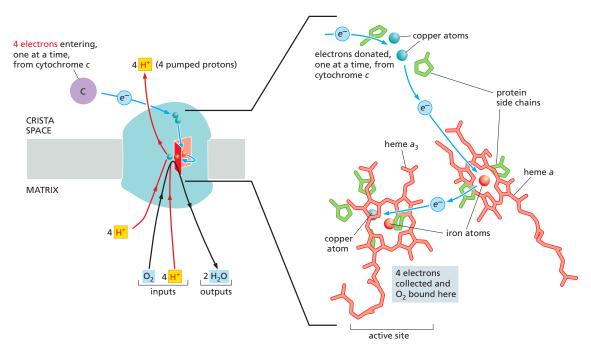

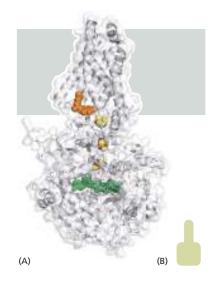

Figure 14–25 The reaction of O_2 with electrons in cytochrome c oxidase. Electrons from cytochrome c pass through the complex via bound copper ions (blue spheres) and hemes (red) to an O_2 molecule bound between heme a_3 and a copper ion. Iron ions are shown as red spheres. The iron atom in heme a serves as an electron queuing point where electrons are held so that they can be released to an O_2 molecule (not shown) that is held at the bimetallic center active site, which is formed by the central iron of the other heme (heme a_3) and a closely apposed copper atom. The four protons needed to reduce O_2 to water are removed from the matrix. For each O_2 molecule that undergoes the reaction $4e^- + 4H^+ + O_2 \rightarrow 2H_2O$, an additional four protons are pumped out of the matrix by mechanisms driven by allosteric changes in protein conformation (see Figure 14–29).

it does not contribute directly to the electrochemical potential utilized for ATP production in mitochondria. Its dual action in the citric acid cycle and in electron transport has implications for human disease that are different from those of the other three respiratory complexes. For example, mutations that cause a decreased activity of Complex II contribute to specific forms of cancer.

The Respiratory Chain Forms a Supercomplex in the Crista Membrane

When the three large mitochondrial respiratory complexes that pump protons in the electron-transport chain are gently isolated, they are found in even larger *supercomplexes*. Such observations support the hypothesis that this massive structure in the crista membrane helps the mobile electron carriers ubiquinone (in the crista membrane) and cytochrome c (in the crista space) transfer electrons more efficiently than could be accomplished with dissociated, freely diffusing electron carriers (**Figure 14–27**). The supercomplex allows a cell to capture as much of the free energy of electron transfer from NADH to O_2 as possible and to avoid potentially damaging, redox side reactions. The formation of this structure depends on the presence of the mitochondrial lipid cardiolipin (see Figure 14–11) and on special proteins that are thought to hold the components together.

Figure 14–26 The structure of succinate dehydrogenase. (A) This membrane-embedded enzyme is composed of four subunits. One subunit, Sdh1, contains a covalently bound FAD cofactor (green) that receives an electron directly from succinate oxidation and passes it successively through the three iron–sulfur clusters (red and yellow) contained within Shd2 to ubiquinone. The membrane component of this complex, formed by the other two subunits, has a bound heme of unknown function (orange). (B) This shows the symbol for succinate dehydrogenase used throughout this chapter. (A, PDB code: 1NEK.)

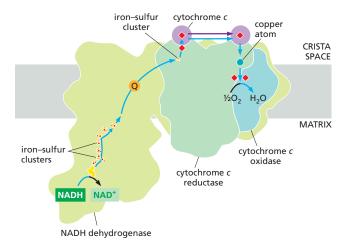

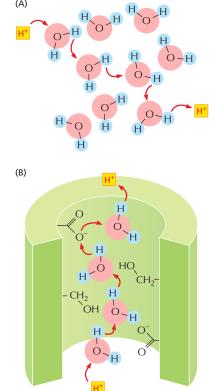

Figure 14–27 The respiratory-chain supercomplex from bovine heart mitochondria. The three proton-pumping complexes of the mitochondrial respiratory chain of mammalian mitochondria assemble into large supercomplexes in the crista membrane. Supercomplexes can be isolated by mild detergent treatment of mitochondria, and their structure has been deciphered by single-particle cryoelectron microscopy. The bovine heart supercomplex has a total mass of 1.7 megadaltons. Shown is a schematic of such a complex that consists of NADH dehydrogenase, cytochrome c reductase, and cytochrome c oxidase, as indicated. The facing quinol-binding sites of NADH dehydrogenase and cytochrome c reductase, plus the short distance between the cytochrome c-binding sites in cytochrome c reductase and cytochrome c oxidase, facilitate fast, efficient electron transfer. Cofactors active in electron transport are marked as a *yellow icon* (flavin mononucleotide), red and red vellow spheres (iron-sulfur clusters), Q (quinone), red diamonds (hemes), and a blue sphere (copper atom). Only cofactors participating in the linear flow of electrons from NADH to water are shown. Blue arrows indicate the path of the electrons through the supercomplex. (Adapted from T. Athoff et al., red r

Protons Can Move Rapidly Through Proteins Along Predefined Pathways

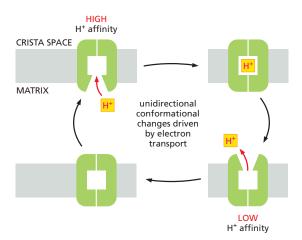

The protons in water are highly mobile: by rapidly dissociating from one water molecule and associating with its neighbor, they can rapidly flit through a hydrogen-bonded network of water molecules (see Figure 2–5). But how can a proton move through the hydrophobic interior of a protein embedded in the lipid bilayer? Proton-translocating proteins contain so-called *proton wires*, which are rows of polar or ionic side chains or water molecules spaced at short distances, so that the protons can jump from one to the next (Figure 14–28). Along such predefined pathways, protons move up to 40 times faster than through bulk water.

How does electron transport cause allosteric changes in protein conformations that pump protons? From the most basic point of view, if electron transport drives sequential allosteric changes in protein conformation that alter the redox state of the components, these conformational changes can be connected to protein wires that allow the protein to pump H⁺ across the crista membrane. This type of H⁺ pumping requires at least three distinct conformations for the pump protein, as schematically illustrated in **Figure 14–29**. Atomic-resolution structures, combined with the effects of specific amino acid changes introduced into the proteins by genetic engineering, are helping to reveal the detailed mechanisms of the proton pumping driven by electron transfer, but how these

Figure 14–28 Proton movement through water and proteins. (A) Protons move rapidly through water, hopping from one H_2O molecule to the next by the continuous formation and dissociation of hydronium ions, H_3O^+ (see Chapter 2). In this diagram, proton jumps are indicated by *red arrows*. (B) Protons can move even more rapidly through a protein along *proton wires*. These are predefined proton paths consisting of suitably spaced amino acid side chains that accept and release protons easily (Asp, Glu) or carry a water-like hydroxyl group (Ser, Thr), along with water molecules trapped in the protein interior.

MBOC7_ptr_ch14_811-872.indd 834 02/12/21 2:31 PM

conformations are formed and regulated in the respiratory complexes remain incompletely understood.

Summary

The respiratory chain is embedded in the crista membrane portion of the inner mitochondrial membrane. It contains three respiratory enzyme complexes through which electrons pass on their way from NADH to O_2 . Within these large protein complexes, electrons are transferred along a series of protein-bound electron carriers that include hemes and iron-sulfur clusters. The energy released as the electrons move to lower and lower energy levels is used by each protein complex to pump protons out of the mitochondrial matrix, coupling lateral electron transport to vectorial proton transport across the membrane. Electrons are shuttled between the enzyme complexes by the mobile electron carriers ubiquinone and cytochrome c to complete the electron-transport chain. The path of electron flow from NADH is as follows: NADH \rightarrow NADH dehydrogenase complex \rightarrow ubiquinone \rightarrow cytochrome c reductase \rightarrow cytochrome c \rightarrow cytochrome c oxidase complex \rightarrow molecular oxygen (O_2) . In addition, electrons derived from a citric acid cycle intermediate, succinate, enter this pathway by flowing through a fourth membrane-embedded, respiratory enzyme complex, succinate dehydrogenase, to ubiquinone.

ATP PRODUCTION IN MITOCHONDRIA

As we have just discussed, the three proton pumps of the respiratory chain each contribute to the formation of an electrochemical proton gradient across the inner mitochondrial membrane. This gradient drives ATP synthesis by ATP synthase, a large membrane-embedded protein complex that performs the extraordinary feat of converting the energy contained in this electrochemical gradient into biologically useful, chemical-bond energy in the form of ATP (see Figure 14–10). Protons flow down their electrochemical gradient through the membrane part of this proton turbine, and this drives the synthesis of ATP from ADP and phosphate in the part of the complex that protrudes into the mitochondrial matrix. As discussed in Chapter 2, the formation of ATP from ADP and phosphate is highly unfavorable energetically. As we shall see, ATP synthase can produce ATP only because of allosteric shape changes in this protein complex that directly couple ATP synthesis to the energetically favorable flow of protons across the membrane.

The Large Negative Value of ΔG for ATP Hydrolysis Makes ATP Useful to the Cell

An average person turns over roughly 50 kg of ATP per day. In athletes running a marathon, this figure can go up to several hundred kilograms. The ATP produced in mitochondria is derived from the energy available in the intermediates NADH,

Figure 14–29 A general model for H⁺ pumping coupled to electron transport.

This type of mechanism for H⁺ pumping by a transmembrane protein is thought to be used by NADH dehydrogenase and cytochrome c oxidase, and by many other proton pumps. The protein is driven through a cycle of three conformations. In one of these conformations, the protein has a high affinity for H+, causing it to pick up an H⁺ on the inside of the membrane. In another conformation, the protein has a low affinity for H+, causing it to release an H⁺ on the outside of the membrane. As indicated, the transitions from one conformation to another occur only in one direction, because they are driven by being allosterically coupled to an energetically favorable process—in this case by the free energy released by electron transport (see also Chapter 11).

MBOC7_ptr_ch14_811-872.indd 835 02/12/21 2:31 PM

TABLE 14-3 Product Yields from the Oxidation of Sugars and Fats

A. Net products from oxidation of one molecule of glucose

In cytosol (glycolysis)

1 glucose → 2 pyruvate + 2 NADH + 2 ATP

In mitochondrion (pyruvate dehydrogenase and citric acid cycle)

2 pyruvate → 2 acetyl CoA + 2 NADH

2 acetyl CoA \rightarrow 6 NADH + 2 FADH₂ + 2 GTP

Net result in mitochondrion

2 pyruvate → 8 NADH + 2 FADH₂ + 2 GTP

B. Net products from oxidation of one molecule of palmitoyl CoA (activated form of palmitate, a fatty acid)

In mitochondrion (fatty acid oxidation and citric acid cycle)

1 palmitoyl CoA \rightarrow 8 acetyl CoA + 7 NADH + 7 FADH₂

8 acetyl CoA → 24 NADH + 8 FADH₂ + 8 GTP

Net result in mitochondrion

1 palmitoyl CoA \rightarrow 31 NADH + 15 FADH₂ + 8 GTP

FADH₂, and GTP. These three energy-rich compounds are produced by the oxidation of glucose (Table 14–3, part A), fats (Table 14–3, part B), and other fuels.

Glycolysis alone can produce only two molecules of ATP for every molecule of glucose that is metabolized, and this is the total energy yield for the fermentation processes that occur in the absence of O₂ (discussed in Chapter 2). In oxidative phosphorylation, each pair of electrons donated by the NADH produced in mitochondria can provide energy for the formation of about 2.5 molecules of ATP. Oxidative phosphorylation also produces about 1.5 ATP molecules per electron pair from the FADH₂ produced by succinate dehydrogenase in the mitochondrial matrix and from the NADH molecules produced by glycolysis in the cytosol. Combining this information with the product yields of glycolysis and the citric acid cycle, we can calculate that the complete oxidation of one molecule of glucose—starting with glycolysis and ending with oxidative phosphorylation—gives a net yield of about 30 molecules of ATP. Nearly all of this ATP is produced by the mitochondrial ATP synthase.

In Chapter 2, we introduced the concept of free energy (G). The free-energy change for a reaction, ΔG , determines whether that reaction will occur in a cell. We showed on pages 67–69 that the ΔG for a given reaction can be written as the sum of two parts: the first, called the standard free-energy change, ΔG° , depends only on the intrinsic characters of the reacting molecules; the second depends only on their concentrations. For the simple reaction $A \rightarrow B$,

$$\Delta G = \Delta G^{\circ} + RT \ln \frac{[B]}{[A]}$$

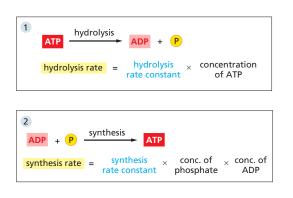

where [A] and [B] denote the concentrations of A and B, and ln is the natural logarithm. ΔG° is the standard reference value, which can be seen to be equal to the value of ΔG when the molar concentrations of A and B are equal (as $\ln 1 = 0$).

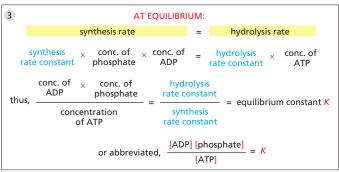

In Chapter 2, we discussed how the large, favorable free-energy change (large negative ΔG) for ATP hydrolysis is used, through coupled reactions, to drive many other chemical reactions in the cell that would otherwise not occur (see pp. 71–73). The ATP hydrolysis reaction produces two products, ADP and phosphate; it is therefore of the type $A \rightarrow B + C$, where, as demonstrated in Figure 14–30,

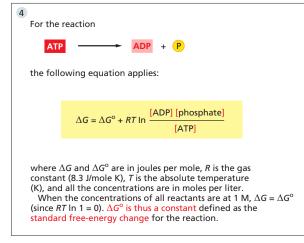

$$\Delta G = \Delta G^{\circ} + RT \ln \frac{[B][C]}{[A]}$$

When ATP is hydrolyzed to ADP and phosphate under the conditions that normally exist in a cell, the free-energy change is roughly -46 to -54 kJ/mole

MBOC7_ptr_ch14_811-872.indd 836 02/12/21 2:31 PM

At equilibrium the reaction has no net effect on the disorder of the universe, so $\Delta G = 0$. Therefore, at equilibrium, $-RT \ln \frac{[\text{ADP}] \text{ [phosphate]}}{[\text{ATP}]} = \Delta G^{\circ}$ But the concentrations of reactants at equilibrium must satisfy the equilibrium equation: $\frac{[\text{ADP}] \text{ [phosphate]}}{[\text{ATP}]} = K$ Therefore, at equilibrium, $\Delta G^{\circ} = -RT \ln K$

We thus see that whereas $\Delta G^{\rm o}$ indicates the equilibrium point for a reaction, ΔG reveals how far the reaction is from equilibrium. ΔG is a measure of the "driving force" for any chemical reaction, just as the proton-motive force is the driving force for the translocation of protons.

(-11 to -13 kcal/mole). This extremely favorable ΔG depends on maintaining a high concentration of ATP compared with the concentrations of ADP and phosphate. When ATP, ADP, and phosphate are all present at the same concentration of 1 mole/liter (so-called standard conditions), the ΔG for ATP hydrolysis drops to the standard free-energy change (ΔG°), which is only -30.5 kJ/mole (-7.3 kcal/mole). At much lower concentrations of ATP relative to ADP and phosphate, ΔG becomes zero. At this point, the rate at which ADP and phosphate will join to form ATP will be equal to the rate at which ATP hydrolyzes to form ADP and phosphate. In other words, when ΔG = 0, the reaction is at *equilibrium* (see Figure 14–30).

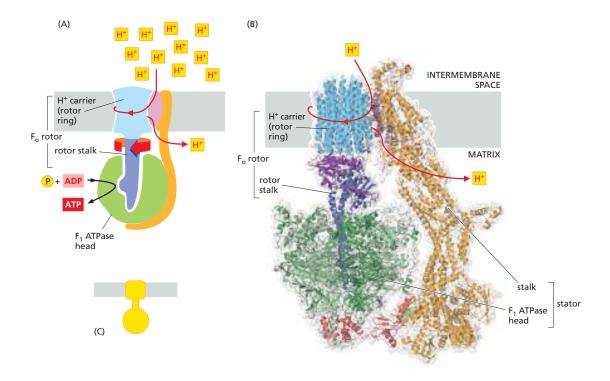

It is ΔG , not ΔG° , that indicates how far a reaction is from equilibrium and determines whether it can drive other reactions. Because the efficient conversion of ADP to ATP in mitochondria maintains such a high concentration of ATP relative to ADP and phosphate, the ATP hydrolysis reaction in cells is kept very far from equilibrium, and ΔG is correspondingly very negative. Without this large disequilibrium, ATP hydrolysis could not be used to drive the reactions of the cell. At low ATP concentrations, many essential reactions would become energetically unfavorable, run backward, and the cell would die.

The ATP Synthase Is a Nanomachine That Produces ATP by Rotary Catalysis

The ATP synthase is a finely tuned nanomachine composed of 23 or more separate protein subunits, with a total mass of about 600,000 daltons. The ATP synthase can work both in the forward direction, producing ATP from ADP and phosphate by consuming an electrochemical gradient, or in reverse, generating an electrochemical gradient by ATP hydrolysis. To distinguish it from other enzymes that hydrolyze ATP, it is also called an F_1F_0 ATP synthase or F-type ATPase.

Figure 14–30 The basic relationship between free-energy changes and equilibrium in the ATP hydrolysis reaction. The rate constants in boxes 1 and 2 are determined from experiments in which product accumulation is measured as a function of time (conc., concentration). The equilibrium constant shown here, *K*, is in units of moles per liter. (See Panel 2–7, pp. 106–107, for a discussion of free energy, and see Figure 3–42 for a discussion of the equilibrium constant.)

MBOC7_ptr_ch14_811-872.indd 837 02/12/21 2:31 PM

Resembling a turbine, ATP synthase is composed of both a rotor and a stator (Figure 14-31). To prevent the catalytic head from rotating, a stalk at the periphery of the complex (the stator stalk) connects the head to stator subunits embedded in the membrane. A second stalk in the center of the assembly (the rotor stalk) is connected to the rotor ring in the membrane, which turns as protons flow through it, driven by the electrochemical gradient across the membrane. As a result, proton flow makes the rotor stalk rotate inside the stationary head, where the catalytic sites that assemble ATP from ADP and phosphate are located. Three α and three β subunits of similar structure alternate to form the head. Each of the three β subunits has a catalytic nucleotide-binding site at the α - β interface. These catalytic sites are all in different conformations, depending on their interaction with the rotor stalk. This stalk acts like a camshaft, the device that opens and closes the valves in a combustion engine. As it rotates within the head, the stalk changes the conformations of the \beta subunits sequentially. One of the possible conformations of the catalytic sites has high affinity for ADP and phosphate, and as the rotor stalk pushes the binding site into a different conformation, these two substrates are driven to form ATP. As the rotor stalk continues to rotate, the binding site releases ATP, allowing the ATP-producing cycle to restart. In this way, the mechanical force exerted by the central rotor stalk is directly converted into the chemical energy of the ATP phosphate bond.

Serving as a proton-driven turbine, the ATP synthase is driven by H^+ flow into the matrix to spin at about 8000 revolutions per minute, generating three molecules of ATP per turn. In this way, each ATP synthase can produce roughly 400 molecules of ATP per second.

The closely related ATP synthases of mitochondria, chloroplasts, and bacteria synthesize ATP by harnessing the proton-motive force across a membrane. This powers the rotation of the rotor against the stator in a counterclockwise direction, as seen from the F_1 head. The same enzyme complex can also pump protons against their electrochemical gradient by hydrolyzing ATP, which then drives the clockwise rotation of the rotor. The direction of operation depends on the net free-energy change (ΔG) for the coupled processes of H^+ translocation across the membrane and the synthesis of ATP from ADP and phosphate (Movie 14.7 and

Figure 14-31 ATP synthase. The three-dimensional structure of the F₁F₀ ATP synthase determined by x-ray crystallography. Also known as an F-type ATPase, it consists of an Fo part (from "oligomycin-sensitive factor") in the membrane and the large, catalytic F₁ head extending into the matrix. (A) Diagram of the enzyme complex showing how its globular head portion (green) is kept stationary as proton flow across the membrane drives a rotor (light blue) that turns the rotor stalk (dark blue) inside the head. (B) In bovine heart mitochondria, the Fo rotor ring in the membrane (light blue) has eight c subunits. It is attached to the γ subunit of the rotor stalk (dark blue) by the ε subunit (purple). The catalytic F_1 head consists of a ring of three $\boldsymbol{\alpha}$ and three β subunits (light and dark green), and it directly converts mechanical energy into chemical-bond energy in ATP, as described in the text. The elongated peripheral stalk of the stator (orange) is connected to the F_1 head by the small δ subunit (red) at one end and to the a subunit in the membrane at the other. Together with the c subunits of the ring rotating past it, the a subunit creates a path for protons through the membrane. (C) The symbol for ATP synthase used throughout this book. (B, PDB codes: 2WPD, 2CLY, 2WSS

Movie 14.8). Measurement of the torque that the ATP synthase can produce by ATP hydrolysis reveals that the ATP synthase is 60 times more powerful than a diesel engine of equal size.

Proton-driven Turbines Are Ancient and Critical for Energy Conversion

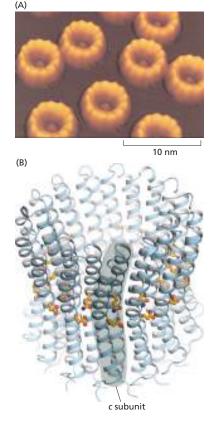

The membrane-embedded rotors of ATP synthases consist of a ring of identical c subunits (**Figure 14–32**). Each c subunit is a hairpin of two membrane-spanning α helices that contain a proton-binding site defined by a glutamate or aspartate in the middle of the lipid bilayer. The a subunit, which is part of the stator (see Figure 14–31), makes two narrow channels at the interface between the rotor and stator, each spanning half of the membrane and converging on the proton-binding site at the middle of the rotor subunit. Protons flow through the two half-channels down their electrochemical gradient from the crista space back into the matrix. The negatively charged glutamate or aspartate side chain in the binding site accepts a proton arriving from the crista space through the first half-channel, as it rotates past the a subunit. The bound proton then rides around in the ring for a full cycle, whereupon it is thought to be displaced by a positively charged arginine in the a subunit to escape through the second half-channel into the matrix. This directional proton flow causes the rotor ring to spin against the stator like a proton-driven turbine.

The mitochondrial ATP synthase is of ancient origin: essentially the same enzyme exists in plant chloroplasts and in the plasma membrane of bacteria or archaea. The main difference between them is the number of *c* subunits in the rotor ring. In mammalian mitochondria, the ring has 8 subunits. In yeast mitochondria, the number is 10; in bacteria and archaea, it ranges from 11 to 13; in plant chloroplasts, there are 14; and the rings of some cyanobacteria contain 15 *c* subunits.

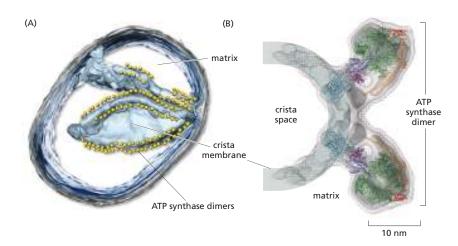

The number of c subunits in the ring determines how many protons need to pass through this marvelous device to make each molecule of ATP. These subunits can be thought of as cogs in the gear wheels of a bicycle. A high gear, with a small number of cogs in the wheel, is advantageous when the supply of protons is limited, as in mitochondria, but a low gear, with a large number of cogs in the wheel, is preferable when the proton gradient is high. This is the case in chloroplasts and cyanobacteria, where protons produced through the action of sunlight are plentiful. Because each rotation produces three molecules of ATP in the head, the synthesis of one ATP requires around three protons in mitochondria but up to five in photosynthetic organisms—allowing the latter organisms to create a higher ratio of ATP to ADP and thus to maintain a greater ΔG for ATP hydrolysis.

Even under scenarios where mitochondrial ATP production is not possible or necessary, mitochondria must maintain a proton gradient to power the proper import of essential proteins and metabolites. In such a situation, ATP synthase can also run in reverse as an ATP-powered proton pump that converts the energy of ATP back into a proton gradient across the membrane. Moreover, in many bacteria, the rotor of the ATP synthase in the plasma membrane changes direction routinely, from ATP synthesis mode in aerobic respiration to ATP hydrolysis mode in anaerobic metabolism. In this latter case, ATP hydrolysis serves to maintain the proton gradient across the plasma membrane, which is used to power many other essential cell functions including nutrient transport and the rotation of bacterial flagella. The V-type ATPases that acidify certain cellular organelles are

Figure 14–32 F_o ATP synthase rotor rings. (A) Atomic force microscopy image of ATP synthase rotors from the cyanobacterium Synechococcus elongatus in a lipid bilayer. Whereas 8 c subunits form the rotor in Figure 14–31, there are 13 c subunits in this ring. (B) The x-ray structure of the F_o ring of the ATP synthase from Spirulina platensis, another cyanobacterium, shows that this rotor has 15 c subunits. In all ATP synthases, the c subunits are hairpins of two membrane-spanning α helices (one subunit is highlighted in gray). The helices are highly hydrophobic, except for glutamine and glutamate side chains (yellow) that create proton-binding sites in the membrane. (A, courtesy of Thomas Meier and Denys Pogoryelov; B, PDB code: 2WIE.)

MBOC7_ptr_ch14_811-872.indd 839 02/12/21 2:31 PM

architecturally similar to the F-type ATP synthases, but they normally function in this ATP-dependent proton-pumping mode (see Figure 13–62).

Mitochondrial Cristae Help to Make ATP Synthesis Efficient

In the electron microscope, the mitochondrial ATP synthase complexes can be seen to project like lollipops on the matrix side of cristae membranes. Recent studies by cryo-electron microscopy and tomography have shown that this large complex is not distributed randomly in the membrane, but forms long rows of dimers along the cristae ridges (Figure 14–33). The dimer rows induce or stabilize these regions of high membrane curvature, which are otherwise energetically unfavorable. Indeed, the formation of ATP synthase dimers and their assembly into rows are required for cristae formation and have far-reaching consequences for cellular fitness. By contrast with bacterial or chloroplast ATP synthases, which do not form dimers, the mitochondrial complex contains additional subunits, located mostly near the membrane end of the stator stalk. If these dimer-specific subunits are mutated in yeast, the ATP synthase in the membrane remains monomeric, the mitochondria have no cristae, cellular respiration drops by half, and the cells grow more slowly.

Electron tomography suggests that the respiratory enzyme complexes that pump protons are located in the crista membrane at either side of the dimer rows. Protons pumped into the crista space by these respiratory-chain complexes are thought to diffuse very rapidly along the membrane surface, with the ATP synthase rows creating a proton "sink" at the cristae tips (Figure 14–34). *In vitro* studies suggest that the ATP synthase needs a proton gradient of about 2 pH units

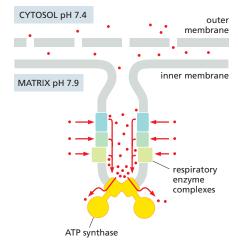

Figure 14-33 Dimers of mitochondrial ATP synthase in cristae membranes. (A) A three-dimensional map of a small mitochondrion obtained by electron microscope tomography shows that ATP synthases form long paired rows along cristae ridges. The outer membrane is gray, and the inner membrane and cristae membranes have been colored light blue. Each head of an ATP synthase is indicated by a yellow sphere. (B) A three-dimensional map of a mitochondrial ATP synthase dimer in the crista membrane obtained by sub-tomogram averaging, with fitted x-ray structures (Movie 14.9). (A, from K. Davies et al., Proc. Natl. Acad. Sci. USA 108:14121-14126, 2011. With permission from the National Academy of Sciences. B, from K. Davies et al., Proc. Natl. Acad. Sci. USA 109:13602-13607, 2012. With permission from the National Academy of Sciences.)

Figure 14–34 ATP synthase dimers at cristae ridges and ATP production. At the cristae ridges, the ATP synthases (yellow) form a sink for protons (red). The proton pumps of the electron-transport chain (blue and green) are located in the membrane regions on either side of the crista. As illustrated, protons tend to be enriched in the crista space and diffuse along the membrane from their source to the proton sink created by the ATP synthase. This allows efficient ATP production despite the small overall H+ gradient between the cytosol and matrix. Red arrows show the direction of the proton flow.

MBOC7_ptr_ch14_811-872.indd 840 02/12/21 2:31 PM

to produce ATP at the rate required by the cell, irrespective of the membrane potential. The $\rm H^+$ gradient across the inner mitochondrial membrane is only 0.5–0.6 pH units. The cristae thus seem to work as proton traps that enable the ATP synthase to make efficient use of the protons pumped out of the mitochondrial matrix. As we shall see in the next part of this chapter, this elaborate arrangement of membrane protein complexes is absent in chloroplasts, where the $\rm H^+$ gradient is much larger.

Special Transport Proteins Move Solutes Through the Inner Membrane

Like all biological membranes, the inner mitochondrial membrane contains numerous specific transport proteins that allow particular substances to pass through. More than 50 of these transporters are members of a single protein family, known as mitochondrial carriers. One of the most abundant of these family members is the ADP/ATP carrier protein (Figure 14-35). This carrier shuttles the ATP produced in the matrix through the inner membrane to the intermembrane space, from where it diffuses through the outer mitochondrial membrane to the cytosol. In exchange, ADP passes from the cytosol into the matrix for recycling into ATP. ATP⁴⁻ has one more negative charge than ADP³⁻, and the exchange of ATP and ADP is driven by the electrochemical gradient across the inner membrane, so that the more negatively charged ATP is pushed out of the matrix, and the less negatively charged ADP is pulled in. Indeed, most of these carriers utilize the electrochemical proton gradient to drive directional transport of solutes across the inner membrane (see Chapter 11). In addition to members of the mitochondrial carrier family, all of which share significant sequence and structural similarity, several unrelated proteins transport pyruvate, calcium, serine, and other critical solutes.

In some specialized fat cells, mitochondrial respiration is uncoupled from ATP synthesis by the *uncoupling protein*, another member of the mitochondrial carrier family. In these cells, known as brown or beige fat cells, most of the energy of oxidation is dissipated as heat rather than being converted into ATP. In the inner

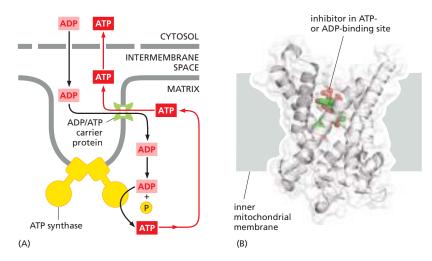

Figure 14–35 The ADP/ATP carrier protein. (A) The ADP/ATP carrier protein is a small membrane protein that carries the ATP produced on the matrix side of the inner membrane to the intermembrane space and carries the ADP that is needed for ATP synthesis into the matrix. (B) In the ADP/ATP carrier, six transmembrane α helices define a cavity that binds either ADP or ATP. In this x-ray structure, the substrate is replaced by a tightly bound inhibitor instead *(colored)*. When ADP binds from outside the inner membrane, it triggers a conformational change and is released into the matrix. In exchange, a molecule of ATP quickly binds to the matrix side of the carrier and is transported to the intermembrane space. From there the ATP diffuses through the outer mitochondrial membrane to the cytoplasm, where it powers the energy-requiring processes in the cell. (PDB code: 10KC.)

MBOC7_ptr_ch14_811-872.indd 841 02/12/21 2:31 PM

membranes of the large mitochondria in these cells, the uncoupling protein allows protons to move down their electrochemical gradient without passing through ATP synthase. This process is switched on when heat generation is required, causing the cells to oxidize their fat stores at a rapid rate and produce heat rather than ATP. Activating this uncoupling process protects newborn human babies against the cold and has been shown to protect against obesity and diabetes in genetically engineered mice.

Chemiosmotic Mechanisms First Arose in Bacteria

Bacteria use enormously diverse energy sources. Some, like animal cells, are aerobic; they synthesize ATP from sugars they oxidize to $\rm CO_2$ and $\rm H_2O$ by glycolysis, the citric acid cycle, and a respiratory chain in their plasma membrane that is similar to the one in the inner mitochondrial membrane. Others are strict anaerobes, deriving their energy either from glycolysis alone (by fermentation, see Figure 2–50) or from an electron-transport chain that employs a molecule other than oxygen as the final electron acceptor. The alternative electron acceptor can be a nitrogen compound (nitrate or nitrite), a sulfur compound (sulfate or sulfite), or a carbon compound (fumarate or carbonate), as examples. A series of electron carriers in the plasma membrane that are comparable to those in mitochondrial respiratory chains transfers the electrons to these acceptors.

Despite this diversity, the plasma membrane of the vast majority of bacteria contains an ATP synthase that is very similar to the one in mitochondria. In bacteria that use an electron-transport chain to harvest energy, the electron-transport chain pumps H⁺ out of the cell and thereby establishes a proton-motive force across the plasma membrane that drives the ATP synthase to make ATP. In other bacteria, the ATP synthase works in reverse, using the ATP produced by glycolysis to pump H⁺ and establish a proton gradient across the plasma membrane.

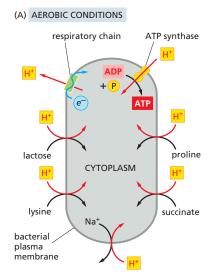

Bacteria, including the strict anaerobes, maintain a proton gradient across their plasma membrane that is harnessed to drive many other processes. It can be used to drive a flagellar motor, for example. The gradient is also harnessed to pump $\mathrm{Na^+}$ out of the bacterium via an $\mathrm{Na^+-H^+}$ antiporter that takes the place of the $\mathrm{Na^+-K^+}$ pump of eukaryotic cells. In addition, the gradient is used for the active inward transport of nutrients, such as most amino acids and many sugars: each nutrient is dragged into the cell along with one or more protons through a specific symporter (Figure 14–36; see also Chapter 11). In animal cells, by contrast, most inward transport across the plasma membrane is driven by the $\mathrm{Na^+}$ gradient (high $\mathrm{Na^+}$ outside, low $\mathrm{Na^+}$ inside) that is established by the $\mathrm{Na^+-K^+}$ pump (see Figure 11–15).

Some unusual bacteria have adapted to live in a very alkaline environment and yet must maintain their cytoplasm at a physiological pH. For these cells, any attempt to generate an electrochemical $\rm H^+$ gradient would be opposed by a large $\rm H^+$ concentration gradient in the wrong direction ($\rm H^+$ higher inside than outside). Presumably for this reason, some of these bacteria substitute $\rm Na^+$ for $\rm H^+$ in all of their chemiosmotic mechanisms. The respiratory chain pumps $\rm Na^+$ out of the cell, the transport systems and flagellar motor are driven by an inward flux of $\rm Na^+$, and an $\rm Na^+$ -driven ATP synthase synthesizes ATP. The existence of such bacteria demonstrates a critical point: the principle of chemiosmosis is more fundamental than the proton-motive force on which it is normally based.

As we discuss in the next part of this chapter, an ATP synthase coupled to chemiosmotic processes is also a central feature of plants, where it plays critical roles in both mitochondria and chloroplasts.

Summary

The large amount of free energy released when H⁺ flows back into the matrix from the cristae provides the basis for ATP production on the matrix side of mitochondrial cristae membranes by a remarkable protein machine—the ATP synthase. The ATP synthase functions like a miniature turbine, and it is a reversible device that

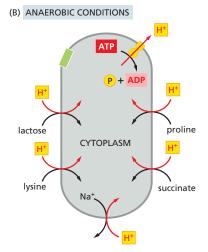

Figure 14-36 Bacteria use a protonmotive force across the plasma membrane to pump nutrients into the cell and expel Na+. (A) In an aerobic bacterium, a respiratory chain fed by the oxidation of substrates produces an electrochemical proton gradient across the plasma membrane. This gradient is then harnessed to make ATP and to transport nutrients (proline, succinate, lactose, and lysine) into the cell and to pump Na+ out of the cell. (B) When the same bacterium grows under anaerobic conditions, it derives its ATP from alvcolvsis. As indicated, the ATP synthase in the plasma membrane then hydrolyzes some of this ATP to establish an electrochemical proton gradient that drives the same transport processes that depend on respiratory chain proton-pumping in A.

MBOC7_ptr_ch14_811-872.indd 842 02/12/21 2:31 PM

can couple proton flow to either ATP synthesis or ATP hydrolysis. The transmembrane electrochemical gradient that drives ATP production in mitochondria also drives the active transport of selected metabolites across the inner mitochondrial membrane, including an efficient ADP/ATP exchange between the mitochondrion and the cytosol that keeps the cell's ATP pool highly charged. The resulting high concentration of ATP inside the cell makes the free-energy change for ATP hydrolysis extremely favorable, allowing this hydrolysis reaction to drive a large number of energy-requiring processes throughout the cell. The universal presence of an ATP synthase in bacteria, mitochondria, and chloroplasts testifies to the central importance of chemiosmotic mechanisms for life.

CHLOROPLASTS AND PHOTOSYNTHESIS

All animals and most microorganisms rely on the continual uptake of large amounts of organic compounds from their environment. These compounds provide both the carbon-rich building blocks for biosynthesis and the metabolic energy for life. It has been proposed that the first organisms on the primitive Earth had access to an abundance of organic compounds produced by geochemical processes, but these would have been used up early in life's evolution. Since then, the vast majority of the organic materials required by living cells has been produced by *photosynthetic organisms*, including plants and photosynthetic bacteria. The core machinery that drives all photosynthesis appears to have evolved more than 3 billion years ago in the ancestors of present-day bacteria; today it provides the major solar energy storage mechanism on Earth.

The most advanced photosynthetic bacteria are the cyanobacteria, which have minimal nutrient requirements. They use electrons from water and the energy of sunlight to convert atmospheric CO_2 into organic compounds—a process called *carbon fixation*. In the course of the overall reaction

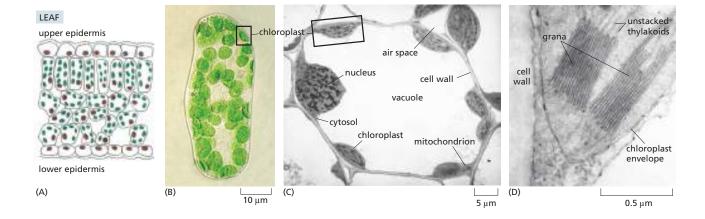

$$nH_2O + nCO_2 \xrightarrow{\text{Light}} (CH_2O)_n + nO_2$$

they also liberate into the atmosphere the molecular oxygen needed for oxidative phosphorylation. In this way, it is thought that the evolution of an organism similar to modern cyanobacteria from more primitive photosynthetic bacteria eventually made possible the development of the many different aerobic lifeforms that populate Earth today.

Chloroplasts Resemble Mitochondria but Have a Separate Thylakoid Compartment

Plants (including algae) developed much later than cyanobacteria, and their photosynthesis occurs in a specialized intracellular organelle—the **chloroplast** (Figure 14–37). There is good evidence that the chloroplast evolved after an endosymbiotic event between a eukaryotic cell and a photosynthetic

Figure 14-37 Chloroplasts in a plant cell. (A) Schematic cross section through the leaf of a green plant. (B) Light microscopy of a plant leaf cell-here, a mesophyll cell from Zinnia elegans - shows chloroplasts as bright green bodies, measuring several micrometers across, in the transparent cell interior. (C) An electron micrograph of a thin, stained section through a wheat leaf cell shows a thin rim of cytoplasmcontaining chloroplasts, the nucleus, and mitochondria—surrounding a large, water-filled vacuole. (D) At higher magnification, electron microscopy reveals the chloroplast envelope membrane and the thylakoid membrane within the chloroplast that is highly folded into grana stacks (Movie 14.10 and Movie 14.11). MBOC7_ptr_ch14_811-872.indd 843 02/12/21 2:31 PM

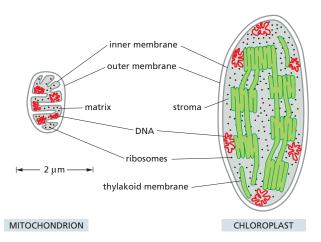

Figure 14-38 A mitochondrion and chloroplast compared. Chloroplasts are generally larger than mitochondria. In addition to an outer and inner envelope membrane, they contain the thylakoid membrane with its internal thylakoid lumen. The chloroplast thylakoid membrane, which is the site of solar energy conversion in plants and algae, corresponds to the mitochondrial cristae, which are the sites of energy conversion by cellular respiration. Unlike the crista membrane, which is continuous with the inner mitochondrial membrane at cristae junctions, the thylakoid membrane is not connected to the inner chloroplast membrane at any point.

cyanobacteria-like organism. Chloroplasts use chemiosmotic mechanisms to carry out their energy interconversions in much the same way that mitochondria do. Although much larger than mitochondria, they are organized on the same principles. They have a highly permeable outer membrane; a much less permeable inner membrane, in which membrane transport proteins are embedded; and a narrow intermembrane space in between. Together, these two membranes form the chloroplast envelope (Figure 14–37D). The inner chloroplast membrane surrounds a large space called the **stroma**, which is analogous to the mitochondrial matrix and to the bacterial cytoplasm. The stroma contains many metabolic enzymes, and, as for the mitochondrial matrix, it is the place where ATP is made by the heads of ATP synthase protein machines. Like the mitochondrion, the chloroplast has its own genome and genetic system. The stroma therefore also contains a special set of ribosomes, RNAs, and the chloroplast DNA.

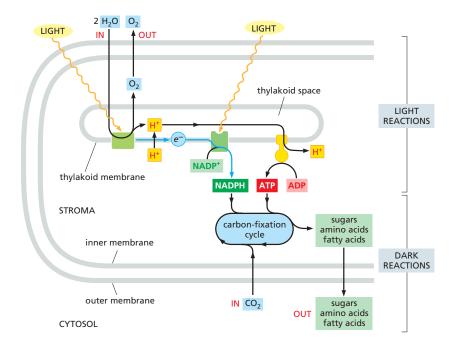

An important difference between the organization of mitochondria and chloroplasts is highlighted in Figure 14–38. The inner membrane of the chloroplast is not folded into cristae and does not contain electron-transport chains. Instead, the electron-transport chains, photosynthetic light-capturing systems, and ATP synthase are all contained in the **thylakoid membrane**, a separate, distinct membrane that forms a set of flattened, disc-like sacs, the *thylakoids*. The thylakoid membrane is highly folded into numerous local stacks of flattened vesicles called *grana*, interconnected by nonstacked thylakoids. The lumen of each thylakoid is connected with the lumen of other thylakoids, thereby defining a third internal compartment called the *thylakoid lumen*. This space represents a separate compartment in each chloroplast that is not connected to either the intermembrane space or the stroma. In addition to serving an analogous function, the thylakoid membrane has other similarities to the mitochondrial crista membrane, including a very high protein density and a unique lipid composition.

Chloroplasts Capture Energy from Sunlight and Use It to Fix Carbon

We can group the reactions that occur during photosynthesis in chloroplasts into two broad categories:

1. The photosynthetic electron-transfer reactions (also called the "light reactions") occur in two large protein complexes, called reaction centers, embedded in the thylakoid membrane (Figure 14-39). A photon (a quantum of light) knocks an electron out of the green pigment molecule chlorophyll in the first reaction center, creating a positively charged chlorophyllion. This high-energy electron then moves along an electron-transport chain and through a second reaction center in much the same way that an electron moves along the respiratory chain in mitochondria. During the electron-transport process, part of the energy released by electron transfer

MBOC7_ptr_ch14_811-872.indd 844 02/12/21 2:31 PM

is harnessed to pump H^+ ions (protons) across the thylakoid membrane. The resulting electrochemical proton gradient is then used by ATP synthase to drive the synthesis of ATP in the stroma. As the final step in this series of reactions, electrons are loaded (together with H^+) onto NADP+, converting it to the energy-rich NADPH molecule. Because the positively charged chlorophyll in the first reaction center quickly regains its electrons from water (H₂O), H⁺ and O₂ gas are produced as by-products. All of these reactions are confined to the chloroplast.

2. The carbon-fixation reactions (also called the "dark reactions") do not require sunlight. Here the ATP and NADPH generated by the above light reactions serve as the source of energy and reducing power, respectively, to drive the conversion of CO₂ to carbohydrate. These carbon-fixation reactions occur in the chloroplast stroma, where they generate the three-carbon sugar glyceraldehyde 3-phosphate. This simple sugar is an intermediate in the glycolysis and gluconeogenesis pathways. Upon export to the cytosol, it is used to produce sucrose and many other organic metabolites in the leaves of the plant. The sucrose is then exported to meet the metabolic needs of the nonphotosynthetic plant tissues, serving as a source of both carbon skeletons and energy for growth.

Thus, the formation of ATP, NADPH, and O_2 (which requires light energy directly) and the conversion of CO_2 to carbohydrate (which requires light energy only indirectly) are separate processes (Figure 14–39). But, they are linked by elaborate feedback mechanisms that allow a plant to manufacture sugars only when it is appropriate to do so. Several of the chloroplast enzymes required for carbon fixation, for example, are inactive in the dark and reactivated by light-stimulated electron-transport processes.

Carbon Fixation Uses ATP and NADPH to Convert CO₂ into Sugars

We have seen earlier in this chapter how mitochondria in eukaryotic cells produce ATP by using the large amount of free energy released when carbohydrates are oxidized to CO_2 and H_2O . The reverse reaction, in which plants make carbohydrate from CO_2 and H_2O , takes place in the chloroplast stroma. The large amounts

Figure 14-39 A summary of the energyconverting metabolism in chloroplasts. Chloroplasts require only water and carbon dioxide as inputs for their lightdriven photosynthesis reactions, and they produce the nutrients for most other organisms on the planet. Each oxidation of two water molecules by a photochemical reaction center in the thylakoid membrane produces one molecule of oxygen, which is released into the atmosphere. At the same time, protons are concentrated in the thylakoid space. These protons create a large electrochemical gradient across the thylakoid membrane, which is utilized by the chloroplast ATP synthase to produce ATP from ADP and phosphate. The electrons withdrawn from water are transferred to a second type of photochemical reaction center to produce NADPH from NADP+. As indicated, the NADPH and ATP are fed into the carbonfixation cycle to reduce carbon dioxide, thereby producing the precursors for sugars, amino acids, and fatty acids. The CO₂ that is taken up from the atmosphere here is the source of the carbon atoms for most organic molecules on Earth.

In a plant cell, a variety of metabolites produced in the chloroplast are exported to the cytoplasm for biosyntheses. Some of the sugar produced is stored in the form of starch granules in the chloroplast, but the rest is transported throughout the plant as sucrose or converted to starch in special storage tissues. These storage tissues serve as a major food source for animals.

$$\begin{array}{c} CH_2O \ \textbf{P} \\ CH_2O \ \textbf{P} \\$$

Figure 14–40 The initial reaction in carbon fixation. This carboxylation reaction allows one molecule each of carbon clioxide and water to be incorporated into organic carbon molecules. It is catalyzed in the chloroplast stroma by the abundant enzyme ribulose 1,5-bisphosphate carboxylase/oxygenase, or Rubisco. As indicated, the product is two molecules of 3-phosphoglycerate.

of ATP and NADPH produced by the photosynthetic electron-transfer reactions are required to drive this energetically unfavorable reaction.

Figure 14–40 illustrates the central reaction of carbon fixation, in which an atom of inorganic carbon is converted to organic carbon: CO_2 from the atmosphere combines with the five-carbon compound ribulose 1,5-bisphosphate plus water to yield two molecules of the three-carbon compound 3-phosphoglycerate. This carboxylation reaction is catalyzed in the chloroplast stroma by a large enzyme called *ribulose 1,5-bisphosphate carboxylase/oxygenase*, or *Rubisco*. Because the reaction is so slow (each Rubisco molecule turns over only about 3 molecules of substrate per second, compared to 1000 molecules per second for a typical enzyme), a very large number of enzyme molecules are needed. Rubisco constitutes up to 50% of the chloroplast protein mass, and it is one of the most abundant proteins on Earth. Of great importance to the global environment, Rubisco also helps to reduce the amount of the greenhouse gas CO_2 in the atmosphere.

Although the production of carbohydrates from CO₂ and H₂O is energetically unfavorable, the fixation of CO₂ catalyzed by Rubisco is an energetically favorable reaction. Carbon fixation is energetically favorable because a continuous supply of the energy-rich ribulose 1,5-bisphosphate is fed into the process via the carbon-fixation cycle described below. This compound is consumed by the addition of CO₂, and it must be replenished. As we describe next, the energy and reducing power needed to regenerate ribulose 1,5-bisphosphate come from the ATP and NADPH produced by the photosynthetic light reactions.

The elaborate series of reactions in which CO_2 combines with ribulose 1,5-bisphosphate to produce a simple sugar—a portion of which is used to regenerate ribulose 1,5-bisphosphate—forms a cycle, called the *carbon-fixation cycle*, or the Calvin–Benson–Bassham cycle (**Figure 14–41**). This cycle was one of the first metabolic pathways to be defined by applying radioisotopes as tracers in biochemistry. As indicated, each turn of the cycle converts six molecules of 3-phosphoglycerate to three molecules of ribulose 1,5-bisphosphate plus one molecule of glyceraldehyde 3-phosphate. The net result of each turn of the cycle is that 9 ATP and 6 NADPH molecules are used to power the conversion of 3 CO_2 molecules into one molecule of glyceraldehyde 3-phosphate.

Glyceraldehyde 3-phosphate, the three-carbon sugar produced by the cycle, occupies a pivotal point in carbohydrate biochemistry as an intermediate in glycolysis and gluconeogenesis, enabling it to serve as the starting material for the synthesis of many other sugars and all of the other organic molecules that form the plant.

Carbon Fixation in Some Plants Is Compartmentalized to Facilitate Growth at Low CO₂ Concentrations

Although ribulose 1,5-bisphosphate carboxylase/oxygenase preferentially adds CO_2 to ribulose 1,5-bisphosphate, it can also use O_2 as a substrate in place of CO_2 , and if the concentration of CO_2 is low, it will add O_2 to ribulose 1,5-bisphosphate

MBOC7_ptr_ch14_811-872.indd 846 02/12/21 2:31 PM

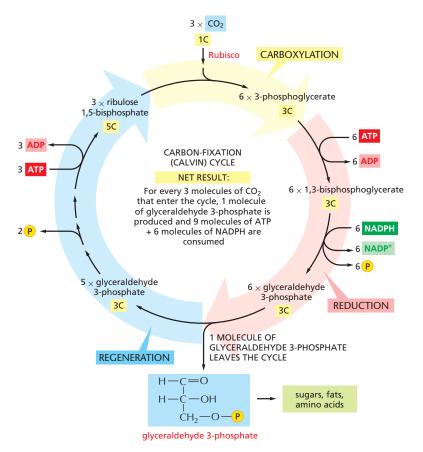

Figure 14–41 The Calvin–Benson–Bassham cycle (Calvin cycle) for carbon fixation. This central metabolic pathway allows organic molecules to be produced from CO_2 and H_2O . In the first stage of the cycle (carboxylation), CO_2 is added to ribulose 1,5-bisphosphate, as shown in Figure 14–40. In the second stage (reduction), ATP and NADPH are consumed to produce glyceraldehyde 3-phosphate molecules. In the final stage (regeneration), some of the glyceraldehyde 3-phosphate produced is used to regenerate ribulose 1,5-bisphosphate. Other glyceraldehyde 3-phosphate molecules are either converted to starch and fat in the chloroplast stroma or transported out of the chloroplast into the cytosol. The number of carbon atoms in each type of molecule is indicated in yellow. There are many intermediates between glyceraldehyde 3-phosphate and ribulose 1,5-bisphosphate, but they have been omitted here for clarity. The entry of water into the cycle is also not shown (but see Figure 14–40).

instead (see Figure 14–40). This is the first step in a pathway called **photorespiration**, whose ultimate effect is to use up O_2 and liberate CO_2 without the production of useful energy stores. In many plants, about one-third of the CO_2 fixed is lost again as CO_2 because of photorespiration.

Photorespiration can be a serious liability for plants in hot, dry conditions, which cause them to close their stomata (the gas-exchange pores in their leaves, each of which is called a stoma) to avoid excessive water loss. This in turn causes the CO₂ levels in the leaf to fall precipitously, thereby favoring photorespiration. A special adaptation, however, occurs in the leaves of many plants, such as corn and sugarcane, that grow in hot, dry environments. In these plants, the carbon-fixation cycle occurs only in the chloroplasts of specialized *bundle-sheath cells*, which contain all of the plant's ribulose 1,5-bisphosphate carboxylase/oxygenase. These cells are protected from the air and are surrounded by a specialized layer of *mesophyll cells* that use the energy harvested by their chloroplasts to "pump" CO₂ into the bundle-sheath cells. This supplies the ribulose 1,5-bisphosphate carboxylase/oxygenase with a high concentration of CO₂, thereby greatly reducing photorespiration.

MBOC7_ptr_ch14_811-872.indd 847 02/12/21 2:31 PM

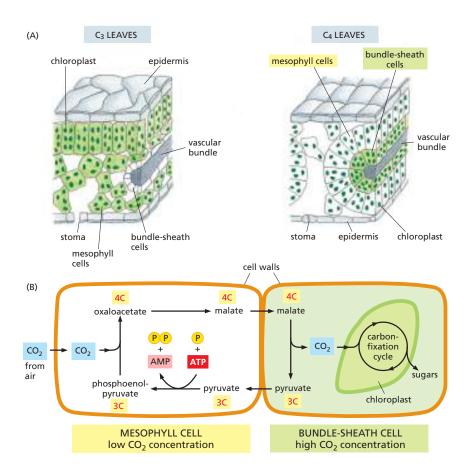

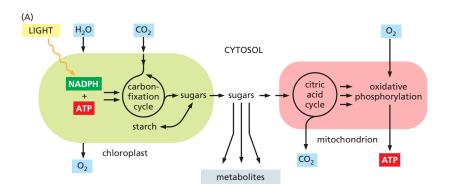

Figure 14-42 The CO₂ pumping in C₄ plants. (A) Comparative leaf anatomy in a C₃ plant and a C₄ plant. The cells with green cytosol in the leaf interior contain chloroplasts that perform the normal carbon-fixation cycle. In C₄ plants, the mesophyll cells are specialized for CO₂ pumping rather than for carbon fixation, and they thereby create a high ratio of CO2 to O₂ in the bundle-sheath cells, which are the only cells in these plants where the carbon-fixation cycle occurs. The vascular bundles carry the sucrose made in the leaf to other tissues. (B) How carbon dioxide is concentrated in bundle-sheath cells by the harnessing of ATP energy in mesophyll cells.

The CO_2 pump mechanism depends on a reaction cycle that begins in the cytosol of the mesophyll cells. An initial CO_2 -fixation step is catalyzed by an enzyme that binds CO_2 (as bicarbonate) and combines it with an activated three-carbon molecule (phosphoenolpyruvate) to produce a four-carbon molecule. The four-carbon molecule diffuses into the bundle-sheath cells, where it is broken down to release the CO_2 and generate a molecule with three carbons. The pumping cycle is completed when this three-carbon molecule (pyruvate) is returned to the mesophyll cells and converted back to its original activated form. Because the CO_2 is initially captured by converting it into a compound containing four carbons, the CO_2 -pumping plants are called C_4 plants. All other plants are called C_3 plants because they capture CO_2 into the three-carbon compound 3-phosphoglycerate (Figure 14-42).

As with any vectorial transport process, pumping CO_2 into the bundle-sheath cells in C_4 plants costs energy (ATP is hydrolyzed; see Figure 14–42B). In hot, dry environments, however, this cost can be much less than the energy lost by photorespiration in C_3 plants, so C_4 plants have a potential advantage. Moreover, because C_4 plants can perform photosynthesis at a lower concentration of CO_2 inside the leaf, they need to open their stomata less often and therefore can fix about twice as much net carbon as C_3 plants per unit of water lost. This type of carbon fixation has evolved independently in several different plant lineages. Although the vast majority of plant species are C_3 plants, C_4 plants such as corn and sugarcane are much more effective at converting sunlight energy into biomass than C_3 plants such as cereal grains. They are therefore of special importance in world agriculture.

Many algae have a different adaptation to manage the challenge of limited CO_2 concentration, which is often a problem in the aquatic environment in which algae grow. The pyrenoid is a complex structure that contains a biomolecular

MBOC7_ptr_ch14_811-872.indd 848 02/12/21 2:31 PM

(B)

condensate highly enriched in Rubisco along with a scaffold protein (see Figure 12–8). This condensate is interwoven with membrane tubules that contain carbonic anhydrase, an enzyme that converts the bicarbonate ions (HCO_3^-) dissolved in water into CO_2 . The pyrenoid therefore provides CO_2 for Rubisco, thereby favoring carbon fixation over deleterious photorespiration.

The Sugars Generated by Carbon Fixation Can Be Stored as Starch or Consumed to Produce ATP

The glyceraldehyde 3-phosphate generated by carbon fixation in the chloroplast stroma can be used in a number of ways, depending on the needs of the plant. During periods of excess photosynthetic activity, much of it is converted to glucose and stored as *starch* in the chloroplast stroma. Like glycogen in animal cells, starch is a storage polymer of glucose that is found as large granules. Starch forms an important part of the diet of all animals that eat plants. Other glyceraldehyde 3-phosphate molecules are converted to different important biosynthetic or storage molecules. For example, fat, which accumulates as triglycerides and other storage esters in fat droplets, serves as an additional energy reserve.

At night, stored starch and fat can be broken down to glucose and fatty acids, which are exported to the cytosol to help support the metabolic needs of the plant. Some of the exported sugar enters the glycolytic pathway (see Figure 2–46), where it is converted to pyruvate. Both that pyruvate and the fatty acids can enter the plant cell mitochondria and be catabolized to acetyl CoA that is fed into the citric acid cycle, ultimately leading to the efficient production of ATP by oxidative phosphorylation (Figure 14–43). In this way, the metabolic transitions of the light/dark cycle of the plant are reminiscent of the fasting/feeding cycles typical of many animals.

In the cytosol, glucose exported from chloroplasts after starch hydrolysis or generated from gluconeogenesis from glyceraldehyde 3-phosphate can also be converted into the disaccharide *sucrose*. Sucrose is the major form in which sugar is transported between the cells of a plant. Just as glucose is transported in the blood of animals, so sucrose is exported from the leaves to provide carbohydrate to the rest of the plant.

The Thylakoid Membranes of Chloroplasts Contain the Protein Complexes Required for Photosynthesis and ATP Generation

We next need to explain how the large amounts of ATP and NADPH required for carbon fixation are generated in the chloroplast. Chloroplasts make use of chemiosmotic energy conversion in much the same way as mitochondria. As we saw in Figure 14–38, chloroplasts and mitochondria are organized on the same principles, although the chloroplast contains a separate thylakoid membrane system in which its chemiosmotic mechanisms occur. The thylakoid membranes contain two large membrane protein complexes, called *photosystems*, which endow photosynthetic organisms with the ability to capture and convert solar energy into usable forms of energy. Two other protein complexes in the thylakoid membrane work together with the photosystems to catalyze photophosphorylation—the

Figure 14-43 How chloroplasts and mitochondria collaborate to supply cells with both metabolites and ATP. (A) The inner chloroplast membrane is impermeable to the ATP and NADPH that are produced in the stroma during the light reactions of photosynthesis. These molecules are instead funneled into the carbon-fixation cycle, where they are used to make sugars. The resulting sugars and their metabolites are either stored within the chloroplast—in the form of starch or fat—or exported to the rest of the plant cell. There. they can enter the energy-generating pathway that ends in ATP synthesis linked to oxidative phosphorylation inside the mitochondrion. Unlike the chloroplast, mitochondrial membranes contain a specific transporter that makes them permeable to ATP (see Figure 14-35). Note that the O₂ released to the atmosphere by photosynthesis in chloroplasts is used for oxidative phosphorylation in mitochondria: similarly, the CO₂ released by the citric acid cycle in mitochondria is used for carbon fixation in chloroplasts. (B) In a leaf, mitochondria (red) tend to cluster close to the chloroplasts (green), as seen in this light micrograph. (B, courtesy of Olivier Grandjean.)

MBOC7_ptr_ch14_811-872.indd 849 02/12/21 2:31 PM

generation of ATP with sunlight. These have mitochondrial equivalents: a heme-containing cytochrome b_6 -f complex, which both functionally and structurally resembles cytochrome c reductase (Complex III) in the respiratory chain; and a chloroplast ATP synthase, which closely resembles the mitochondrial ATP synthase and works in the same way.

Chlorophyll-Protein Complexes Can Transfer Either Excitation Energy or Electrons

The photosystems in the thylakoid membrane are multiprotein assemblies of a complexity comparable to that of the protein complexes in the mitochondrial electron-transport chain. They contain large numbers of specifically bound chlorophyll molecules, in addition to cofactors that will be familiar from our discussion of mitochondria (heme, iron–sulfur clusters, and quinones). **Chlorophyll**, the green pigment of photosynthetic organisms, has a long hydrophobic tail that makes it behave like a lipid, plus a porphyrin ring that has an extensive system of delocalized electrons in conjugated double bonds and a central Mg atom (structurally analogous to heme and its central Fe atom; **Figure 14–44**).

When a chlorophyll molecule absorbs a quantum of sunlight (a photon), the energy of the photon causes one of these electrons to move from a low-energy orbital to another orbital of higher energy. A photon of red light (\sim 600–700 nm wavelength) moves an electron to a low-level excited state. A higher-energy photon of blue light (\sim 400–500 nm) kicks an electron to a higher-energy excited state, which rapidly decays to the low-level excited state by converting the extra energy into heat (molecular motion). The excited electrons in the low-energy state tend to return to their ground state in one of three ways:

- By converting the extra energy into heat (molecular motion) or to some combination of heat and light of a longer wavelength (fluorescence); this is what usually happens when light is absorbed by an isolated chlorophyll molecule in solution.
- 2. By transferring the energy—but not the electron—directly to a neighboring chlorophyll molecule by a process called *resonance energy transfer*.
- 3. By transferring the excited electron with its negative charge to another nearby molecule, an *electron acceptor*, after which the positively charged chlorophyll returns to its original state by taking up an electron from some other molecule, an *electron donor*.

Only the latter two mechanisms are useful for the capturing of energy from sunlight, and they are enabled by the chlorophylls being precisely positioned within a *chlorophyll-protein complex*. The protein coordinates the central Mg atom in the chlorophyll porphyrin, most often through a histidine side chain located in the hydrophobic interior of a membrane, causing each of the chlorophylls in the protein complex to be held at exactly defined distances and orientations. The flow of excitation energy or electrons then depends on both the precise spatial arrangement and the local protein environment of the protein-bound chlorophylls.

When excited by a photon, most protein-bound chlorophylls simply transmit the absorbed energy to another nearby chlorophyll by the process of resonance energy transfer. However, in a few specially positioned chlorophylls, the energy difference between the ground state and the excited state is just right for the photon to trigger a light-induced chemical reaction. The special state of such chlorophyll molecules derives from their close interaction with a second chlorophyll molecule in the same chlorophyll–protein complex. Together, these two chlorophylls form a *special pair*.

The photosynthetic electron-transfer process starts when a photon of suitable energy ionizes a chlorophyll molecule in such a special pair, dissociating it into an electron and a positively charged chlorophyll ion. The energized electron is then passed rapidly to a quinone in the same protein complex, preventing its unproductive reassociation with the chlorophyll ion. This light-induced transfer of

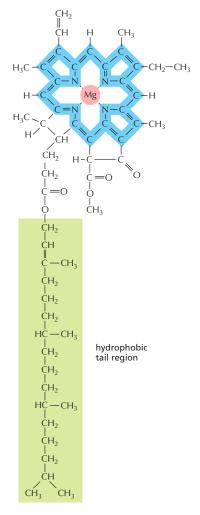

Figure 14–44 The structure of chlorophyll a. A magnesium atom is held in a porphyrin ring, which is related to the porphyrin ring that binds iron in heme (see Figure 14–15). Electrons are delocalized over the bonds shaded in blue, and the hydrophobic tail is shaded in green.

MBOC7_ptr_ch14_811-872.indd 850 02/12/21 2:31 PM

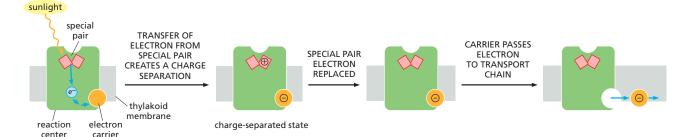

Figure 14–45 A general scheme for the charge-separation step in a photosynthetic reaction center. In a reaction center, light energy is harnessed to transfer electrons from chlorophyll to mobile electron carriers in which the electrons are held in a high-energy state. Light energy is thereby converted to chemical energy. The process starts when a photon absorbed by the special pair of chlorophylls in the reaction center knocks an electron out of one of the chlorophylls. This electron is rapidly taken up by a mobile electron carrier (orange) bound at the opposite membrane surface, because a set of intermediary carriers embedded in the reaction center (not shown) provides the path from the special pair to this carrier. The physical distance between the positively charged chlorophyll ion and the negatively charged electron carrier stabilizes the charge-separated state for a short time, during which the chlorophyll ion, a strong oxidant, withdraws an electron from a suitable compound (for example, from water, an event we will discuss in detail shortly). The mobile electron carrier then diffuses away from the reaction center as a strong electron donor that will transfer its electron to an electron-transport chain.

an electron from a chlorophyll to a mobile electron carrier is the central *charge-separation* step in photosynthesis, in which a chlorophyll becomes positively charged and an electron carrier becomes negatively charged (**Figure 14–45**). A positively charged chlorophyll ion is a very strong oxidant that is able to withdraw an electron from a low-energy substrate; in the first step of oxygenic photosynthesis, this low-energy substrate is water.

Upon transfer to a mobile carrier in the electron-transport chain, the electron has been stabilized as part of a strong electron donor and made available for subsequent reactions. These subsequent reactions require more time to complete, and we shall see how they cause the production of light-generated energy-rich compounds.

A Photosystem Contains Chlorophylls in Antennae and a Reaction Center

There are two distinct types of chlorophyll–protein complexes in the photosynthetic membrane. A *photochemical reaction center* contains the special pair of chlorophylls just described. The other type engages exclusively in light absorption and resonance energy transfer and contains *antenna chlorophylls*. Together, the two types of chlorophyll–protein complexes help to create a **photosystem** (Figure 14–46).

Most of the chlorophylls in a photosystem are present in *light-harvesting com*plexes, whose role is to efficiently collect the energy of photons for photosynthesis.

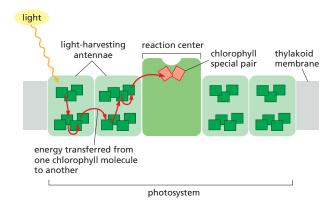

Figure 14-46 A photosystem. Each photosystem consists of a reaction center plus a large number of light-harvesting protein-bound chlorophylls (more than depicted in this figure). The solar energy for photosynthesis is collected by the antenna chlorophylls, which account for most of the chlorophyll in a plant cell. The energy hops randomly by resonance energy transfer (red arrows) from one chlorophyll molecule to another, until it reaches the reaction center complex, where it ionizes a chlorophyll in the special pair. The chlorophyll special pair holds its electrons at a lower energy than that of the electrons of the antenna chlorophylls, causing the energy transferred to it to become trapped there. Note that it is only energy, not electrons, that moves from one antenna chlorophyll molecule to another (Movie 14.12).

MBOC7_ptr_ch14_811-872.indd 851 02/12/21 2:31 PM

Without these antennae, the process would be slow and inefficient, inasmuch as each reaction-center chlorophyll would absorb only about one light quantum per second, even in broad daylight, whereas hundreds per second are needed for effective photosynthesis. When light excites an antenna chlorophyll molecule, the energy passes rapidly from one protein-bound chlorophyll to another by resonance energy transfer until it reaches the special pair in the reaction center.

Additional light-harvesting complexes, or LHCs, serve an accessory antenna role by collecting photon energy and transferring it to the photosystem. In addition to many chlorophyll molecules, an LHC contains orange carotenoid pigments. The carotenoids collect light of a different wavelength than that absorbed by chlorophylls, helping to make the antennae more efficient. They also have an important protective role in preventing the formation of harmful oxygen radicals in the photosynthetic membrane.

The Thylakoid Membrane Contains Two Different Photosystems Working in Series

As just described, the excitation energy collected by the antenna chlorophylls is delivered to the special pair in the **photochemical reaction center**. The reaction center is a transmembrane chlorophyll–protein complex that lies at the heart of photosynthesis. It harbors the special pair of chlorophyll molecules, which acts as an irreversible trap for excitation energy (see Figure 14–46).

Chloroplasts contain two functionally different although structurally related photosystems, each of which feeds electrons generated by the action of sunlight into an electron-transfer chain. In the chloroplast thylakoid membrane, *photosystem I* is confined to the unstacked stroma thylakoids, while the stacked grana thylakoids contain *photosystem II*. The two photosystems were named in order of their discovery, not of their actions in the photosynthetic pathway, and electrons are first activated in photosystem II before being transferred to photosystem I (Figure 14–47). The path of the electron through the two photosystems can be

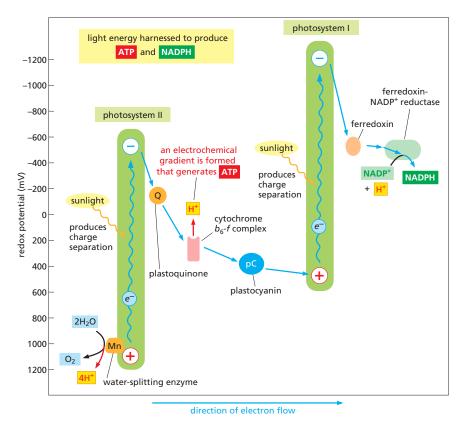

Figure 14-47 Changes in redox potential during photosynthesis. The redox potential for each molecule is indicated by its position along the vertical axis. Using excitation energy from sunlight, photosystem II passes electrons derived from water to photosystem I, which also uses sunlight energy to pass them to NADP+ through ferredoxin-NADP reductase. The net electron flow through the two photosystems is from water to NADP+, and it produces NADPH as well as an electrochemical proton gradient. This proton gradient is used by the ATP synthase to produce ATP. Details in this figure will be explained in the subsequent text. Note that, for historical reasons, the two photosystems were named opposite to the order in which they act, with photosystem II passing its electrons to photosystem I.

MBOC7_ptr_ch14_811-872.indd 852 02/12/21 2:31 PM

described as a Z-like trajectory and is known as the Z scheme. In the Z scheme, the reaction center of photosystem II first withdraws an electron from water. The electron passes via an electron-transport chain (composed of the electron carrier plastoquinone, the cytochrome b_6 -f complex, and the protein plastocyanin) to photosystem I, which propels the electron across the membrane in a second light-driven charge-separation reaction that leads to NADPH production. In the process, an electrochemical proton gradient is established across the thylakoid membrane that is used to fuel ATP production.

The Z scheme is necessary to bridge the very large energy gap between water and NADPH (Figure 14–47). A single quantum of visible light does not contain enough energy both to withdraw electrons from water, which holds on to its electrons very tightly (redox potential $+820~\rm mV$) and therefore is a very poor electron donor, and to force them on to NADP+, which is a very poor electron acceptor (redox potential $-320~\rm mV$). The Z scheme first evolved in cyanobacteria to enable them to use water as a universally available electron source. Other, simpler photosynthetic bacteria have only one photosystem. As we shall see, they cannot use water as an electron source and must rely on other, more energy-rich substrates instead, from which electrons are more readily withdrawn. The ability to extract electrons from water (and thereby to produce molecular oxygen) was acquired by plants when their ancestors took up the endosymbiotic cyanobacteria that later evolved into chloroplasts (see Figure 1–29).

Photosystem II Uses a Manganese Cluster to Withdraw Electrons from Water

In biology, only photosystem II is able to withdraw electrons from water and to generate molecular oxygen as a by-product. This remarkable specialization of photosystem II is conferred by the unique properties of one of the two chlorophyll molecules of its special pair and by a *manganese cluster* linked to the protein. The special pair of chlorophyll molecules plus the manganese cluster form the catalytic core of the photosystem II reaction center, whose mechanism is outlined in **Figure 14-48**.

Water is an inexhaustible source of electrons, but it is also extremely stable; therefore, a large amount of energy is required to make it part with its electrons. The only compound in living organisms that is able to achieve this feat, after its ionization by light, is the chlorophyll special pair called P_{680} (P_{680}/P_{680}^+ redox potential = +1270 mV). The reaction $2H_2O + 4$ photons $\rightarrow 4H^+ + 4e^- + O_2$ is catalyzed by its adjacent manganese cluster. Except for the electrons, the intermediates remain firmly attached to the manganese cluster until two water molecules have been fully oxidized to O_2 , thus ensuring that no dangerous oxygen radicals are released as the reaction proceeds. The four protons released by the two water molecules are discharged to the thylakoid space, contributing to the proton gradient across the thylakoid membrane (pH lower in the thylakoid

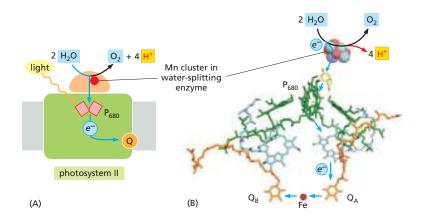

Figure 14-48 The conversion of light energy to chemical energy in the photosystem II complex. (A) Schematic diagram of the photosystem II reaction center, whose special pair of chlorophyll molecules is designated as P₆₈₀ on the basis of the wavelength of its absorbance maximum (680 nm). (B) Cofactors and pigments at the core of the reaction center. Shown are the manganese (Mn) cluster. the tyrosine side chain that connects it to the P₆₈₀ special pair, four chlorophylls (green), two pheophytins (light blue), two plastoquinones (orange), and an iron atom (red). The path of electrons is shown by blue arrows. In the manganese cluster, four manganese atoms (light blue), one calcium atom (purple), and five oxygen atoms (red) work together to catalyze the oxidation of water. The water-splitting reaction occurs in four successive steps, each requiring the energy of one photon. Each photon turns a P₆₈₀ reaction-center chlorophyll into a positively charged chlorophyll ion. Through an ionized tyrosine side chain (yellow), this chlorophyll ion pulls an electron away from a water molecule bound at the manganese cluster. In this way, a total of four electrons are withdrawn from two water molecules to generate molecular oxygen, which is released into the atmosphere (see also Figure 4-49).

Each electron that is energized by light passes from the special pair to an electrontransfer chain inside the complex, along the indicated path to the permanently bound plastoquinone Q_A and then to plastoquinone QB. Once QB has picked up two electrons (plus two protons; see Figure 14-17), it dissociates from its binding site in the complex and enters the lipid bilaver as a mobile electron carrier. being immediately replaced by a new. nonreduced molecule of plastoquinone. Note that the chlorophylls and pheophytins form two symmetrical branches of a potential electron-transport chain. Only one branch is active, thus ensuring that the plastoquinones become fully reduced in minimum time.

MBOC7_ptr_ch14_811-872.indd 853 02/12/21 2:31 PM

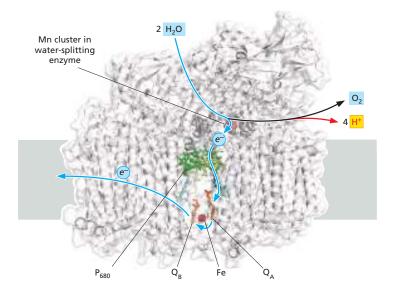

Figure 14-49 The structure of the complete photosystem II complex. This photosystem contains at least 16 protein subunits, along with 36 chlorophylls, two pheophytins, two hemes, and a number of protective carotenoids (colored). Most of these pigments and cofactors are deeply buried, tightly complexed to protein (gray). The path of electrons is indicated by the blue arrows and is explained in Figure 14-48B. The photosystem II complex presented here is the cyanobacterial complex, which is simpler and more stable than the plant complex, which works in the same way. (PDB code: 3WU2.)

space than in the stroma). The unique protein environment that endows life with this all-important ability to oxidize water has remained essentially unchanged throughout billions of years of evolution (Figure 14–49). All of the oxygen in Earth's atmosphere is believed to have been generated in this way.

The Cytochrome b_6 -f Complex Connects Photosystem II to Photosystem I

Following the path shown previously in Figure 14–49, the electrons extracted from water by photosystem II are transferred to plastoquinol, a strong electron donor similar to ubiquinol in mitochondria. This quinol, which can diffuse rapidly in the lipid bilayer of the thylakoid membrane, transfers its electrons to the *cytochrome* b_6 -f *complex*, whose structure is similar to the cytochrome c reductase in mitochondria. The cytochrome b_6 -f complex pumps H^+ into the thylakoid space using the same Q cycle that is utilized in mitochondria (see Figure 14–21), thereby adding to the proton gradient across the thylakoid membrane.

The cytochrome b_6 -f complex forms the connecting link between photosystems II and I in the chloroplast electron-transport chain. It passes its electrons one at a time to the mobile electron carrier plastocyanin (a small copper-containing protein that takes the place of the cytochrome c in mitochondria), which transfers those electrons to photosystem I (**Figure 14–50**). As we discuss next, photosystem I then uses a second photon of light to boost the electrons that it receives to an even higher energy level.

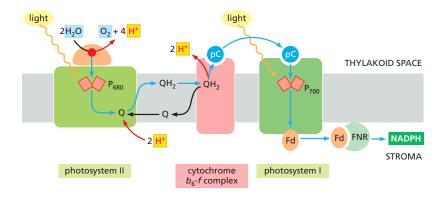

Figure 14–50 Electron flow through the cytochrome b_6 -f complex to NADPH.

The cytochrome b_6 -f complex is the functional equivalent of cytochrome c reductase (the cytochrome *b-c*₁ complex) in mitochondria (see Figure 14-22). Like its mitochondrial homolog, the b₆-f complex receives its electrons from a quinone and engages in a complicated Q cycle that pumps two protons across the membrane (details not shown). It passes its electrons, one at a time, to plastocyanin (pC) Plastocyanin diffuses along the membrane surface to photosystem I and transfers the electrons via ferredoxin (Fd) to the ferredoxin-NADP+ reductase (FNR), where they are utilized to produce NADPH. P₇₀₀ is a special pair of chlorophylls that absorbs light of wavelength 700 nm.

MBOC7_ptr_ch14_811-872.indd 854 02/12/21 2:31 PM

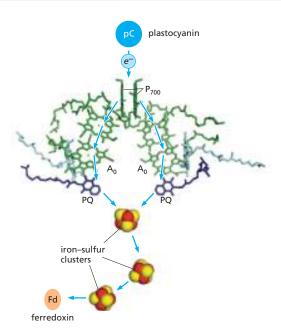

Figure 14–51 Structure and function of photosystem I. At the heart of the photosystem I complex assembly is the electron-transfer chain shown. At one end is a special pair of chlorophylls called P₇₀₀ (because it absorbs light of 700-nm wavelength), receiving electrons from plastocyanin (pC). At the other end are the A₀ chlorophylls, which hand the electrons on to ferredoxin via two plastoquinones (PQ: purple) and three iron-sulfur clusters. Even though the roles of photosystems I and II in photosynthesis are very different, their central electron-transfer chains are structurally similar, suggesting a common evolutionary origin (see Figure 14-53). Note that in photosystem I both branches of the electron-transfer chain are active, unlike in photosystem II (see Figure 14-48). (PDB code: 3LW5.)

Photosystem I Carries Out the Second Charge-Separation Step in the Z Scheme

Photosystem I receives electrons from plastocyanin in the thylakoid space and transfers them, via a second charge-separation reaction, to the small protein ferredoxin on the opposite membrane surface (Figure 14–51). Then, in a final step, ferredoxin feeds its electrons to a membrane-associated enzyme complex, the *ferredoxin-NADP*⁺ *reductase*, which uses the electrons to reduce NADP⁺ to NADPH (see Figure 14–50). The reduced NADPH is released into the chloroplast stroma, where it is used for biosynthesis of glyceraldehyde 3-phosphate, amino acid precursors, and fatty acids.

The redox potential of the NADP $^+$ /NADPH pair (-320 mV) is already very low, and the reduction of NADP $^+$ therefore requires a compound with an even lower redox potential. This turns out to be a chlorophyll molecule near the stromal membrane surface of photosystem I that has a redox potential of –1000 mV (chlorophyll A_0), making it the strongest known electron donor in biology.

The Chloroplast ATP Synthase Uses the Proton Gradient Generated by the Photosynthetic Light Reactions to Produce ATP

The sequence of events that results in light-driven production of ATP and NADPH in chloroplasts and cyanobacteria is summarized in **Figure 14–52**. Starting with the withdrawal of electrons from water, the light-driven charge-separation steps in photosystems II and I enable the energetically unfavorable flow of electrons from water to NADPH (see Figure 14–47). Three small mobile electron carriers—plastoquinone, plastocyanin, and ferredoxin—participate in this process. Together with the electron-driven proton pump of the cytochrome b_6 -f complex, the photosystems generate a large proton gradient across the thylakoid membrane. The ATP synthase molecules embedded in the thylakoid membranes then harness this proton gradient to produce ATP in the chloroplast stroma, analogous to the synthesis of ATP in the mitochondrial matrix.

The linear Z scheme for photosynthesis thus far discussed can switch to a circular mode of electron flow through photosystem I and the b_6 -f complex. Here, the electrons held in the reduced ferredoxin are transferred back to the b_6 -f complex to reduce plastoquinone, instead of being passed to the ferredoxin-NADP⁺ reductase enzyme complex. This, in effect, turns photosystem I into a light-driven

MBOC7_ptr_ch14_811-872.indd 855 02/12/21 2:31 PM

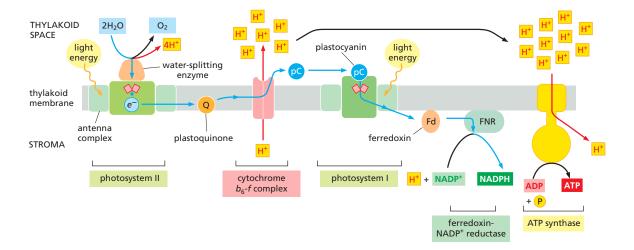

Figure 14–52 Summary of electron and proton movements during photosynthesis in the thylakoid membrane. Electrons are withdrawn, through the action of light energy, from a water molecule that is held by the manganese cluster in photosystem II. The electrons pass on to plastoquinone, which delivers them to the cytochrome b_6 -f complex that resembles the cytochrome c reductase of mitochondria and the cytochrome b-c complex of bacteria. They are then carried to photosystem I by the soluble electron carrier plastocyanin, the functional equivalent of cytochrome c in mitochondria. From photosystem I they are transferred to ferredoxin-NADP+ reductase (FNR) by the soluble carrier ferredoxin (Fd; a small protein containing an iron-sulfur center). Protons are pumped into the thylakoid space by the cytochrome b_6 -f complex, in the same way that protons are pumped into mitochondrial cristae by cytochrome c reductase (see Figure 14–23). In addition, the H+ released into the thylakoid space by water oxidation, and the H+ consumed during NADPH formation in the stroma, contribute to the generation of the electrochemical H+ gradient across the thylakoid membrane. As illustrated, this gradient drives ATP synthesis by an ATP synthase that sits in the same membrane (see Figure 14–47).

proton pump, thereby increasing the proton gradient and thus the amount of ATP made by the ATP synthase. An elaborate set of regulatory mechanisms controls this switch, which enables the chloroplast to generate either more NADPH (linear mode) or more ATP (circular mode), depending on the metabolic needs of the cell.

The Proton-Motive Force for ATP Production in Mitochondria and Chloroplasts Is Essentially the Same

The proton gradient across the thylakoid membrane depends both on the proton-pumping activity of the cytochrome b_6 -f complex and on the photosynthetic activity of the two photosystems. In chloroplasts exposed to light, H $^+$ is pumped out of the stroma (pH around 8, similar to the mitochondrial matrix) into the thylakoid space (pH 5–6), creating a gradient of 2–3 pH units across the thylakoid membrane, representing a proton-motive force of about 180 mV. This is very similar to the proton-motive force in respiring mitochondria. However, a membrane potential across the inner mitochondrial membrane makes the largest contribution to the proton-motive force that drives the mitochondrial ATP synthase to make ATP, whereas an H $^+$ gradient predominates for chloroplasts.

Chemiosmotic Mechanisms Evolved in Stages

The first living cells on Earth may have consumed geochemically produced organic molecules and generated their ATP by fermentation. Because oxygen was not yet present in the atmosphere, such anaerobic fermentation reactions would have dumped organic acids—such as lactic or formic acids, for example—into the environment (see Figure 2–50). Perhaps such acids lowered the pH of the environment, favoring the survival of cells that evolved transmembrane proteins that

MBOC7_ptr_ch14_811-872.indd 856 02/12/21 2:31 PM

could pump H^+ out of the cytosol, thereby preventing the cell from becoming too acidic (stage 1 in Figure 14–53). One of these pumps may have used the energy available from ATP hydrolysis to eject H^+ from the cell; such a proton pump could have been the ancestor of present-day ATP synthases.

As Earth's supply of geochemically produced nutrients began to dwindle, organisms that could find a way to pump $\mathrm{H^+}$ without consuming ATP would have been at an advantage: they could save the small amounts of ATP they derived from the fermentation of increasingly scarce foodstuffs to fuel other important activities. This need to conserve resources might have led to the evolution of electron-transport proteins that allowed cells to use the movement of electrons between molecules of different redox potentials as a source of energy for pumping $\mathrm{H^+}$ across the plasma membrane (stage 2 in Figure 14–53). Some of these cells might have used the nonfermentable organic acids that neighboring cells had excreted as waste to provide the electrons needed to feed this electron-transport system. Some present-day bacteria grow on formic acid, for example, using the small amount of redox energy derived from the transfer of electrons from formic acid to fumarate to pump $\mathrm{H^+}$.

Eventually, some bacteria would have developed $\mathrm{H^+}$ -pumping electron-transport systems that were so efficient that the bacteria could harvest more redox energy than they needed to maintain their internal pH. Such cells would probably have generated large electrochemical proton gradients, which they could then use to produce ATP. Protons could leak back into the cell through the ATP-driven $\mathrm{H^+}$ pumps, essentially running them in reverse so that they synthesized ATP (stage 3 in Figure 14–53). Because such cells would require much less of the dwindling supply of fermentable nutrients, they would have proliferated at the expense of their neighbors.

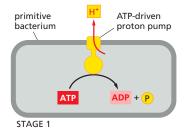

By Providing an Inexhaustible Source of Reducing Power, Photosynthetic Bacteria Overcame a Major Evolutionary Obstacle

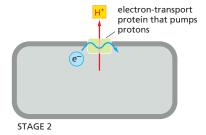

The gradual depletion of nutrients from the environment on the early Earth meant that organisms had to find some alternative source of carbon to make the sugars that serve as the precursors for so many other cell components. Although the CO_2 in the atmosphere provides an abundant potential carbon source, to convert it into an organic molecule such as a carbohydrate requires reducing the fixed CO_2 with a strong electron donor, such as NADPH, which can generate (CH_2O) units from CO_2 (see Figure 14–41). Early in cellular evolution, strong reducing agents (electron donors) are thought to have been plentiful. But once an ancestor of ATP synthase began to generate most of the ATP, it paved the way for cells to evolve a new way of generating strong reducing agents.

A major evolutionary breakthrough in energy metabolism came with the development of photochemical reaction centers that could use the energy of sunlight to produce molecules such as NADPH. It is thought that this occurred early in the process of cellular evolution in the ancestors of the green sulfur bacteria. Present-day green sulfur bacteria use light energy to transfer hydrogen atoms (as an electron plus a proton) from $\rm H_2S$ to NADPH, thereby producing the strong reducing power required for carbon fixation. Because the redox potential of $\rm H_2S$ is much lower than that of $\rm H_2O$ (–230 mV for $\rm H_2S$ compared with +820 mV for $\rm H_2O$), one quantum of light absorbed by the single photosystem in these bacteria is sufficient to generate NADPH via a relatively simple photosynthetic electron-transport chain.

The Photosynthetic Electron-Transport Chains of Cyanobacteria Produced Atmospheric Oxygen and Permitted New Life-Forms

The next evolutionary step, which is thought to have occurred with the development of the cyanobacteria perhaps 3 billion years ago, was the evolution of organisms capable of using water as the electron source for CO_2 reduction. This

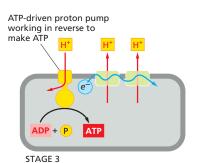

Figure 14-53 How ATP synthesis by chemiosmosis might have evolved in stages. The first stage could have involved the evolution of an ATPase that pumped protons out of the cell using the energy of ATP hydrolysis. Stage 2 could have involved the evolution of a different proton pump, driven by an electron-transport chain. Stage 3 would then have linked these two systems together to generate a primitive ATP synthase that used the protons pumped by the electron-transport chain to synthesize ATP. An early bacterium with this final system would have had a selective advantage over bacteria with neither of the systems or only one.

MBOC7_ptr_ch14_811-872.indd 857

entailed the evolution of a water-splitting enzyme and also required the addition of a second photosystem, acting in series with the first, to bridge the large gap in redox potential between $\rm H_2O$ and NADPH. The biological consequences of this evolutionary step were far-reaching. For the first time, there would have been organisms that could survive on water, $\rm CO_2$, and sunlight (plus several other elements; see Figure 2–1). These cells would have been able to spread and evolve in ways denied to the earlier photosynthetic bacteria, which needed $\rm H_2S$ or organic acids as a source of electrons. Consequently, large amounts of biologically synthesized, reduced organic materials accumulated, and oxygen entered the atmosphere for the first time.

Oxygen is highly toxic because the oxidation of biological molecules alters their structure and properties indiscriminately and irreversibly. Most anaerobic bacteria, for example, occupy environments devoid of oxygen and are rapidly killed when exposed to air. Thus, organisms on the primitive Earth would have had to evolve mechanisms to protect them from the rising O_2 levels in the environment. Late evolutionary arrivals, such as ourselves, have numerous detoxifying mechanisms that protect our cells from the ill effects of oxygen.

The increase in atmospheric O_2 was very slow at first and would have allowed a gradual evolution of protective devices. For example, the early seas contained large amounts of iron in its reduced, ferrous state (Fe²⁺), and nearly all the O_2 produced by early photosynthetic bacteria would have been used up in oxidizing Fe²⁺ to ferric Fe³⁺. This conversion caused the precipitation of huge amounts of stable oxides, and the extensive banded iron formations in sedimentary rocks, beginning about 2.7 billion years ago, help to date the spread of the cyanobacteria. By about 2 billion years ago, the supply of Fe²⁺ was exhausted, and the deposition of further iron precipitates ceased. Geological evidence reveals how O_2 levels in the atmosphere have changed over billions of years, approximating current levels only about 0.5 billion years ago (Figure 14–54).

The availability of O_2 enabled the rise of bacteria that developed an aerobic metabolism to make their ATP. These organisms could harness the

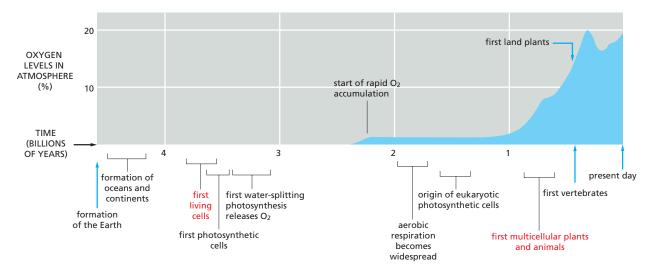

Figure 14–54 Major events during the evolution of living organisms on Earth. With the evolution of the membrane-based process of photosynthesis, organisms were able to make their own organic molecules from CO_2 gas. The delay of more than a billion years between the appearance of bacteria that split water and released O_2 during photosynthesis and the accumulation of high levels of O_2 in the atmosphere is thought to be due to the initial reaction of the oxygen with the abundant ferrous iron (Fe^{2+}) that was dissolved in the early oceans. Only when the ferrous iron was used up would oxygen have started to accumulate in the atmosphere. In response to the rising oxygen levels, nonphotosynthetic oxygen-consuming organisms evolved, and the concentration of oxygen in the atmosphere equilibrated at its present-day level.

MBOC7_ptr_ch14_811-872.indd 858 02/12/21 2:31 PM

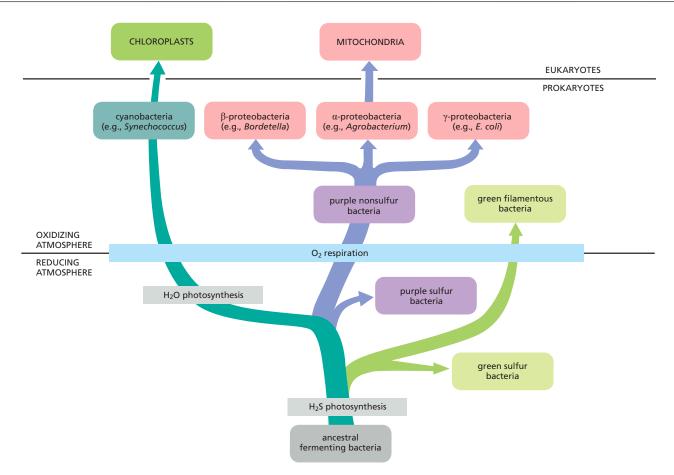

Figure 14–55 Evolutionary scheme showing the postulated origins of mitochondria and chloroplasts and their bacterial ancestors. The consumption of oxygen by respiration is thought to have first developed about 2 billion years ago. Nucleotide-sequence analyses suggest that an endosymbiotic oxygen-evolving cyanobacterium gave rise to chloroplasts (green), while mitochondria (pink) arose from an α -proteobacterium. The nearest relatives of mitochondria are members of three closely related groups of α -proteobacteria—the rhizobacteria, agrobacteria, and rickettsias—known to form intimate associations with present-day eukaryotic cells. Proteobacteria are pink, purple photosynthetic bacteria are purple, and other photosynthetic bacteria are pink green.

large amount of energy released by breaking down carbohydrates and other reduced organic molecules all the way to CO_2 and $\mathrm{H}_2\mathrm{O}$, as explained when we discussed mitochondria. Components of preexisting electron-transport complexes were modified to produce a cytochrome oxidase, so that the electrons obtained from organic or inorganic substrates could be transported to O_2 as the terminal electron acceptor. Some present-day purple photosynthetic bacteria can switch between photosynthesis and respiration depending on the availability of light and O_2 , with only relatively minor reorganizations of their electron-transport chains.

In **Figure 14–55**, we relate these postulated evolutionary pathways to different types of bacteria. By necessity, evolution is always conservative, taking parts of the old and building on them to create something new. Thus, parts of the electron-transport chains that were derived to service anaerobic bacteria 3–4 billion years ago survive today, in altered form, in the mitochondria and chloroplasts of higher eukaryotes. A good example is the overall similarity in structure and function between the cytochrome c reductase that pumps c in the central segment of the mitochondrial respiratory chain and the analogous cytochrome c complex in the electron-transport chains of both bacteria and chloroplasts, revealing their common evolutionary origin (**Figure 14–56**).

MBOC7_ptr_ch14_811-872.indd 859 02/12/21 2:31 PM

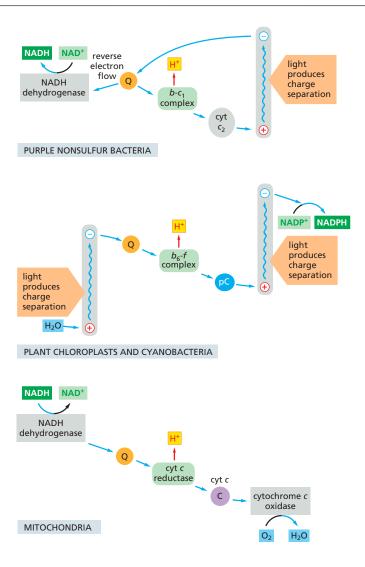

Figure 14-56 A comparison of three electron-transport chains discussed in this chapter. Bacteria, chloroplasts, and mitochondria all contain a membranebound enzyme complex that resembles the cytochrome c reductase of mitochondria. These complexes all accept electrons from a quinone carrier (Q) and pump H⁺ across their respective membranes. Moreover, in reconstituted in vitro systems, the different complexes can substitute for one another, and the structures of their protein components reveal that they are evolutionarily related. Note that the purple nonsulfur bacteria use a cyclic flow of electrons to produce a large electrochemical proton gradient that drives a reverse electron flow through NADH dehydrogenase to produce NADH from $NAD^{+} + H^{+} + e^{-}$.

Summary

Chloroplasts and photosynthetic bacteria have the unique ability to harness the energy of sunlight to produce energy-rich compounds. This is achieved by the photosystems, in which chlorophyll molecules attached to proteins are excited when hit by a photon. Photosystems are composed of light-harvesting antennae that collect solar energy and a photochemical reaction center, in which the collected energy is funneled to a chlorophyll molecule held in a special position, enabling it to withdraw electrons from an electron donor. Chloroplasts and cyanobacteria contain two distinct photosystems. The two photosystems are normally linked in series in the Z scheme, and they transfer electrons from water to NADP+ to form NADPH, while also generating a transmembrane electrochemical potential. One of the two photosystems-photosystem II-can split water by removing electrons from this ubiquitous, low-energy compound. It is believed that essentially all of the molecular oxygen (O_2) in our atmosphere is a by-product of the water-splitting reaction in this photosystem. The three-dimensional structures of photosystems I and II are strikingly similar to those of the photosystems of purple photosynthetic bacteria, demonstrating a remarkable degree of conservation over billions of years of evolution.

The two photosystems and the cytochrome b_6 -f complex reside in the thylakoid membrane, a separate membrane system in the central stroma compartment of the chloroplast that is differentiated into stacked grana and unstacked stroma thylakoids. Electron-transport processes in the thylakoid membrane cause protons to be released

MBOC7_ptr_ch14_811-872.indd 860 02/12/21 2:31 PM

into the thylakoid space. The backflow of protons through the chloroplast ATP synthase then generates ATP. This ATP is used in conjunction with the NADPH produced by photosynthesis to drive many biosynthetic reactions in the chloroplast stroma, including the carbon-fixation cycle, which generates large amounts of carbohydrates from CO₂.

In the early evolution of life, cyanobacteria overcame a major obstacle by devising a way to use solar energy to split water and fix carbon dioxide. By proliferating widely on Earth, the cyanobacteria eventually produced both abundant organic nutrients and the molecular oxygen that enabled the rise of a multitude of aerobic life-forms. The chloroplasts in plants have evolved from a cyanobacterium that was endocytosed long ago by an aerobic eukaryotic host organism.

THE GENETIC SYSTEMS OF MITOCHONDRIA AND CHLOROPLASTS

As we discussed in Chapter 1, mitochondria and chloroplasts are thought to have evolved from endosymbiotic bacteria (see Figures 1–27 and 1–29). Both types of organelles still contain their own genomes (Figure 14–57). As we will discuss shortly, they also retain their own machinery for transcribing that DNA into RNA and for translating mRNAs into organelle proteins.

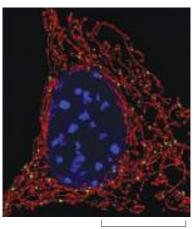

Like bacteria, mitochondria and chloroplasts proliferate by growth and division of an existing organelle. In actively dividing cells, each type of organelle must double in mass in each cell generation and then be distributed into each daughter cell. In addition, nondividing cells must replenish organelles that are degraded as part of the continual process of organelle turnover or produce additional organelles as the need arises. Organelle growth and proliferation are therefore carefully controlled. The process is complicated because mitochondrial and chloroplast proteins are encoded in two places: the nuclear genome and the separate genomes harbored in the organelles themselves. The biogenesis of mitochondria and chloroplasts thus requires contributions from two separate genetic systems, which must be closely coordinated (see pp. 867–868).

Most organellar proteins are encoded by the nuclear DNA. The organelle imports these proteins from the cytosol, after they have been synthesized on cytosolic ribosomes. In Chapter 12, we discuss how this process is catalyzed by mitochondrial protein translocase complexes of the outer and inner mitochondrial membrane. Here, we describe the organellar genomes and genetic systems and consider the consequences of separate organelle genomes for the cell and the organism as a whole.

The Genetic Systems of Mitochondria and Chloroplasts Resemble Those of Prokaryotes

As discussed in Chapter 12, it is thought that eukaryotic cells originated through a symbiotic relationship between an archaeon and an aerobic bacterium (an α -proteobacterium). The two organisms are postulated to have merged to form the ancestor of all nucleated cells, with the archaeon providing the nucleus and the proteobacterium serving as a respiring, ATP-producing endosymbiont—one that would eventually evolve into the mitochondrion (see Figure 12–3). This most likely occurred roughly 1.6 billion years ago, when oxygen had entered the atmosphere in substantial amounts (see Figure 14–54). The chloroplast was derived later, after the plant and animal lineages diverged, through endocytosis of an oxygen-producing cyanobacterium.

This *endosymbiont hypothesis* of organelle development receives strong support from the observation that the genetic systems of mitochondria and chloroplasts are similar to those of present-day bacteria. For example, bacterial, chloroplast, and mitochondrial genomes are typically circular and share many features of genome organization. In addition, chloroplast ribosomes are very similar to bacterial ribosomes, both in their structure and in their sensitivity to various antibiotics (such as chloramphenicol, streptomycin, erythromycin, and tetracycline). In addition, protein synthesis in chloroplasts starts with *N*-formylmethionine, as in bacteria, and

5 μm

Figure 14-57 Staining of nuclear and mitochondrial DNA. In this confocal micrograph of a single fibroblast cell, the nuclear DNA is stained with a fluorescent dye (blue) while the mitochondrial DNA is visualized indirectly using a tagged mitochondrial transcription factor (green). The mitochondrial network is stained with a fluorescent mitochondrial matrix marker (red). The image was acquired using a structured illumination microscope (SIM), which yields approximately double the resolution of a confocal microscope. Numerous copies of the mitochondrial genome can be seen distributed in distinct nucleoids throughout the mitochondria that snake through the cytoplasm. [From C. Kukat et al., Proc. Natl. Acad. Sci. USA 108(33):13534-13539, 2011. Copyright 2011 National Academy of Sciences, USA. With permission from National Academy of Sciences.1

MBOC7_ptr_ch14_811-872.indd 861 02/12/21 2:31 PM

not with methionine, as in the cytosol of eukaryotic cells. Although mitochondrial genetic systems are much less similar to those of present-day bacteria than are the genetic systems of chloroplasts, their ribosomes are also structurally similar and are sensitive to antibacterial antibiotics, and the transcriptional system of mitochondria is reminiscent of bacterial and bacteriophage systems.

The processes of organellar DNA transcription, protein synthesis, and DNA replication take place where the genome is located: in the matrix of mitochondria or the stroma of chloroplasts. The enzymes that mediate these genetic processes are unique to the organelle and resemble those of bacteria (or even of bacterial viruses) rather than their eukaryotic analogs. In spite of the complexity of the system required to maintain independent organellar genomes, the nuclear genome encodes the vast majority of mitochondrial proteins, including the enzymes required for genome expression in most species. The chloroplast genome is larger than that of mitochondria and encodes several enzymes involved in transcription and translation, but even so more than 95% of chloroplast proteins are typically encoded in the nuclear genome.

Over Time, Mitochondria and Chloroplasts Have Exported Most of Their Genes to the Nucleus by Gene Transfer

The nature of the organellar genes located in the nucleus of the cell reveals that, over the course of eukaryotic evolution, an extensive transfer of genes from organelle to nuclear DNA has occurred. Each such successful *gene transfer* is expected to be very difficult, because any gene moved from the organelle needs to adapt to both nuclear transcription and cytoplasmic translation requirements. In addition, the protein produced needs to acquire a signal sequence that directs it to the correct organelle after its synthesis in the cytosol (see Chapter 12).

By comparing the genes in the mitochondria from different organisms, we can infer that some of the gene transfers to the nucleus occurred relatively recently. The smallest and presumably most highly evolved mitochondrial genomes, for example, encode only a few hydrophobic inner-membrane proteins of the electron-transport chain, plus ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs). Other mitochondrial genomes that have remained more complex tend to contain this same subset of genes along with others (Figure 14–58). The

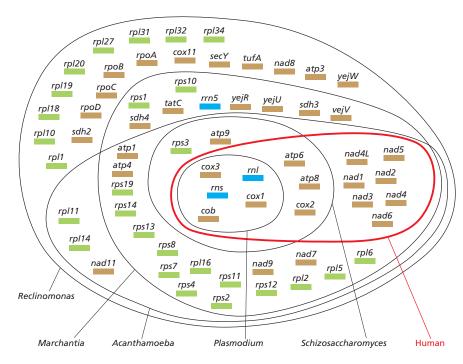

Figure 14-58 Comparison of mitochondrial genomes. Less complex mitochondrial genomes contain subsets of the genes found in larger mitochondrial genomes. Even the smallest mitochondrial genomes contain genes encoding respiratory-chain proteins and ribosomal RNAs. In the comparison shown, there are only five genes that are shared by all six mitochondrial genomes; these encode ribosomal RNAs (rns and rnl), cvtochrome b (cob), and two cytochrome oxidase subunits (cox1 and cox3). Blue indicates ribosomal RNAs; green, ribosomal proteins; and brown, components of the respiratory chain and other proteins. (Adapted from M.W. Gray et al., Science 283:1476-1481, 1999.)

MBOC7_ptr_ch14_811-872.indd 862 02/12/21 2:31 PM

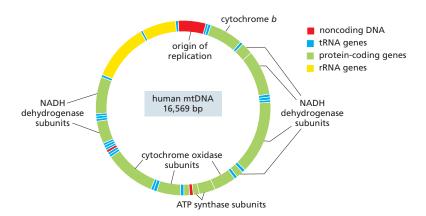

Figure 14–59 The organization of the human mitochondrial genome. The human mitochondrial genome of ~16,600 nucleotide pairs contains 2 rRNA genes, 22 tRNA genes, and 13 protein-coding sequences. There are two transcriptional promoters, one for each strand of the mitochondrial DNA (mtDNA). The DNAs of many other animal mitochondrial genomes have been completely sequenced. Most of these animal mitochondrial DNAs contain precisely the same genes as those contained in the mitochondrial DNA of humans, with the gene order being identical for animals ranging from fish to mammals.

most complex mitochondrial genomes include genes that encode components of the mitochondrial genetic system, such as RNA polymerase subunits and ribosomal proteins; these same genes are found in the cell nucleus in yeast and all animal cells. There are only 13 protein-coding genes in human mitochondrial DNA (Figure 14–59).

The proteins that are encoded by genes in the organellar DNA are synthesized on ribosomes within the organelle, using organelle-produced messenger RNA (mRNA) to specify their amino acid sequence (Figure 14–60). The protein traffic between the cytosol and these organelles seems to be almost exclusively unidirectional: protein export from mitochondria or chloroplasts to the cytosol is rare. An important exception occurs when a cell is about to undergo apoptosis. As will be discussed in detail in Chapter 18, during apoptosis the mitochondrion releases proteins (most notably cytochrome c) from the crista space through its outer mitochondrial membrane as part of an elaborate signaling pathway that is triggered to cause cells to undergo programmed cell death.

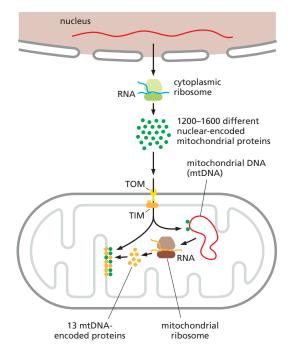

Figure 14–60 Biogenesis of the respiratory-chain proteins in human mitochondria. Most of the protein components of the mitochondrial respiratory chain are encoded by nuclear DNA (dark green dots), with only a small number (orange dots) encoded by mitochondrial DNA (mtDNA). The mtDNA-encoded subunits assemble together with the nuclear-encoded subunits to form a functional oxidative phosphorylation system.

Transcription of mtDNA produces 13 mRNAs, all of which encode subunits of the oxidative phosphorylation system, and 24 of the RNAs (22 transfer RNAs and 2 ribosomal RNAs) needed for translation of these mRNAs on the mitochondrial ribosomes. The mRNAs produced by transcription of nuclear genes are translated on cytoplasmic ribosomes (light green), which are distinct from the mitochondrial ribosomes (brown). The nuclear-encoded mitochondrial proteins are imported into mitochondria through protein translocases called TOM and TIM (see Figure 12-49), and they constitute the vast majority of the approximately 1200-1600 different protein species present in mammalian mitochondria. These nuclear-encoded mitochondrial proteins in humans include the majority of the oxidative phosphorylation system subunits, all proteins needed for expression and maintenance of mtDNA, and the proteins of the mitochondrial ribosomes. MBOC7_ptr_ch14_811-872.indd 863 02/12/21 2:31 PM

Mitochondria Have a Relaxed Codon Usage and Can Have a Variant Genetic Code

The human mitochondrial genome has several surprising features that distinguish it from nuclear, chloroplast, and bacterial genomes:

- 1. Dense gene packing. Unlike other genomes, the human mitochondrial genome seems to contain almost no noncoding DNA: nearly every nucleotide seems to be part of a coding sequence, either for a protein or for one of the rRNAs or tRNAs. Because these coding sequences run directly into each other, there is very little room left for regulatory DNA sequences. The little noncoding DNA present in the human mitochondrial genome is primarily at the origin of replication, which has essential functions in guiding replication and controlling transcription.
- 2. Relaxed codon usage. Whereas 30 or more tRNAs specify amino acids in the cytosol and in chloroplasts, only 22 tRNAs are required for mitochondrial protein synthesis. The normal codon-anticodon pairing rules are relaxed in mitochondria, so that many tRNA molecules recognize any one of the four nucleotides in the third (wobble) position. Such "2 out of 3" pairing allows one tRNA to pair with any one of four codons and permits protein synthesis with fewer tRNA molecules.
- 3. *Variant genetic code*. Perhaps most surprising, comparisons of mitochondrial gene sequences and the amino acid sequences of the corresponding proteins indicate that the genetic code is different: 4 of the 64 codons have different "meanings" from those of the same codons in other genomes (Table 14–4).

The close similarity of the genetic code in all organisms provides strong evidence that they all have evolved from a common ancestor. How, then, do we explain the differences in the genetic code in many mitochondria? A hint comes from the finding that the mitochondrial genetic code in different organisms is not the same. In the mitochondrion with the largest number of genes in Figure 14-58, that of the protozoan Reclinomonas, the genetic code is unchanged from the standard genetic code of the cell nucleus. Yet UGA, which is a stop codon elsewhere, is read as tryptophan in the mitochondria of mammals, fungi, and invertebrates. Similarly, the codon AGG normally codes for arginine, but it codes for stop in the mitochondria of mammals and codes for serine in the mitochondria of Drosophila (see Table 14-4). Such variation suggests that a random drift has occurred over evolutionary time in the genetic code in mitochondria. Presumably, the unusually small number of proteins encoded by the mitochondrial genome makes an occasional change in the meaning of a rare codon tolerable, whereas such a change in a larger genome would alter the function of many proteins and thereby destroy the cell.

TABLE 14–4 Some Differences Between the "Universal" Code and Mitochondrial Genetic Codes*						
	"Universal"	Mitochondrial codes				
Codon	code	Mammals	Invertebrates	Fungi	Plants

AUA	lle	Met	Met	Met	lle	
CUA	Leu	Leu	Leu	Thr	Leu	
AGA AGG	Arg	STOP	Ser	Arg	Arg	
*Red italics indicate that the code differs from the "universal" code.						

MBOC7_ptr_ch14_811-872.indd 864 02/12/21 2:31 PM

Notably, in many species, one or two tRNAs for mitochondrial protein synthesis are encoded in the nucleus. Some parasites, for example trypanosomes, have not retained any tRNA genes in their mitochondrial DNA. Instead, the required tRNAs are all produced in the cytosol and are thought to be imported into the mitochondrion by special tRNA translocases that are poorly characterized but are distinct from the mitochondrial protein import system.

Chloroplasts and Bacteria Share Many Striking Similarities

The chloroplast genomes of land plants range in size from 70,000 to 200,000 nucleotide pairs. Of the hundreds of chloroplast genomes that have now been sequenced, many are surprisingly similar, even in distantly related plants (such as tobacco and liverwort), and even those of green algae are closely related (Figure 14–61). Chloroplast genes are involved in three main processes: transcription, translation, and photosynthesis. Plant chloroplast genomes typically encode 80–90 proteins and around 45 RNAs, including 37 or more tRNAs. As in mitochondria, most of the organelle-encoded proteins are part of larger protein complexes that also contain one or more subunits encoded in the nucleus and imported from the cytosol.

The genomes of chloroplasts and bacteria have striking similarities. Basic regulatory sequences, such as transcription promoters and terminators, are virtually identical. The amino acid sequences of the proteins encoded in chloroplasts are clearly recognizable as bacterial, and several clusters of genes with related functions (such as those encoding ribosomal proteins) are organized in the same way in the genomes of chloroplasts, the bacterium *E. coli*, and cyanobacteria.

The mechanisms by which chloroplasts and bacteria divide are also similar. Both utilize *FtsZ* proteins, which are self-assembling GTPases related to tubulins (see Chapter 16). Bacterial FtsZ is a soluble protein that assembles into a dynamic ring of membrane-attached protofilaments beneath the plasma membrane in the middle of the dividing cell. The FtsZ ring acts as a scaffold for recruitment of other cell-division proteins and generates a contractile force that results in membrane constriction and eventually in cell division. Presumably, chloroplasts divide in very much the same way.

Although both employ membrane-interacting\GTPases, the mechanisms by which mitochondria and chloroplasts divide are fundamentally different. The machinery for chloroplast division acts from the inside, as in bacteria,

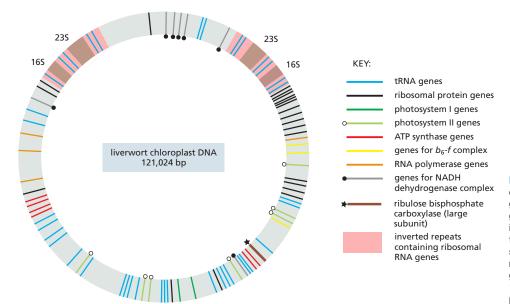

Figure 14–61 The organization of the liverwort chloroplast genome. The chloroplast genome organization is similar in all higher plants, although the size varies from species to species—depending on how much of the DNA surrounding the genes encoding the chloroplast's 16S and 23S ribosomal RNAs is present in two copies.

MBOC7_ptr_ch14_811-872.indd 865 02/12/21 2:31 PM

while the dynamin-like GTPases divide mitochondria from the outside (see Figure 14–8). The chloroplasts have remained closer to their bacterial origins than have mitochondria, inasmuch as the eukaryotic mechanisms of membrane constriction and vesicle formation have been adapted for mitochondrial fission.

The RNA editing and RNA processing that is prevalent in chloroplasts owes everything to their eukaryotic hosts. This RNA processing includes the generation of transcript 5' and 3' termini and the cleavage of polycistronic transcripts. In addition, an RNA editing process converts specific C residues to U and can change the amino acid specified by the edited codon. These and other RNA-based processes are catalyzed by protein families that are not found in prokaryotes.

Organellar Genes Are Maternally Inherited in Animals and Plants

In Saccharomyces cerevisiae (baker's yeast), when two haploid cells mate, they are equal in size and contribute equal amounts of mitochondrial DNA to the diploid zygote. Mitochondrial inheritance in yeasts is therefore biparental: both parents contribute equally to the mitochondrial gene pool of the progeny. However, during the course of the subsequent asexual, vegetative growth, the mitochondria become distributed more or less randomly to daughter cells. After a few generations, the mitochondria of any given cell contain only the DNA from one or the other parent cell, because only a small sample of the mitochondrial DNA passes from the mother cell to the bud of the daughter cell. This process is known as mitotic segregation, and it gives rise to a distinct form of inheritance that is called non-Mendelian, or cytoplasmic inheritance, in contrast to the Mendelian inheritance of nuclear genes.

The inheritance of mitochondria in animals and plants is quite different. In these organisms, the egg cell contributes much more cytoplasm to the zygote than does the male gamete (sperm in animals, pollen in plants). For example, a typical human oocyte contains about 100,000 copies of maternal mitochondrial DNA, whereas a sperm cell contains only a few. In addition, two active processes ensure that the sperm mitochondria do not compete with those in the egg. First, as sperm mature, the DNA in their mitochondria is degraded. Sperm mitochondria are also specifically recognized and eliminated from the fertilized egg cell by autophagy in very much the same way that damaged mitochondria are removed (by ubiquitylation followed by delivery to lysosomes, as discussed in Chapter 13). Because of both processes, the mitochondrial inheritance in both animals and plants is *uniparental*. More precisely, the mitochondrial DNA passes from one generation to the next by **maternal inheritance**.

In about two-thirds of higher plants, the chloroplast precursors from the male parent (contained in pollen grains) fail to enter the zygote, so that chloroplast as well as mitochondrial DNA is maternally inherited. In other plants, the chloroplast precursors from the pollen grains enter the zygote, making chloroplast inheritance biparental. In such plants, defective chloroplasts are a cause of variegation: a mixture of normal and defective chloroplasts in a zygote may sort out by mitotic segregation during plant growth and development, thereby producing alternating green and white patches in leaves. Leaf cells in the green patches contain normal chloroplasts, while those in the white patches contain defective chloroplasts (Figure 14–62).

Mutations in Mitochondrial DNA Can Cause Severe Inherited Diseases

Mitochondria are marvels of efficiency in energy conversion, and they supply the cells of our body with a readily available source of ATP and perform other critical metabolic and signaling functions. But the same marvelous mechanisms that enable these essential functions also are the main source of *reactive oxygen species* (ROS) such as H_2O_2 , superoxide, or hydroxyl radicals. These damaging species contribute to the inevitable accumulation of deletions and point mutations in mitochondrial DNA, which are often observed.

Figure 14–62 A variegated leaf. In the white patches, the plant cells have inherited a defective chloroplast. (Courtesy of John Innes Foundation.)

MBOC7_ptr_ch14_811-872.indd 866 02/12/21 2:31 PM

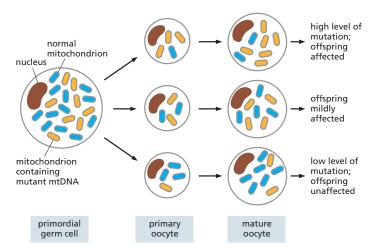

Figure 14–63 Mitochondrial DNA mutations and inheritance. When a primordial germ cell carries a mixed population of normal and mutated mtDNA, those genomes are distributed randomly to primary oocytes, where they are replicated during the oocyte maturation process. Those oocytes that inherit a higher load of mutant mtDNA lead to offspring that are more likely to be afflicted with mitochondrial disease. Those that inherit a lower fraction of mutated mtDNA are more likely to be unaffected. [Adapted from R.W. Taylor and D.M. Turnbull, *Nat. Rev. Genet.* 6(5):389–402, 2005. With permission from Nature.]

The less complex DNA replication and repair systems in mitochondria mean that such accidents are corrected less efficiently. This results in a 100-fold higher occurrence of deletions and point mutations than in nuclear DNA. Mathematical modeling suggests that most of these mutations and lesions are acquired in childhood or early adult life and then proliferate by *clonal expansion* in later life. Because of mitotic segregation, some cells will accumulate higher levels of faulty mitochondrial DNA than others and will exhibit impaired metabolic function. In rare cases, these mutations are passed to progeny.

In humans, as we have explained, all the mitochondrial DNA in a fertilized egg cell is inherited from the mother. Some mothers carry a mixed population of both mutant and normal mitochondrial genomes (Figure 14–63). Their daughters and sons typically inherit this mixture of normal and mutant mitochondrial DNAs, although oocytes (and therefore children) frequently have a higher or lower fraction of mutant mitochondrial DNA. If the child receives a low fraction of mutant DNA, she or he will be healthy unless the process of mitotic segregation results in enrichment of defective mitochondria in a particular tissue.

Diseases caused by mutations in mitochondrial DNA are clinically recognized by their passage from affected mothers to both their daughters and their sons, with the daughters but not the sons producing children with the disease. As expected from the random nature of mitotic segregation, the symptoms of these diseases vary greatly between different family members—including not only the severity and age of onset, but also which tissue is affected. Muscle and the nervous system are the most common body systems to be affected by mitochondrial disease, likely because of their particularly high demand for ATP. There are also mitochondrial diseases that are caused by mutations in nuclear-encoded mitochondrial proteins; these diseases are inherited in the regular, Mendelian fashion.

Why Do Mitochondria and Chloroplasts Maintain a Costly Separate System for DNA Transcription and Translation?

Why do mitochondria and chloroplasts require their own separate genetic systems, when other organelles that share the same cytoplasm, such as peroxisomes and lysosomes, do not? The question is not trivial, because maintaining a separate genetic system is costly: more than 90 proteins—including many ribosomal

MBOC7_ptr_ch14_811-872.indd 867 02/12/21 2:31 PM

proteins, aminoacyl-tRNA synthetases, DNA polymerase, RNA polymerase, and RNA-processing and RNA-modifying enzymes—must be encoded by nuclear genes specifically for this purpose. As we have seen, the mitochondrial genetic system also entails the risk of disease.

The nature of the proteins encoded by the organellar genomes provides an additional layer of complexity in the maintenance of distinct genomes. The vast majority of organelle-encoded proteins act as components of large complexes that also contain proteins encoded in the nuclear genome, which must be translated in and imported from the cytosol. This creates a substantial need for coordination among the gene expression systems of the two genomes, and presumably also creates a substantial burden of quality control when protein abundance is not perfectly matched. For this and other reasons, signaling systems have evolved that regulate transcription of nuclear genes in response to damage and/or other perturbations in the function of mitochondria or chloroplasts.

Several possible reasons have been proposed for maintaining this costly and potentially hazardous arrangement. (1) The nonribosomal proteins encoded by the organellar genome are typically highly hydrophobic. This may make their production in and import from the cytoplasm simply too difficult and energyconsuming; however, several very hydrophobic proteins are synthesized in the cytosol and imported. (2) The current genome organization could be a remnant of an ancient endosymbiotic conflict. In the current arrangement, organelle function is completely dependent on the coordinated expression of both genomes. Neither the nucleus nor the organelle can control these critical functions without the concomitant response from the other. (3) It is also possible that the evolution (and eventual elimination) of the organellar genetic systems is still ongoing, but for now there is no alternative for the cell than to maintain separate genetic systems for its nuclear, mitochondrial, and chloroplast genes. As of now, the reason for the maintenance of distinct organellar genomes remains one of the most interesting and important unanswered questions in evolutionary biology.

Summary

Mitochondria are organelles that allow eukaryotes to carry out oxidative phosphorylation, while chloroplasts are organelles that allow plants to carry out photosynthesis. As a result of their prokaryotic origins, each organelle maintains and reproduces itself in a highly coordinated process that requires the contribution of two separate genetic systems—one in the organelle and the other in the cell nucleus. The vast majority of the proteins in these organelles are encoded by nuclear DNA, synthesized in the cytosol, and then imported individually into the organelle. Other organellar proteins, as well as organellar ribosomal and transfer RNAs, are encoded by the organellar DNA; these are synthesized in the organelle itself.

The ribosomes of chloroplasts closely resemble bacterial ribosomes, while the origin of mitochondrial ribosomes is more difficult to trace. Extensive protein similarities, however, suggest that both organelles originated from bacteria: the mitochondrion when a proto-eukaryotic archaeal cell entered into a stable endosymbiotic relationship with a respiratory bacterium, and the chloroplast when a distant descendant of this first eukaryotic cell entered into a stable endosymbiotic relationship with a cyanobacterium. Although some of the genes of these former bacteria still function to make organellar proteins and RNA, most of them have been transferred into the nuclear genome, where they encode bacteria-like enzymes that are synthesized on cytosolic ribosomes and then imported into the organelle. This situation creates substantial challenges for the inter-genome coordination of gene expression, as well as producing an increased risk of mutation and disease.

PROBLEMS 869

PROBLEMS

Which statements are true? Explain why or why not.

14–1 The three respiratory enzyme complexes in the mitochondrial inner membrane tend to associate with each other in ways that facilitate the correct transfer of electrons between appropriate complexes.

14–2 The number of *c* subunits in the rotor ring of ATP synthase defines how many protons need to pass through the turbine to make each molecule of ATP.

14–3 Mutations that are inherited according to Mendelian rules affect nuclear genes; mutations whose inheritance violates Mendelian rules are likely to affect organellar genes.

Discuss the following problems.

14–4 Heart muscle gets most of the ATP needed to power its continual contractions through oxidative phosphorylation. When oxidizing glucose to CO_2 , heart muscle consumes O_2 at a rate of $10 \mu mol/min$ per gram of tissue, in order to replace the ATP used in contraction and give a steady-state ATP concentration of $5 \mu mol/g$ of tissue. At this rate, how many seconds would it take the heart to consume an amount of ATP equal to its steady-state levels? (Complete oxidation of one molecule of glucose to CO_2 yields 30 ATP, 26 of which are derived by oxidative phosphorylation using the 12 pairs of electrons captured in the electron carriers NADH and FADH₂. One pair of electrons is used to reduce each atom of oxygen.)

14–5 The transport of ions and small molecules across the inner mitochondrial membrane is often affected by the electrochemical gradient, whose components—the pH gradient and the membrane potential—may either oppose or drive the transport. How would the components of the electrochemical gradient affect the simultaneous transport of phosphate and protons into the matrix (Figure Q14–1)?

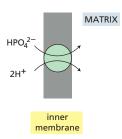

Figure Q14–1 Coupled transport of phosphate and protons across the inner mitochondrial membrane into the matrix (Problem 14–5).

14–6 If isolated mitochondria are incubated with a source of electrons such as succinate, but without oxygen, electrons enter the respiratory chain, reducing each of the electron carriers almost completely. When oxygen is then

introduced, the carriers become oxidized at different rates (Figure Q14-2). How does this result allow you to order the electron carriers in the respiratory chain? What is their order?

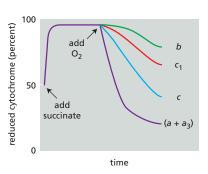

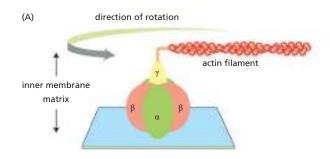

Figure Q14–2 Rapid spectrophotometric analysis of the rates of oxidation of electron carriers in the respiratory chain (Problem 14–6). Cytochromes a and a_3 cannot be distinguished and thus are listed as cytochrome $(a + a_3)$.

14–7 Both H^+ and Ca^{2+} are ions that move through the cytosol. Why is the movement of H^+ ions so much faster than that of Ca^{2+} ions? How do you suppose the speed of these two ions would be affected by freezing the solution? Would you expect them to move faster or slower? Explain your answer.

14–8 In the 1860s, Louis Pasteur noticed that when he added $\rm O_2$ to a culture of yeast growing anaerobically on glucose, the rate of glucose consumption declined dramatically. Explain the basis for this result, which is known as the Pasteur effect.

14–9 ATP synthase is the world's smallest rotary motor. Passage of H^+ ions through the membrane-embedded portion of ATP synthase (the F_o component) causes rotation of the single, central, axle-like γ subunit (the rotor stalk) inside the head group (the F_1 ATPase head). The tripartite head is composed of the three $\alpha\beta$ dimers, the β subunits of which are responsible for synthesis of ATP. The rotation of the γ subunit induces conformational changes in the $\alpha\beta$ dimers that allow ADP and phosphate to be converted into ATP. A variety of indirect evidence had suggested rotary catalysis by ATP synthase, but seeing is believing.

To demonstrate rotary motion, a modified form of the $\alpha_3\beta_3\gamma$ complex was used. The β subunits were modified so they could be firmly anchored to a solid support, and the γ subunit was modified (on the end that normally inserts into the F_o component in the inner membrane) so that a fluorescently tagged, readily visible filament of actin could be attached (Figure Q14–3A). This arrangement allows rotations of the γ subunit to be visualized as revolutions of the long actin filament. In these experiments, ATP synthase was studied in the reverse of its normal mechanism by allowing it to hydrolyze ATP. At low ATP concentrations, the actin filament was observed to revolve in steps of 120° and then pause for variable lengths of time, as shown in Figure Q14–3B.

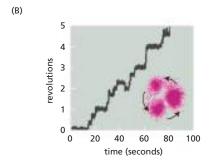

Figure Q14–3 Experimental setup for observing rotation of the γ subunit of ATP synthase (Problem 14–9). (A) The β subunits are anchored to a solid support, and a fluorescent actin filament is attached to the γ subunit. (B) The indicated trace is a typical example from one experiment. The inset shows the positions in the revolution at which the actin filament paused. (B, from R. Yasuda et al., *Cell* 93:1117–1124, 1998. With permission from Elsevier.)

- A. Why does the actin filament revolve in steps with pauses in between? What does this rotation correspond to in terms of the structure of the $\alpha_3\beta_3\gamma$ complex?
- B. In its normal mode of operation inside the cell, how many ATP molecules do you suppose would be synthesized for each complete 360° rotation of the γ subunit? Explain your answer.
- 14–10 In actively respiring liver mitochondria, the pH in the matrix is about half a pH unit higher than it is in the cytosol. Assuming that the cytosol is at pH 7 and the matrix is a sphere with a diameter of 1 μ m [$V = (4/3)\pi r^3$], calculate the total number of protons in the matrix of a respiring liver mitochondrion. If the matrix began at pH 7 (equal to that in the cytosol), how many protons would have to be pumped out to establish a matrix pH of 7.5 (a difference of 0.5 pH units)?
- **14–11** Normally, the flow of electrons to O_2 is tightly linked to the production of ATP via the electrochemical gradient. If ATP synthase is inhibited, for example, electrons do not flow down the electron-transport chain and respiration ceases. Since the 1940s, several substances—such as 2,4-dinitrophenol—have been known to uncouple electron flow from ATP synthesis. Dinitrophenol was once prescribed as a diet drug to aid in weight loss. How would an uncoupler of oxidative phosphorylation promote weight loss? Why do you suppose dinitrophenol is no longer prescribed?

14–12 How much energy is available in visible light? How much energy does sunlight deliver to Earth? How efficient are plants at converting light energy into chemical energy? The answers to these questions provide an important backdrop to the subject of photosynthesis.

Each quantum or photon of light has energy hv, where h is Planck's constant $(6.6 \times 10^{-37} \text{ kJ sec/photon})$, and v is the frequency in seconds⁻¹. The frequency of light is equal to c/λ , where c is the speed of light $(3.0 \times 10^{17} \text{ nm/sec})$, and λ is the wavelength in nanometers. Thus, the energy (E) of a photon is

$$E = h\nu = hc/\lambda$$

- A. Calculate the energy of a mole of photons (6×10^{23} photons/mole) at 400 nm (violet light), at 680 nm (red light), and at 800 nm (near-infrared light).
- B. Bright sunlight strikes Earth at the rate of about 1.3 kJ/sec per square meter. Assuming for the sake of calculation that sunlight consists of monochromatic light of wavelength 680 nm, how many seconds would it take for a mole of photons to strike a square meter?
- C. Assuming that it takes eight photons to fix one molecule of CO_2 as carbohydrate under optimal conditions, calculate how long it would take a tomato plant with a leaf area of 1 square meter to make a mole of glucose from CO_2 . Assume that photons strike the leaf at the rate calculated above and, furthermore, that all the photons are absorbed and used to fix CO_2 .
- D. If it takes 468 kJ/mole to fix a mole of CO₂ into carbohydrate, what is the efficiency of conversion of light energy into chemical energy after photon capture? Assume again that eight photons of red light (680 nm) are required to fix one molecule of CO₂.
- **14–13** Why are plants green? ("They contain chlorophyll" is not a sufficient answer.)
- **14–14** Examine the variegated leaf shown in Figure Q14–4. Yellow patches surrounded by green are common, but there are no green patches surrounded by yellow. Propose an explanation for this phenomenon.

Figure Q14-4 A variegated leaf of *Aucuba japonica* with green and yellow patches (Problem 14-14).

Cell Signaling

CHAPTER

15

When things change, cells respond. Every cell, from the humble bacterium to the most sophisticated eukaryotic cell, monitors its intracellular and extracellular environment, processes the information it gathers, and responds accordingly. Unicellular organisms, for example, modify their behavior in response to changes in environmental nutrients or toxins. The cells of multicellular organisms detect and respond to countless internal and extracellular signals that control their growth, division, and differentiation during development, as well as their behavior in adult tissues. At the heart of all these communication systems are regulatory proteins that produce chemical signals, which are sent from one place to another in the body or within a cell, and other proteins that recognize the signals and respond to them, often integrating the signals and passing them on to produce an appropriate cell response.

The study of cell signaling has traditionally focused on the mechanisms by which eukaryotic cells communicate with one another using *extracellular signal molecules* such as hormones and growth factors. In this chapter, we describe the features of some of these cell-cell communication systems, and we use them to illustrate the general principles by which any regulatory system, inside or outside the cell, is able to generate, process, and respond to signals. Our main focus is on animal cells, but we end by considering the special features of cell signaling in plants.

PRINCIPLES OF CELL SIGNALING

Long before multicellular creatures roamed the Earth, unicellular organisms had developed mechanisms for responding to physical and chemical changes in their environment. These almost certainly included mechanisms for responding to the presence of other cells. Evidence comes from studies of present-day unicellular organisms such as bacteria and yeasts. Although these cells lead mostly independent lives, they can communicate and influence one another's behavior. Many bacteria, for example, respond to chemical signals that are secreted by their neighbors and accumulate at higher population density. This process, called quorum sensing, allows bacteria to coordinate their behavior, including their motility, antibiotic production, spore formation, and sexual conjugation. Similarly, yeast cells communicate with one another in preparation for mating. The budding yeast Saccharomyces cerevisiae provides a well-studied example: when a haploid individual is ready to mate, it secretes a peptide mating factor that signals cells of the opposite mating type to stop proliferating and prepare to mate. The subsequent fusion of two haploid cells of opposite mating type produces a diploid zygote.

Intercellular communication achieved an astonishing level of complexity during the evolution of multicellular organisms. These organisms are tightly knit societies of cells, in which the well-being of the individual cell is often set aside for the benefit of the organism as a whole. Complex systems of intercellular communication have evolved to allow the collaboration and coordination of different tissues and cell types. Bewildering arrays of signaling systems govern every conceivable feature of cell and tissue function during development and in the adult.

IN THIS CHAPTER

Principles of Cell Signaling

Signaling Through G-Proteincoupled Receptors

Signaling Through Enzymecoupled Receptors

Alternative Signaling Routes in Gene Regulation

Signaling in Plants

MBOC7_ptr_ch15_873-948.indd 873 08/12/21 12:23 PM

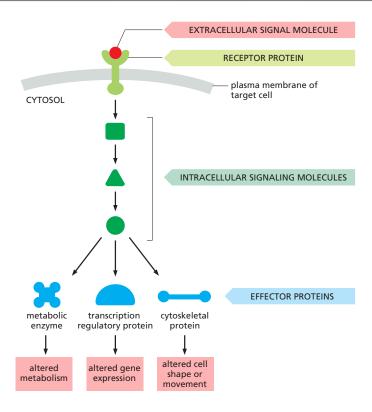

Figure 15–1 A simple intracellular signaling pathway activated by an extracellular signal molecule. The signal molecule usually binds to a receptor protein that is embedded in the plasma membrane of the target cell. The receptor activates one or more intracellular signaling pathways, involving a series of signaling proteins and small chemical messengers. Finally, one or more of the intracellular signaling molecules alters the activity of effector proteins and thereby the behavior of the cell.

Communication between cells in multicellular organisms is mediated mainly by extracellular signal molecules. Some of these operate over long distances, signaling to cells far away; others signal only to immediate neighbors. Most cells in multicellular organisms both emit and receive signals. Reception of the signals depends on receptor proteins, usually (but not always) at the cell surface, which bind the signal molecule. The binding activates the receptor, which in turn activates one or more intracellular signaling pathways or systems. These systems depend on intracellular signaling proteins, which process the signal inside the receiving cell and distribute it to the appropriate intracellular targets. Some of these proteins produce small chemical messengers called second messengers, which carry the signal to other signaling proteins. The targets that lie at the end of signaling pathways are generally called effector proteins, which are altered in some way by the incoming signal and implement the appropriate change in cell behavior. Depending on the signal and the type and state of the receiving cell, these effectors can be transcription regulators, ion channels, components of a metabolic pathway, or parts of the cytoskeleton (Figure 15-1).

The fundamental features of cell signaling have been conserved throughout the evolution of the eukaryotes. In budding yeast, for example, the response to mating factor depends on cell-surface receptor proteins, intracellular GTP-binding proteins, and protein kinases that are clearly related to functionally similar proteins in animal cells. Through gene duplication and divergence, however, the signaling systems in animals have become much more elaborate than those in yeasts; the human genome, for example, contains more than 1500 genes that encode receptor proteins, and the number of different receptor proteins is further increased by alternative RNA splicing and post-translational modifications.

Extracellular Signals Can Act Over Short or Long Distances

Many extracellular signal molecules remain bound to the surface of the signaling cell and influence only cells that contact it (Figure 15–2A). Such contact-dependent signaling is especially important during development and in immune responses.

MBOC7_ptr_ch15_873-948.indd 874 08/12/21 12:23 PM

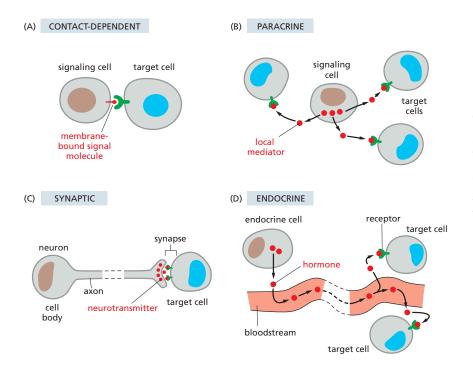

Figure 15-2 Four forms of intercellular signaling. (A) Contact-dependent signaling requires cells to be in direct membranemembrane contact. (B) Paracrine signaling depends on local mediators that are released into the extracellular space and act on neighboring cells. (C) Synaptic signaling is performed by neurons that transmit signals electrically along their axons and release neurotransmitters at chemical synapses, which are often located far away from the neuronal cell body. (D) Endocrine signaling depends on endocrine cells, which secrete hormones into the bloodstream for distribution throughout the body. Many of the same types of signaling molecules are used in paracrine, synaptic, and endocrine signaling; the crucial differences lie in the speed and selectivity with which the signals are delivered to their targets.

Contact-dependent signaling during development can sometimes operate over relatively large distances if the communicating cells extend long, thin processes to make contact with one another.

In most cases, however, signaling cells secrete signal molecules into the extracellular fluid. Often, the secreted molecules are **local mediators**, which act only on cells in the local environment of the signaling cell. This is called **paracrine signaling** (**Figure 15–2B**). Usually, the signaling and target cells in paracrine signaling are of different cell types, but cells may also produce signals that they themselves respond to: this is referred to as *autocrine signaling*. Cancer cells, for example, often produce extracellular signals that stimulate their own survival and proliferation.

Large multicellular organisms like us also need long-range signaling mechanisms to coordinate the behavior of cells in remote parts of the body. Thus, they have evolved cell types specialized for intercellular communication over large distances. The most sophisticated of these are nerve cells, or neurons, which typically extend long, branching processes (axons) that enable them to contact target cells far away, where the processes terminate at the specialized sites of signal transmission known as *chemical synapses*. When a neuron is activated by stimuli from other nerve cells, it sends electrical impulses (action potentials) rapidly along its axon; when the impulse reaches the synapse at the end of the axon, it triggers secretion of a chemical signal that acts as a **neurotransmitter**. The tightly organized structure of the synapse ensures that the neurotransmitter is delivered specifically to receptors on the postsynaptic target cell (**Figure 15–2C**). The details of this **synaptic signaling** process are discussed in Chapter 11.

A quite different strategy for signaling over long distances makes use of **endocrine cells**, which secrete their signal molecules, called **hormones**, into the bloodstream. The blood carries the molecules far and wide, allowing them to act on target cells that may lie almost anywhere in the body (Figure 15–2D).

Extracellular Signal Molecules Bind to Specific Receptors

Cells in multicellular animals communicate by means of hundreds of kinds of extracellular signal molecules. These include proteins, small peptides, amino acids, nucleotides, steroids, retinoids, fatty acid derivatives, and even dissolved

MBOC7_ptr_ch15_873-948.indd 875 08/12/21 12:23 PM

Figure 15–3 The binding of extracellular signal molecules to either cell-surface or intracellular receptors. (A) Most signal molecules are hydrophilic and are therefore unable to cross the target cell's plasma membrane directly; instead, they bind to cell-surface receptors, which in turn generate signals inside the target cell (see Figure 15–1). (B) Some small signal molecules, by contrast, diffuse across the plasma membrane and bind to receptor proteins inside the target cell—either in the cytosol or in the nucleus (as shown here). Many of these small signal molecules are hydrophobic and poorly soluble in aqueous solutions; they are therefore transported in the bloodstream and other extracellular fluids bound to carrier proteins, from which they dissociate before entering the target cell.

gases such as nitric oxide and carbon monoxide. Most of these signal molecules are released into the extracellular space by exocytosis from the signaling cell, as discussed in Chapter 13. Some, however, are emitted by diffusion through the signaling cell's plasma membrane, whereas others are displayed on the external surface of the cell and remain attached to it, signaling to target cells only upon contact. Transmembrane signal proteins may operate in this way, although in some cases their extracellular domains are released from the signaling cell's surface by proteolytic cleavage and then act at a distance.

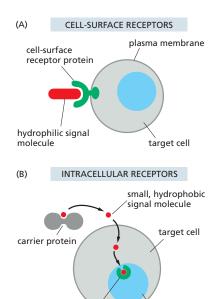

Regardless of the nature of the signal, the *target cell* responds by means of a **receptor**, which binds the signal molecule and then initiates a response in the target cell. The binding site of the receptor has a complex structure that is shaped to recognize the signal molecule with high specificity, helping to ensure that the receptor responds only to the appropriate signal and not to the many other signaling molecules the cell is exposed to. Many signal molecules act at very low concentrations (typically $\leq 10^{-8}$ M), and their receptors usually bind them with high affinity (dissociation constant $K_{\rm d} \leq 10^{-8}$ M; see Figure 3–42).

In most cases, receptors are transmembrane proteins on the target-cell surface. When these proteins bind an extracellular signal molecule (a *ligand*), they become activated and generate various intracellular signals that alter the behavior of the cell. In other cases, the receptor proteins are inside the target cell, and the signal molecule has to enter the cell to bind to them: this requires that the signal molecule be sufficiently small and hydrophobic to diffuse across the target cell's plasma membrane (Figure 15–3). This chapter focuses primarily on signaling through cell-surface receptors, but we will briefly describe signaling through intracellular receptors later in the chapter.

Each Cell Is Programmed to Respond to Specific Combinations of Extracellular Signals

A typical cell in a multicellular organism is exposed to hundreds of different signal molecules in its environment. The molecules can be soluble, bound to the extracellular matrix, or bound to the surface of a neighboring cell; they can be stimulatory or inhibitory; they can act in innumerable different combinations; and they can influence almost any aspect of cell behavior. The cell responds to this blizzard of signals selectively, in large part by expressing only those receptors and intracellular signaling systems that respond to the signals that are required for the regulation of that cell.

Most cells respond to many different signals in the environment, and some of these signals may influence the response to other signals. One of the key challenges in cell biology is to determine how a cell integrates all of this signaling information in order to make decisions—to divide, to move, to differentiate, and so on. Many cells, for example, require a specific combination of extracellular survival factors to allow the cell to continue living; when deprived of these signals, the cell activates a suicide program and kills itself—usually by *apoptosis*, as discussed in Chapter 18. Cell proliferation often depends on a combination of signals that promote both cell division and survival, as well as signals that stimulate cell growth (Figure 15–4). On the other hand, differentiation into a nondividing state (called *terminal differentiation*) frequently requires a different combination of survival and differentiation signals that must override any signal to divide.

intracellular receptor protein

nucleus

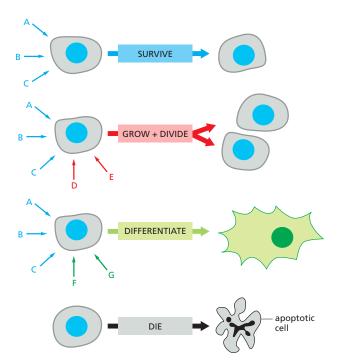

Figure 15-4 An animal cell's dependence on multiple extracellular signal molecules. Each cell type displays a set of receptors that enables it to respond to a corresponding set of signal molecules produced by other cells. These signal molecules work in various combinations to regulate the behavior of the cell. As shown here, an individual cell often requires multiple signals to survive (blue arrows) and additional signals to grow and divide (red arrows) or differentiate (green arrows). If deprived of appropriate survival signals, a cell will undergo a form of cell suicide known as apoptosis. The actual situation is even more complex. Although not shown, some extracellular signal molecules act to inhibit these and other cell behaviors or even to induce apoptosis.

A signal molecule often has different effects on different types of target cells. The neurotransmitter acetylcholine (Figure 15–5A), for example, decreases the rate of action potential firing in heart pacemaker cells (Figure 15–5B) and stimulates the production of saliva by salivary gland cells (Figure 15–5C), even though the acetylcholine receptors are the same on both cell types. In skeletal muscle, acetylcholine causes the cells to contract by binding to a different type of acetylcholine receptor (Figure 15–5D). The different effects of acetylcholine in these cell types result from differences in the intracellular signaling proteins, effector proteins, and genes that are activated. Thus, an extracellular signal itself has little information content; it simply induces the cell to respond according to its predetermined state, which depends on the cell's developmental history and the specific genes it expresses.

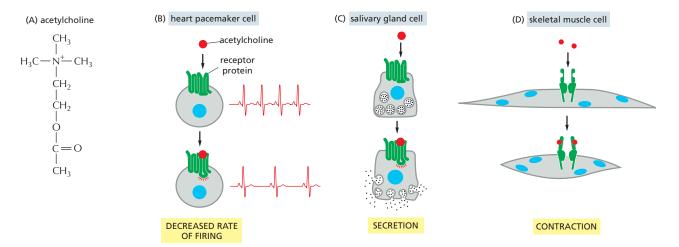

Figure 15–5 Various responses induced by the neurotransmitter acetylcholine. (A) The chemical structure of acetylcholine. (B–D) Different cell types are specialized to respond to acetylcholine in different ways. In some cases (B and C), acetylcholine binds to the same type of acetylcholine receptor (a G-protein-coupled receptor; see Figure 15–6), but the intracellular signals produced are interpreted differently in cells specialized for different functions. In other cases (D), the acetylcholine receptor protein is different (an ion-channel-coupled receptor; see Figure 15–6).

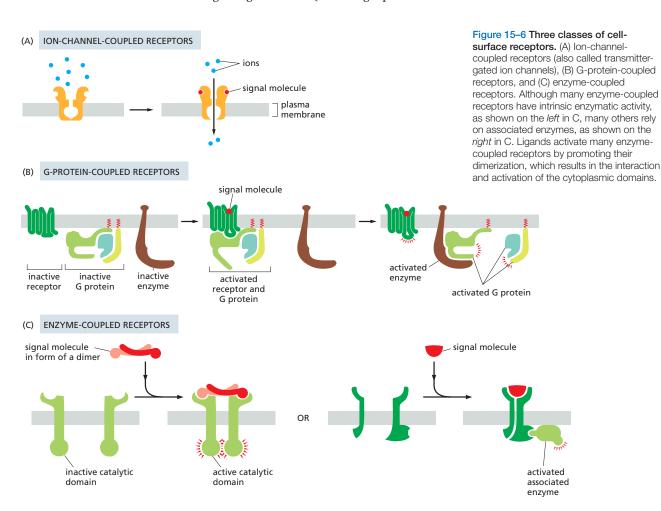

MBOC7_ptr_ch15_873-948.indd 877 08/12/21 12:23 PM

There Are Three Major Classes of Cell-Surface Receptor Proteins

Most extracellular signal molecules bind to specific receptor proteins on the surface of the target cells they influence and do not enter the cytosol or nucleus. These cell-surface receptors act as *signal transducers* by converting an extracellular ligand-binding event into intracellular signals that alter the behavior of the target cell.

Most cell-surface receptor proteins belong to one of three classes, defined by their transduction mechanism. *Ion-channel-coupled receptors*, also known as *transmitter-gated ion channels* or *ionotropic receptors*, are involved in rapid synaptic signaling between nerve cells and other electrically excitable target cells such as muscle cells (Figure 15–6A). This type of signaling is mediated by a small number of neurotransmitters that transiently open or close an ion channel formed by the protein to which they bind, briefly changing the ion permeability of the plasma membrane and thereby changing the excitability of the postsynaptic target cell. Most ion-channel-coupled receptors belong to a large family of homologous, multipass transmembrane proteins. Because they are discussed in detail in Chapter 11, we will not consider them further here.

G-protein-coupled receptors act by indirectly regulating the activity of a separate plasma-membrane-bound target protein, which is generally either an enzyme or an ion channel. A *heterotrimeric GTP-binding protein* (*G protein*) mediates the interaction between the activated receptor and this target protein (**Figure 15–6B**). The activation of the target protein can change the concentration of one or more small intracellular signaling molecules (if the target protein is an

MBOC7_ptr_ch15_873-948.indd 878 08/12/21 12:23 PM

enzyme) or it can change the ion permeability of the plasma membrane (if the target protein is an ion channel). The small intracellular signaling molecules act in turn to alter the behavior of yet other signaling proteins in the cell.

Enzyme-coupled receptors either function as enzymes or associate directly with enzymes that they activate (Figure 15-6C). They are usually single-pass transmembrane proteins that have their ligand-binding site outside the cell and their catalytic or enzyme-binding site inside. Enzyme-coupled receptors are heterogeneous in structure compared with the other two classes; the great majority, however, are either protein kinases or associate with protein kinases, which phosphorylate specific sets of proteins in the target cell when activated.

There are also some types of cell-surface receptors that do not fit easily into any of these classes but have important functions in controlling the specialization of different cell types during development and in tissue renewal and repair in adults. We discuss these in a later section, after we explain how G-protein-coupled receptors and enzyme-coupled receptors operate. First, we continue our general discussion of the principles of signaling via cell-surface receptors.

Cell-Surface Receptors Relay Signals Via Intracellular Signaling Molecules

Numerous intracellular signaling molecules relay signals received by cell-surface receptors into the cell interior. The resulting chain of intracellular signaling events ultimately alters effector proteins that are responsible for modifying the behavior of the cell (see Figure 15–1).

Some intracellular signaling molecules are small chemicals, which are often called **second messengers** (the "first messengers" being the extracellular signals). They are generated in large amounts in response to receptor activation and diffuse away from their source, spreading the signal to other parts of the cell. Some, such as *cyclic AMP* and Ca^{2+} , are water soluble and diffuse in the cytosol, while others, such as *diacylglycerol*, are lipid soluble and diffuse in the plane of the plasma membrane. In either case, they pass the signal on by binding to and altering the behavior of selected signaling or effector proteins.

Most intracellular signaling molecules are proteins, which help relay the signal into the cell by either generating second messengers or activating the next signaling or effector protein in the pathway. Many of these proteins behave like *molecular switches*. When they receive a signal, they switch from an inactive to an active state, until another process switches them off, returning them to their inactive state. The switching off can be just as important as the switching on. If a signaling pathway is to recover after transmitting a signal so that it can be ready to transmit another, every activated molecule in the pathway must return to its original, unactivated state.

The largest class of molecular switches consists of proteins that are activated or inactivated by **phosphorylation** (discussed in Chapter 3). For these proteins, the switch is thrown in one direction by a **protein kinase**, which covalently adds one or more phosphate groups to specific amino acids on the signaling protein, and in the other direction by a **protein phosphatase**, which removes the phosphate groups (**Figure 15–7A**). The activity of any protein regulated by phosphorylation depends on the balance between the activities of the kinases that phosphorylate it and of the phosphatases that dephosphorylate it. About 30–50% of human proteins contain covalently attached phosphate, and the human genome encodes about 520 protein kinases and about 150 protein phosphatases. A typical mammalian cell makes use of hundreds of distinct types of protein kinases at any moment.

Protein kinases attach phosphate to the hydroxyl group of specific amino acids on the target protein. There are two main types of protein kinase in eukaryotic cells. The great majority are **serine/threonine kinases**, which phosphorylate the hydroxyl groups of serines and threonines in their targets. Others are **tyrosine kinases**, which phosphorylate proteins on tyrosines. Tyrosine kinases are found

MBOC7_ptr_ch15_873-948.indd 879 08/12/21 12:23 PM

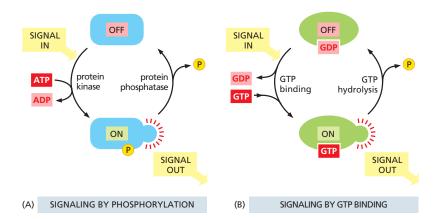

Figure 15–7 Two types of intracellular signaling proteins that act as molecular switches. (A) A protein kinase covalently adds a phosphate from ATP to the signaling protein, and a protein phosphatase removes the phosphate. Although not shown, many signaling proteins are activated by dephosphorylation rather than by phosphorylation. (B) A GTP-binding protein is induced to exchange its bound GDP for GTP, which activates the protein; the protein then inactivates itself by hydrolyzing its bound GTP to GDP.

primarily in multicellular animals; these kinases are not present, for example, in yeast.

Many intracellular signaling proteins controlled by phosphorylation are themselves protein kinases, and these are often organized into **kinase cascades**. In such a cascade, one protein kinase, activated by phosphorylation, phosphorylates the next protein kinase in the sequence, and so on, relaying the signal onward and, in some cases, amplifying it or spreading it to other signaling pathways.

Like the protein kinases, the protein phosphatases are categorized by their specificity for serine/threonine phosphate or tyrosine phosphate. There are about 100 **protein tyrosine phosphatases** encoded in the human genome, including some *dual-specificity phosphatases* that also dephosphorylate serines and threonines.

The other important class of molecular switches consists of **GTP-binding proteins** (discussed in Chapter 3). These proteins switch between two distinct structural conformations: an "on" state when GTP is bound and an "off" state when GDP is bound. In the "on" state, they bind and thereby activate specific signaling proteins. GTP-binding proteins usually have intrinsic GTPase activity and shut themselves off by hydrolyzing their bound GTP to GDP (**Figure 15–7B**). The inactive protein then returns to the "on" state when GDP dissociates, allowing a new GTP to bind. There are two major types of GTP-binding proteins. Large, *heterotrimeric GTP-binding proteins* (also called *G proteins*) help relay signals from G-protein-coupled receptors that activate them (see Figure 15–6B). Small **monomeric GTPases** (also called *monomeric GTP-binding proteins*) help relay signals from many classes of cell-surface receptors.

For most GTP-binding proteins, the inactivation process (GTP hydrolysis to GDP) and the activation process (GDP dissociation) are slow in the absence of other proteins. Inside the cell, regulatory proteins are used to accelerate one or the other process, thereby governing the activation state of the GTP-binding protein. GTPase-activating proteins (GAPs) drive the proteins into an "off" state by increasing the rate of hydrolysis of bound GTP. Conversely, guanine nucleotide exchange factors (GEFs) activate GTP-binding proteins by promoting the release of bound GDP, which allows a new GTP to bind. In the case of heterotrimeric G proteins, the activated receptor serves as the GEF. Figure 15–8 illustrates the regulation of monomeric GTPases.

Not all molecular switches in signaling systems depend on phosphorylation or GTP binding. We see later that some signaling proteins are switched on or off by the binding of another signaling protein or a second messenger, such as cyclic AMP or Ca^{2+} , or by covalent modifications other than phosphorylation or dephosphorylation, such as ubiquitylation (discussed in Chapter 3).

For simplicity, we often portray a signaling pathway as a series of activation steps (see Figure 15–1). It is important to note, however, that most signaling pathways contain inhibitory steps, and a sequence of two inhibitory steps can

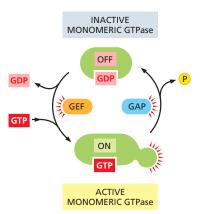

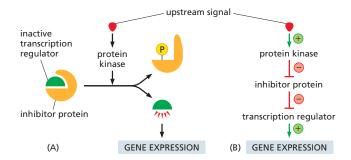

Figure 15–8 The regulation of a monomeric GTPase. GTPase-activating proteins (GAPs) inactivate the protein by stimulating it to hydrolyze its bound GTP to GDP, which remains tightly bound to the inactivated GTPase. Guanine nucleotide exchange factors (GEFs) activate the inactive protein by stimulating it to release its GDP; because the concentration of GTP in the cytosol is 10 times greater than the concentration of GDP, the protein rapidly binds GTP and is thereby activated.

have the same effect as one activating step (Figure 15-9). This activation scheme is very common in signaling systems, as we will see when we describe specific pathways later in this chapter.

Intracellular Signals Must Be Specific and Robust in a Noisy Cytoplasm

In an idealized signaling pathway like that shown in Figure 15–1, each intracellular signaling molecule interacts only with the appropriate downstream target. Similarly, the target is activated only by the appropriate upstream signal. In reality, however, the cell is crowded with closely related signaling molecules that control a diverse array of cellular processes. It is inevitable that a signaling molecule will sometimes interact with molecules in other signaling pathways, potentially creating unwanted cross-talk and interference between signaling systems. How does a signal remain strong and specific under these noisy conditions?

A key to signaling specificity is the high affinity and specificity of the interactions between intracellular signaling molecules and their correct partners. The binding of a signaling molecule to its target is determined by precise and complex interactions between complementary surfaces on the two molecules. Some protein kinases, for example, contain active sites that recognize a specific amino acid sequence around the phosphorylation site on the correct target protein, and many signaling enzymes employ additional *docking sites*, outside their active site, that promote a specific, high-affinity interaction with a complementary site on the target. These and related mechanisms provide a strong and persistent interaction between the correct partners, thereby enhancing the likelihood that a signal is passed to the appropriate target.

The specificity of signaling systems also depends on noise filters that reduce or remove undesirable background signals. Consider a signaling pathway, for example, in which a response is triggered by phosphorylation of several sites on a target protein. Inside the cell, we can generally assume that a constant low level of phosphatase activity is present to remove these phosphorylations. As a result, a strong response is possible only if the appropriate protein kinase reaches a high and persistent level of activity that is sufficient to overcome the opposing phosphatase activity. If by some random accident another protein kinase interacts briefly with the target protein and catalyzes phosphorylation on one or two sites, these will be removed by the opposing phosphatase and no response will occur. The weak background signal is thereby ignored.

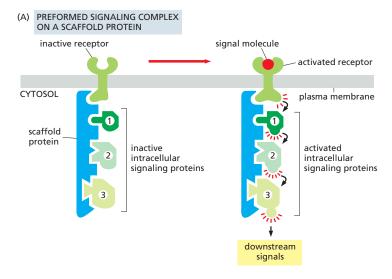

Cells in a population often exhibit random variations in the concentration or activity of their intracellular signaling molecules. Similarly, individual molecules in a large population of molecules vary in their activity or interactions with other molecules. This *signal variability* introduces another form of noise that can interfere with the precision and efficiency of signaling. Most signaling systems, however, generate remarkably robust and precise responses even when upstream signals are variable or some components of the system are disabled. In some cases, this *robustness* depends on the presence of parallel mechanisms; for example, a signal might employ two parallel pathways to activate a single common downstream target protein, allowing the response to occur even if one pathway is crippled.

Figure 15–9 A sequence of two inhibitory signals produces a positive signal. (A) In this simple signaling system, a transcription regulator is kept in an inactive state by a bound inhibitor protein. In response to some upstream signal, a protein kinase is activated and phosphorylates the inhibitor, causing its dissociation from the transcription regulator, which can now activate gene expression. (B) The signaling pathway consists of a sequence of four steps, including two sequential inhibitory steps that are equivalent to a single activating step.

MBOC7_ptr_ch15_873-948.indd 881 08/12/21 12:23 PM

Intracellular Signaling Complexes Form at Activated Cell-Surface Receptors

One simple and effective strategy for enhancing the specificity of interactions between intracellular signaling molecules and reducing background noise is to localize the molecules in the same part of the cell, often within large protein complexes, thereby promoting their interaction with one another and not with inappropriate partners. Such mechanisms often involve **scaffold proteins**, which bring together groups of interacting signaling proteins into *signaling complexes*, often before a signal has been received (**Figure 15–10A**). Because the

inactive receptor activated intracellular signaling proteins activated of intracellular signaling proteins activated intracellular signaling proteins downstream signals

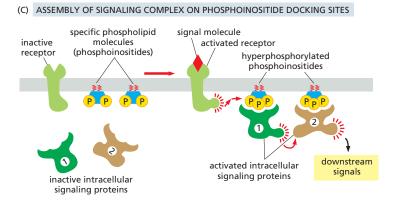

Figure 15-10 Three types of intracellular signaling complexes. (A) A receptor and some of the intracellular signaling proteins it activates in sequence are preassembled into a signaling complex on the inactive receptor by a large scaffold protein. (B) A signaling complex assembles transiently on a receptor only after the binding of an extracellular signal molecule has activated the receptor; here, the activated receptor phosphorylates itself at multiple sites, which then act as docking sites for intracellular signaling proteins. (C) Activation of a receptor leads to the increased phosphorylation of specific phospholipids (phosphoinositides) in the adjacent plasma membrane; these then serve as docking sites for specific intracellular signaling proteins, which can now interact with each other.

MBOC7_ptr_ch15_873-948.indd 882 08/12/21 12:23 PM

scaffold holds the proteins in close proximity, they can interact at high local concentrations and be activated rapidly, efficiently, and selectively in response to an appropriate extracellular signal, avoiding unwanted cross-talk with other signaling pathways.

In other cases, such signaling complexes form transiently in response to an extracellular signal and rapidly disassemble when the signal is gone. They often assemble around a cell-surface receptor after an extracellular signal molecule has activated it. In many of these cases, the cytoplasmic tail of an activated enzyme-coupled receptor is phosphorylated during the activation process, and the phosphorylated amino acids then serve as docking sites for the assembly of other signaling proteins (Figure 15–10B). In yet other cases, receptor activation leads to the production of modified phospholipid molecules (called phosphoinositides) in the adjacent plasma membrane, which then recruit specific intracellular signaling proteins to this region of membrane, where they are activated (Figure 15–10C).

Modular Interaction Domains Mediate Interactions Between Intracellular Signaling Proteins

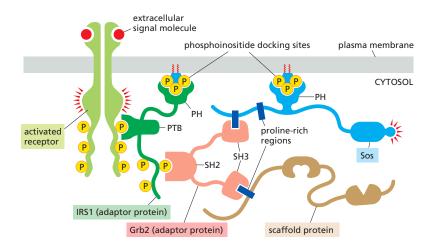

Simply bringing intracellular signaling proteins together into close proximity is sometimes sufficient to activate them. Thus, *induced proximity*, where a signal triggers assembly of a signaling complex, is commonly used to relay signals from protein to protein along a signaling pathway. The assembly of such signaling complexes depends on various highly conserved, small **interaction domains**, which are found in many intracellular signaling proteins. Each of these compact protein modules binds to a particular structural motif in another protein or lipid. The recognized motif in the interacting protein can be a short peptide sequence, a covalent modification (such as a phosphorylated amino acid), or another protein domain. The use of modular interaction domains presumably facilitated the evolution of new signaling pathways. Because it can be inserted at many locations in a protein without disturbing the protein's folding or function, a new interaction domain can connect the protein to additional signaling pathways.

There are many types of interaction domains in signaling proteins. *Src homology 2 (SH2) domains* and *phosphotyrosine-binding (PTB) domains*, for example, bind to phosphorylated tyrosines in a particular peptide sequence on activated receptors or intracellular signaling proteins. *Src homology 3 (SH3)* domains bind to short, proline-rich amino acid sequences. Some *pleckstrin homology (PH)* domains bind to the charged head groups of specific phosphoinositides that are produced in the plasma membrane in response to an extracellular signal; they enable the protein they are part of to dock on the membrane and interact with other similarly recruited signaling proteins (see Figure 15–10C). Some signaling proteins consist solely of two or more interaction domains and function only as **adaptors** to link two other proteins together in a signaling pathway. Some adaptor proteins have multiple interaction domains as well as their own signal-propagation activity (see Figure 15–12).

Interaction domains enable signaling proteins to bind to one another in multiple specific combinations. Like Lego bricks, the proteins can form linear or branching chains or three-dimensional networks, which determine the route followed by the signaling pathway. As an example, Figure 15–11 illustrates how some interaction domains mediate the formation of a large signaling complex around the receptor for the hormone *insulin*.

Modular interaction domains are generally located in flexible, unstructured regions of signaling proteins, arrayed along the polypeptide-like beads on a string. Proteins with multiple interaction domains can therefore nucleate the formation of large, cross-linked protein matrices around clusters of activated receptors (Figure 15–12). These protein matrices behave like gels or biomolecular condensates, thereby creating a local microenvironment that is distinct in composition from the surrounding cytosol (discussed in Chapter 3).

MBOC7_ptr_ch15_873-948.indd 883 08/12/21 12:23 PM

Concentration of activated receptors and specific signaling proteins in these matrices is thought to enhance the strength and specificity of the receptor signal while reducing interference from other pathways.

Another way of bringing receptors and intracellular signaling proteins together is to locate them in a specific region of the cell. An important example is the *primary cilium* that projects like an antenna from the surface of most vertebrate cells (discussed in Chapter 16). A number of surface receptors and signaling proteins are concentrated there—particularly the components of the Hedgehog signaling system, as we discuss later. Light and smell receptors are also concentrated in specialized cilia.

Figure 15–11 A specific signaling complex formed using modular interaction domains. This example is based on the insulin receptor, which is a dimeric enzyme-coupled receptor (a receptor tyrosine kinase, discussed later). First, the activated receptor phosphorylates itself on tyrosines, and one of the phosphotyrosines then recruits an adaptor protein called insulin receptor substrate-1 (IRS1) via a PTB domain of IRS1: the PH domain of IRS1 also binds to specific phosphoinositides on the inner surface of the plasma membrane. Then, the activated receptor phosphorylates IRS1 on tyrosines, and one of these phosphotyrosines binds the SH2 domain of the adaptor protein Grb2. Next, Grb2 uses one of its two SH3 domains to bind to a proline-rich region of a protein called Sos, which is thereby brought to the membrane to relay the signal downstream by acting as a GEF (see Figure 15-8) to activate a monomeric GTPase called Ras (not shown). Sos also binds to phosphoinositides in the plasma membrane via its PH domain. Grb2 uses its other SH3 domain to bind to a proline-rich sequence in a scaffold protein, which binds several other signaling proteins (not shown). The other phosphorylated tyrosines on IRS1 recruit additional signaling proteins that have SH2 domains (not shown).

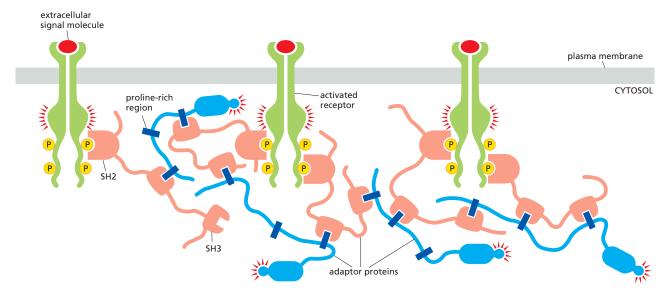

Figure 15–12 Formation of large receptor clusters by multivalent interactions among signaling proteins. The system pictured here contains activated receptor tyrosine kinases that are extensively phosphorylated on disordered regions in the receptor tails. The system also includes two adaptor proteins. One adaptor protein (pink) contains one SH2 domain, which binds phosphorylated tyrosines on the receptors, and two SH3 domains. The other adaptor protein (blue) contains three proline-rich regions that can bind to SH3 domains, plus a protein kinase domain. Numerous multivalent binding interactions can occur among the three components in this system, generating a cross-linked protein matrix or condensate in which the protein kinases of the receptor and adaptor protein are concentrated, potentially providing a more effective signal output. The cross-linking of the matrix can be enhanced further by including adaptor proteins with domains that interact with modified phospholipids in the membrane (see Figure 15–11).

MBOC7_ptr_ch15_873-948.indd 884 08/12/21 12:23 PM

The Relationship Between Signal and Response Varies in Different Signaling Pathways

The function of an intracellular signaling system is to detect and measure a specific stimulus in one location of a cell and then generate an appropriately timed and measured response, often at another location. The system accomplishes this task by sending information in the form of molecular "signals" from the receptor to the final effector proteins, often through a series of intermediaries that do not simply pass the signal along but also process it along the way. Signaling systems work in various ways: each has evolved to produce a response that is appropriate for the cell function the system controls. In the following paragraphs, we list some basic signaling properties and how they vary in different systems, as a foundation for more detailed discussions later.

- 1. Response timing varies dramatically in different signaling systems, according to the speed required for the response. In some cases, such as synaptic signaling (see Figure 15–2C), the response can occur within milliseconds. In other cases, as in the control of cell fate by morphogens during development, a full response can require hours or days.
- 2. Sensitivity to extracellular signals can vary greatly. Hormones tend to act at very low concentrations on their distant target cells, which are therefore highly sensitive to low concentrations of signal. Neurotransmitters, on the other hand, operate at much higher concentrations at a synapse, reducing the need for high sensitivity in postsynaptic receptors. Sensitivity is often controlled by changes in the number or affinity of the receptors on the target cell. A particularly important mechanism for increasing sensitivity is signal amplification, whereby a small number of activated cell-surface receptors evokes a large intracellular response by either producing large amounts of a second messenger or by activating many copies of a downstream signaling protein.
- 3. *Dynamic range* of a signaling system is related to its sensitivity. Some systems, like those involved in simple developmental decisions, are responsive over a narrow range of extracellular signal concentrations. Others, like those controlling vision or some metabolic responses to hormones, are highly responsive over a much broader range of signal strengths. We will see that a broad dynamic range is often achieved by *adaptation* mechanisms that adjust responsiveness according to the prevailing amount of signal.
- 4. Persistence of a response can vary greatly. A transient response of less than a second is appropriate in some synaptic responses, for example, while a prolonged or even permanent response is required in cell-fate decisions during development. Numerous mechanisms, including positive and negative feedback, can be used to alter the duration and reversibility of a response.
- 5. Signal processing can convert a simple signal into a complex response. In many systems, for example, a gradual increase in an extracellular signal is converted into an abrupt, switchlike response. In other cases, a simple input signal is converted into an oscillatory response, produced by a repeating series of transient intracellular signals. Feedback usually lies at the heart of biochemical switches and oscillators, as we describe later.
- 6. *Integration* allows a response to be governed by multiple inputs. As discussed earlier, for example, specific combinations of extracellular signals are generally required to stimulate complex cell behaviors such as cell growth, proliferation, and differentiation (see Figure 15–4). The cell therefore has to integrate information coming from multiple signals, which often depends on intracellular *coincidence detectors*; these proteins are equivalent to *AND gates* in the microprocessor of a computer, in that they are only activated if they receive multiple converging signals (Figure 15–13).

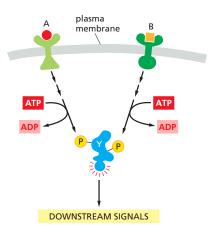

Figure 15–13 An example of signal integration. Extracellular signals A and B activate different intracellular signaling pathways, each of which leads to the phosphorylation of protein Y but at different sites on the protein. Protein Y is activated only when both of these sites are phosphorylated, and therefore it becomes active only when signals A and B are simultaneously present.

MBOC7_ptr_ch15_873-948.indd 885 08/12/21 12:23 PM

7. *Coordination* of multiple responses in one cell can be achieved by a single extracellular signal. Some extracellular signal molecules, for example, stimulate a cell to both grow and divide. This coordination generally depends on mechanisms for distributing a signal to multiple effectors, by creating branches in the signaling pathway. In some cases, the branching of signaling pathways can allow one extracellular signal to *modulate* the strength of a response to other extracellular signals.

Given the complexity that arises from behaviors like signal integration, coordination, and feedback, it is clear that signaling systems rarely depend on a simple linear sequence of steps but more often operate like a signaling network, in which information flows in multiple directions, including backwards. A major research challenge is to understand the nature of these networks and how they control complex cell behaviors.

The Speed of a Response Depends on the Turnover of Signaling Molecules

The speed of any signaling response depends on the nature of the intracellular signaling molecules that carry out the target cell's response. When the response requires only changes in proteins already present in the cell, it can occur very rapidly: an allosteric change in a neurotransmitter-gated ion channel (discussed in Chapter 11), for example, can alter the plasma membrane electrical potential in milliseconds, and responses that depend solely on protein phosphorylation can occur within seconds or minutes. When the response involves changes in gene expression and the synthesis of new proteins, however, it usually requires many minutes or hours, regardless of the mode of signal delivery (Figure 15–14).

When thinking about the speed of a response, it is natural to think of signaling systems in terms of the changes produced when the signal is delivered. But it can be just as important to consider what happens when the signal is withdrawn. In many signaling pathways, the response fades when the signal ceases. Often the effect is transient because the signal exerts its effects by increasing the concentrations of intracellular molecules that are short-lived (unstable), undergoing continual turnover. Thus, when the extracellular signal is removed, degradation of the molecules quickly wipes out all traces of the signal's action. The same principle applies to signals that induce protein phosphorylation by activating a

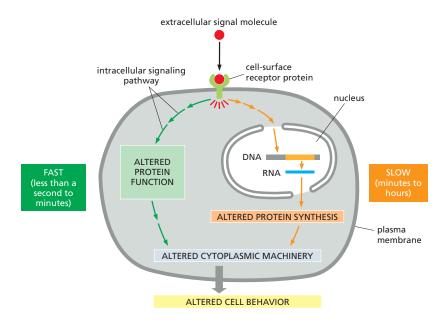

Figure 15-14 Slow and rapid responses to an extracellular signal. Certain types of signal-induced cellular responses, such as increased cell growth and division, involve changes in gene expression and the synthesis of new proteins: they therefore occur slowly, often starting an hour or more after the signal is received. Other responses - such as changes in cell movement, secretion, or metabolismneed not involve changes in gene transcription and therefore occur much more quickly, often starting in seconds or minutes; they may involve the rapid phosphorylation of effector proteins in the cytoplasm, for example. Synaptic responses mediated by changes in membrane potential are even quicker and can occur in milliseconds (not shown). Some signaling systems generate both rapid and slow responses as shown here, allowing the cell to respond quickly to a signal while simultaneously initiating a more long-term, persistent response.

MBOC7_ptr_ch15_873-948.indd 886 08/12/21 12:23 PM

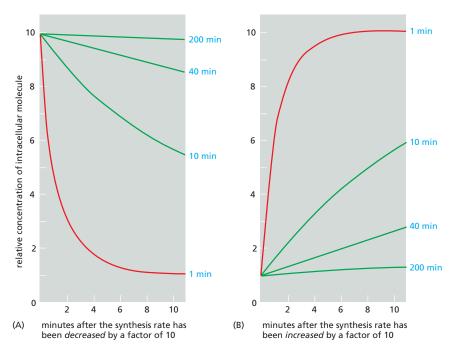

Figure 15–15 The importance of rapid turnover. The graphs show the predicted relative rates of change in the intracellular concentrations of molecules with differing turnover times when their synthesis rates are either (A) decreased or (B) increased suddenly by a factor of 10. In both cases, the concentrations of those molecules that are normally degraded rapidly in the cell (red lines) change quickly, whereas the concentrations of those that are normally degraded slowly (green lines) change proportionally more slowly. The numbers (in blue) on the right are the half-lives assumed for each of the different molecules.

protein kinase: because most phosphorylation is continually removed by phosphatases, the effects of the increased protein kinase activity are quickly reversed when kinase activity declines. It follows that the speed with which a cell responds to removal of a signal depends on the rate of destruction, or turnover, of the molecules or modifications that the signal affects.

It is also true, although much less obvious, that this turnover rate can determine the promptness of the response when an extracellular signal arrives. Consider, for example, two intracellular signaling molecules, X and Y, both of which are normally maintained at a steady-state concentration of 1000 molecules per cell. The cell synthesizes and degrades molecule Y at a rate of 100 molecules per second, with each molecule having an average lifetime of 10 seconds. Molecule X has a turnover rate that is 10 times slower than that of Y: it is both synthesized and degraded at a rate of 10 molecules per second, so that each molecule has an average lifetime in the cell of 100 seconds. If a signal acting on the cell causes a tenfold increase in the synthesis rates of both X and Y with no change in the molecular lifetimes, at the end of 1 second the concentration of Y will have increased by nearly 900 molecules per cell ($10 \times 100 - 100$), while the concentration of X will have increased by only 90 molecules per cell. In fact, after a molecule's synthesis rate has been either increased or decreased abruptly, the time required for the molecule to shift halfway from its old to its new equilibrium concentration is equal to its half-life; that is, equal to the time that would be required for its concentration to fall by half if all synthesis were stopped (Figure 15–15).

Cells Can Respond Abruptly to a Gradually Increasing Signal

Some signaling systems are capable of generating a smoothly graded response over a wide range of extracellular signal concentrations (**Figure 15–16**, *blue line*); such systems are useful, for example, in the fine-tuning of metabolic processes

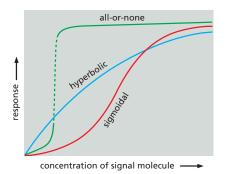

Figure 15-16 Signal processing can produce smoothly graded or switchlike responses. Some cell responses increase gradually as the concentration of extracellular signal molecule increases. eventually reaching a plateau as the signaling pathway is saturated, resulting in a hyperbolic response curve (blue line). In other cases, the signaling system reduces the response at low signal concentrations and then produces a steeper response at some intermediate signal concentration resulting in a sigmoidal response curve (red line). In still other cases, the response is more abrupt and switchlike; the cell switches completely between a low and high response, without any stable intermediate response (green line).

MBOC7_ptr_ch15_873-948.indd 887 08/12/21 12:23 PM

by some hormones. Other signaling systems generate significant responses only when the signal concentration rises beyond some threshold value. These abrupt responses are of two types. One is a *sigmoidal* response, in which low concentrations of stimulus do not have much effect, but then the response rises steeply and continuously at intermediate stimulus levels (Figure 15–16, *red line*). Such systems provide a filter to reduce inappropriate responses to low-level background signals but respond with high sensitivity when the stimulus rises to physiological signal concentrations. A second type of abrupt response is the *discontinuous* or *all-or-none* response, in which the response switches on completely (and often irreversibly) when the signal reaches some threshold concentration (Figure 15–16, *green line*). Such responses are particularly useful for controlling the choice between two alternative cell states, and they generally involve positive feedback, as we describe in more detail shortly.

Cells use a variety of molecular mechanisms to produce a sigmoidal response to increasing signal concentrations. In one mechanism, more than one intracellular signaling molecule must bind to its downstream target protein to induce a response. As we discuss later, for example, four molecules of the second messenger cyclic AMP must bind simultaneously to each molecule of *cyclic-AMP-dependent protein kinase* (*PKA*) to activate the kinase. A similar sharpening of response is seen when the activation of an intracellular signaling protein requires phosphorylation at more than one site. Such responses become sharper as the number of required molecules or phosphate groups increases, and if the number is large enough, responses become almost all-or-none (Figure 15–17).

Responses are also sharpened when an intracellular signaling molecule activates one enzyme and also inhibits another enzyme that catalyzes the opposite reaction. A well-studied example of this common type of regulation is the stimulation of glycogen breakdown in skeletal muscle cells induced by the hormone epinephrine. Epinephrine's binding to a G-protein-coupled cell-surface receptor increases the intracellular concentration of cyclic AMP, which both activates an enzyme that promotes glycogen breakdown and inhibits an enzyme that promotes glycogen synthesis.

Positive Feedback Can Generate an All-or-None Response

Like intracellular metabolic pathways (discussed in Chapter 2) and the systems controlling gene activity (discussed in Chapter 7), most intracellular signaling systems incorporate feedback loops, in which the output of a process acts back to regulate that same process. We discussed the mathematical analysis of feedback loops in Chapter 8. In *positive feedback*, the output stimulates its own production; in *negative feedback*, the output inhibits its own production (**Figure 15–18**). Feedback loops are of great general importance in biology, and they regulate many chemical and physical processes in cells. Even the simplest of these loops can produce complex and interesting effects.

Positive feedback in a signaling pathway can transform the behavior of the responding cell. If the positive feedback is of only moderate strength, its effect will be simply to steepen the response to the signal, generating a sigmoidal response like those described earlier; but if the feedback is strong enough, it can produce an all-or-none response (see Figure 15–16). This response goes hand in hand with a further property: once the responding system has switched to the high level of activation, this condition is often self-sustaining and can persist even after the signal strength drops back below its critical value. In such a case, the system is said to be *bistable*: it can exist in either a "switched-off" or a "switched-on" state, and a transient stimulus can flip it from one state to the other (Figure 15–19A and B).

Through positive feedback, a transient extracellular signal can induce long-term changes in cells and their progeny that can persist for the lifetime of the organism. The signals that trigger muscle-cell specification, for example, turn on the transcription of a series of genes that encode muscle-specific transcription

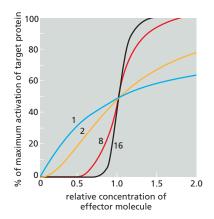

Figure 15–17 Activation curves for an allosteric protein as a function of effector molecule concentration.

The curves show how the sharpness of the activation response increases with an increase in the number of effector molecules that must be bound simultaneously to activate the target protein. The curves shown are those expected, under certain conditions, if the activation requires the simultaneous binding of 1, 2, 8, or 16 effector molecules.

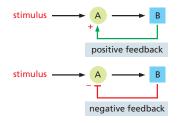

Figure 15–18 Positive and negative feedback. In these simple examples, a stimulus activates protein A, which, in turn, activates protein B. Protein B then acts back to either increase or decrease the activity of A.

regulatory proteins, which stimulate the transcription of their own genes, as well as genes encoding various other muscle-cell proteins; in this way, the decision to become a muscle cell is made permanent. This type of cell memory, which depends on positive feedback, is one of the basic ways in which a cell can undergo a lasting change of character without any alteration in its DNA sequence.

Studies of signaling responses in large populations of cells can give the false impression that a response is smoothly graded, even when strong positive feedback is causing an abrupt, discontinuous switch in the response in individual cells. Only by studying the response in single cells is it possible to see its all-or-none

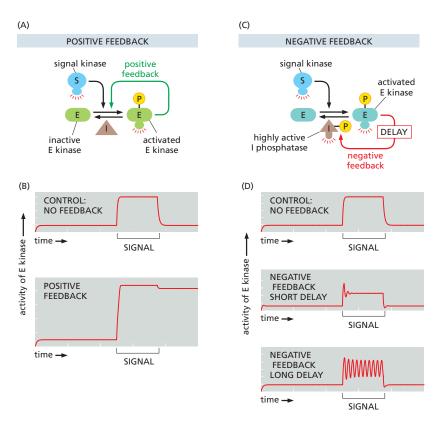

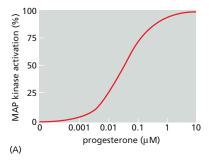

Figure 15–19 Some effects of simple feedback. The graphs show the computed effects of simple positive and negative feedback loops (discussed in Chapter 8). In each case, the input signal is an activated protein kinase (S) that phosphorylates and thereby activates another protein kinase (E); a protein phosphatase (I) dephosphorylates and inactivates the activated E kinase. In the graphs, the red line indicates the activity of the E kinase over time; the underlying black bracket indicates the time during which the input signal (activated S kinase) is present. (A) Diagram of a positive feedback loop, in which the activated E kinase acts back to promote its own phosphorylation and activation; the basal activity of the I phosphatase dephosphorylates activated E at a steady, low rate. (B) The top graph shows that, without feedback, the activity of the E kinase is simply proportional to the level of stimulation by the S kinase. The bottom graph shows that, with the positive feedback loop, the transient stimulation by S kinase switches the system from an "off" state to an "on" state, which then persists after the stimulus has been removed. (C) Diagram of a negative feedback loop, in which the activated E kinase phosphorylates and activates the I phosphatase, thereby increasing the rate at which the phosphatase dephosphorylates and inactivates the phosphorylated E kinase. (D) The top graph shows, again, the response in E kinase activity without feedback. The other graphs show the effects on E kinase activity of negative feedback operating after a short or long delay. With a short delay, the system shows a response when the signal is first increased, but the feedback quickly dampens the response—which then declines to some intermediate level at which the input signal and feedback are balanced. With a long delay, the response rises unopposed at first, allowing kinase activity to reach maximum levels before it feeds back to shut itself off. Then the sudden drop in activity removes the negative feedback, unleashing another pulse of kinase activity. If conditions are right, the result is sustained oscillations for as long as the stimulus is present.

MBOC7_ptr_ch15_873-948.indd 889 08/12/21 12:23 PM

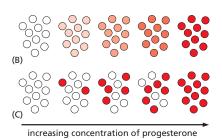

Figure 15-20 The importance of examining individual cells to detect all-or-none responses to increasing concentrations of an extracellular signal. In these experiments, immature from eggs (oocytes) were stimulated with increasing concentrations of the hormone progesterone. The response was assessed by analyzing the activation of MAP kinase (discussed later), which is one of the protein kinases activated by phosphorylation in the response. The amount of phosphorylated (activated) MAP kinase in extracts of the oocytes was assessed biochemically. In (A), extracts of populations of stimulated oocytes were analyzed, and the activation of MAP kinase appeared to increase progressively with increasing progesterone concentration. There are two possible ways of explaining this result: (B) MAP kinase could have increased gradually in each individual cell with increasing progesterone concentration; or (C) individual cells could have responded in an all-ornone way, with the gradual increase in total MAP kinase activation reflecting the increasing number of cells responding with increasing progesterone concentration. When extracts of individual oocytes were analyzed, it was found that cells had either very low amounts or very high amounts, but not intermediate amounts, of the activated kinase, indicating that the response was essentially all-ornone at the level of individual cells, as diagrammed in C. Subsequent studies revealed that this all-or-none response is due in part to strong positive feedback in the progesterone signaling system. (Adapted from J.E. Ferrell and E.M. Machleder, Science 280:895-898, 1998. With permission from AAAS.)

character (Figure 15–20). The misleading smooth response in a cell population is due to the random, intrinsic variability in signaling systems that we described earlier: all cells in a population do not respond identically to the same concentration of extracellular signal, especially at intermediate signal concentrations where the receptors are only partially occupied.

Negative Feedback Is a Common Feature of Intracellular Signaling Systems

By contrast with positive feedback, negative feedback counteracts the effect of a stimulus and thereby abbreviates and limits the level of the response, making the system less sensitive to perturbations (discussed in Chapter 8). As with positive feedback, however, qualitatively different responses can be obtained when the feedback operates in different ways. Negative feedback with a long delay can produce responses that oscillate. The oscillations may persist for as long as the stimulus is present (Figure 15–19C and D) or they may even be generated spontaneously, without need of an external signal to drive them. Many such oscillators also contain positive feedback loops that generate sharper oscillations. Later in this chapter, we will encounter specific examples of oscillatory behavior in the intracellular responses to extracellular signals; all of them depend on negative feedback, generally accompanied by positive feedback.

If negative feedback operates with a short delay, the system generates a brief response to a stimulus, but the response decays rapidly even while the stimulus persists. If the stimulus is increased further, the system responds strongly again, but, again, the response soon decays. This is the phenomenon of *adaptation*, which we now discuss.

Cells Can Adjust Their Sensitivity to a Signal

We have seen that most signaling systems generate an output response that is proportional to the strength of the input signal. In many cases, the response remains constant as long as the input signal remains, and the response declines

MBOC7_ptr_ch15_873-948.indd 890 08/12/21 12:23 PM

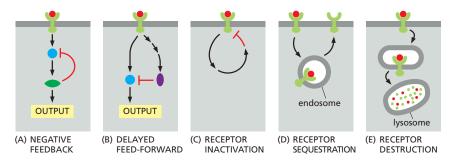

Figure 15–21 Some ways in which target cells can become adapted (desensitized) to an extracellular signal molecule. (A) Negative feedback with a short delay can dampen the initial response to receptor activation. (B) In some cases, the activated receptor rapidly activates a stimulatory pathway while also initiating a slower inhibitory pathway—resulting in a transient output response. This is called a delayed feed-forward loop. (C, D, E) Various mechanisms can inactivate a cell-surface receptor after a signal molecule binds, including mechanisms that depend on internalization of the receptor into endosomes, from which the receptor can be returned to the cell surface or destroyed in lysosomes.

when the input signal stops. In other systems, like those involving positive feedback, an input signal can generate a strong output signal that persists even after the input signal is removed. Finally, we have just discussed negative feedback systems in which an input signal triggers a response that rises and then falls even if the stimulus persists. A second, stronger input signal can then generate another transient response like the first one, and so on.

This phenomenon is called **adaptation**, or **desensitization**, and it allows cells to respond to *changes* in the strength of an input signal (rather than to the absolute amount of the signal) over a very wide range of signal levels. The visual system, discussed later in this chapter, provides the ideal illustration of this concept: it uses adaptation at varying signal strengths to allow us to see clearly over an astonishing range of light intensities, from starlight to bright sunshine.

Adaptation requires that some component of the signaling system generates a delayed inhibitory signal that reduces the strength of the output. There are several variations on this theme. One common mechanism, as just discussed, is negative feedback that operates with a short delay (Figure 15–21A). Many signaling pathways that begin with enzyme-coupled receptors, for example, include protein kinases that phosphorylate and thereby inhibit an upstream signaling protein in the pathway. A second mechanism of adaptation occurs when an extracellular signal rapidly activates a signaling response through one pathway while also triggering a parallel, slower signaling pathway that inhibits the response (Figure 15–21B). In some enzyme-coupled signaling pathways, for example, an activated receptor promotes recruitment to the membrane of a GEF called Sos, which stimulates the activity of a small GTP-binding protein called Ras (see Figure 15–11). Activation of the receptor also leads more slowly to recruitment of a GAP that inactivates Ras after a delay, thereby leading to a reduced output signal.

A particularly effective mechanism of adaptation, discussed in more detail later in the chapter, depends on receptor inactivation, whereby some activated receptors shut themselves off after some short period of activity. Ligand binding to some G-protein-coupled receptors, for example, leads to a change in the receptor that promotes its association with heterotrimeric G proteins and the resulting downstream response. Ligand binding also results in phosphorylation of the receptor and association with inhibitory molecules called *arrestins*, which interfere with G-protein activation and thereby reduce the response. The response is dampened further by endocytosis of the ligand-bound receptors, which can be sequestered inside the cell or simply destroyed (Figure 15–21C, D, and E).

Though bewildering in their complexity, the multiple cross-regulatory signaling pathways and feedback loops that we describe in this chapter are not just a

MBOC7_ptr_ch15_873-948.indd 891 08/12/21 12:23 PM

haphazard tangle, but a highly evolved system for processing and interpreting the vast number of extracellular signals that impinge upon animal cells. The entire signaling network can be viewed as a computing device; like that other biological computing device, the brain, it presents one of the most difficult problems in biology. We can identify the components and discover how they work individually. We can understand how small subsets of components work together as regulatory modules, noise filters, or adaptation mechanisms, as we have seen. However, it is a much more daunting task to understand how the system works as a whole. This is not only because the system is complex; it is also because the way it behaves is strongly dependent on the quantitative details of the molecular interactions, and, for most animal cells, we have only rough qualitative information. A major challenge for the future of signaling research is to develop more sophisticated quantitative and computational methods for the analysis of signaling systems, as described in Chapter 8.

Summary

Each cell in a multicellular animal is programmed to respond to a specific set of extracellular signal molecules produced by other cells. The signal molecules act by binding to a complementary set of receptor proteins expressed by the target cells. Most extracellular signal molecules activate cell-surface receptor proteins, which act as signal transducers, converting the extracellular signal into intracellular ones that alter the behavior of the target cell. Activated receptors relay the signal into the cell interior by activating intracellular signaling proteins. Collectively, some of these signaling proteins help transduce, amplify, and spread the signal as they relay it, while others integrate signals from different signaling pathways. Some function as switches that are transiently activated by phosphorylation or GTP binding. Large signaling complexes form by means of modular interaction domains in the signaling proteins, which allow the proteins to form complex signaling networks.

Target cells use various mechanisms, including feedback loops, to adjust the ways in which they respond to extracellular signals. Positive feedback loops can help cells respond in an all-or-none fashion to a gradually increasing concentration of an extracellular signal or convert a short-lasting signal into a long-lasting or even irreversible response. Negative feedback is one way that allows cells to adapt to a signal molecule, which enables them to respond to small changes in the concentration of the signal molecule over a large concentration range.

SIGNALING THROUGH G-PROTEIN-COUPLED RECEPTORS

G-protein-coupled receptors (GPCRs) form the largest family of cell-surface receptors, and they mediate most responses to signals from the external world, as well as signals from other cells, including hormones, neurotransmitters, and local mediators. Our senses of sight, smell, and taste also depend on them. There are more than 800 GPCRs in humans, and in mice there are about 1000 concerned with the sense of smell alone. The signal molecules that act on GPCRs are as varied in structure as they are in function and include proteins and small peptides, derivatives of amino acids and fatty acids, photons of light, and all the molecules that we can smell or taste. The same signal molecule can activate many different GPCR family members; for example, epinephrine activates at least 9 distinct GPCRs, acetylcholine another 5, and the neurotransmitter serotonin at least 14. The different receptors for the same signal are usually expressed in different cell types and elicit different responses.

Despite the chemical and functional diversity of the signal molecules that activate them, all GPCRs have a similar structure. They consist of a single polypeptide chain that threads back and forth across the lipid bilayer seven times, forming a cylindrical structure, often with a deep ligand-binding site in its core

MBOC7_ptr_ch15_873-948.indd 892 08/12/21 12:23 PM

Figure 15-22 A G-protein-coupled receptor (GPCR). (A) GPCRs that bind small ligands such as epinephrine have small extracellular domains, and the ligand usually binds deep within the plane of the plasma membrane to a site that is formed by amino acids from several transmembrane segments. GPCRs that bind protein ligands have a large extracellular domain (not shown here) that contributes to ligand binding. (B) The structure of the β_2 -adrenergic receptor, a receptor for the neurotransmitter epinephrine, illustrates the typical cylindrical arrangement of the seven transmembrane helices in a GPCR. The ligand (orange) binds in a pocket between the helices, resulting in conformational changes on the cytoplasmic surface of the receptor that promote G-protein activation (not shown). (PDB code: 3P0G.)

(**Figure 15–22**). In addition to their characteristic orientation in the plasma membrane, they all use G proteins to relay the signal into the cell interior.

The GPCR superfamily includes *rhodopsin*, the light-activated protein in the vertebrate eye, as well as the large number of olfactory receptors in the vertebrate nose. Other family members are found in unicellular organisms: the receptors in yeasts that recognize secreted mating factors are an example. It is likely that the GPCRs that mediate cell-cell signaling in multicellular organisms evolved from the sensory receptors in their unicellular eukaryotic ancestors.

It is remarkable that almost half of all known drugs work through GPCRs or GPCR-coupled signaling pathways. Of the many hundreds of genes in the human genome that encode GPCRs, about 150 encode orphan receptors, for which the ligand is unknown. Many of them are likely targets for new drugs that remain to be discovered.

Heterotrimeric G Proteins Relay Signals from GPCRs

When an extracellular signal molecule binds to a GPCR, the receptor undergoes a conformational change that enables it to activate a **heterotrimeric GTP-binding protein (G protein)**, which couples the receptor to enzymes or ion channels in the plasma membrane. In some cases the G protein is physically associated with the receptor before the receptor is activated, whereas in others it binds only after receptor activation. There are various types of G proteins, each specific for a particular set of GPCRs and for a particular set of target proteins in the plasma membrane. They all have a similar structure, however, and operate similarly.

G proteins are composed of three protein subunits: α , β , and γ . In the unstimulated state, the α subunit has GDP bound and the G protein is inactive (Figure 15–23). When a GPCR is activated, it acts like a guanine nucleotide

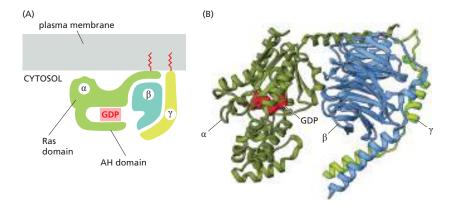

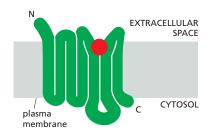

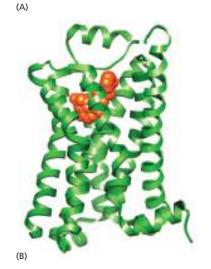

Figure 15–23 The structure of an inactive G protein. (A) Note that both the α and γ subunits have covalently attached lipid molecules (red tails) that help them bind to the plasma membrane, and the α subunit has GDP bound. (B) The three-dimensional structure of the inactive, GDP-bound form of a G protein called Gi, which interacts with numerous GPCRs, including the β_2 -adrenergic receptor shown in Figure 15–22. The α subunit contains the GTPase domain and binds to one side of the β subunit. The γ subunit binds to the opposite side of the β subunit, and the β and γ subunits together form a single functional unit. The GTPase domain of the α subunit contains two major subdomains: the Ras domain, which is related to other GTPases and provides one face of the GTP-binding pocket; and the α -helical or AH domain, which clamps the GTP in place (see Figure 15–24). (PDB code: 1GG2.)

MBOC7_ptr_ch15_873-948.indd 893 08/12/21 12:23 PM

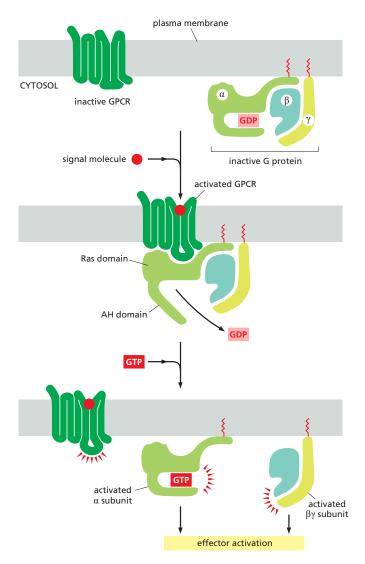

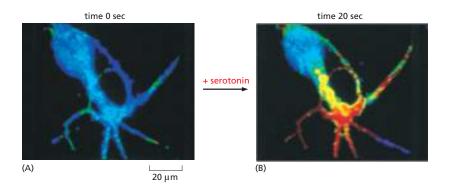

Figure 15–24 Activation of a G protein by an activated GPCR. Binding of an extracellular signal molecule to a GPCR changes the conformation of the receptor, which allows the receptor to bind and alter the conformation of a heterotrimeric G protein. The AH domain of the G protein α subunit moves outward to open the GTP-binding site, thereby promoting dissociation of GDP. GTP binding then promotes closure of the binding site, triggering conformational changes that cause dissociation of the α subunit from the receptor and from the $\beta\gamma$ complex. The GTP-bound α subunit and the $\beta\gamma$ complex each regulate the activities of downstream signaling molecules (not shown). The receptor stays active while the extracellular signal molecule is bound to it, and it can therefore catalyze the activation of many G-protein molecules (Movie 15.1).

exchange factor (GEF) and induces the α subunit to release its bound GDP, allowing GTP to bind in its place. GTP binding then causes an activating conformational change in the $G\alpha$ subunit, releasing the G protein from the receptor and triggering dissociation of the GTP-bound $G\alpha$ subunit from the $G\beta\gamma$ pair—both of which then interact with various targets, such as enzymes and ion channels in the plasma membrane, which relay the signal onward (Figure 15–24).

The α subunit is a GTPase and becomes inactive when it hydrolyzes its bound GTP to GDP. The time required for GTP hydrolysis is usually short because the GTPase activity is greatly enhanced by the binding of the α subunit to a second protein, which can be either the target protein or a specific **regulator of G protein signaling (RGS)**. RGS proteins act as α -subunit-specific GTPase-activating proteins (GAPs) (see Figure 15–8), and they help shut off G-protein-mediated

MBOC7_ptr_ch15_873-948.indd 894 08/12/21 12:23 PM

responses in all eukaryotes. There are about 25 RGS proteins encoded in the human genome, each of which interacts with a particular set of G proteins.

Some G Proteins Regulate the Production of Cyclic AMP

Cyclic AMP (cAMP) acts as a second messenger in some signaling pathways. An extracellular signal can increase cAMP concentration more than twenty-fold in seconds (**Figure 15–25**). As explained earlier (see Figure 15–15), such a rapid response requires balancing a rapid synthesis of the molecule with its rapid breakdown or removal. Cyclic AMP is synthesized from ATP by an enzyme called **adenylyl cyclase**, and it is rapidly and continually destroyed by **cyclic AMP phosphodiesterases** (**Figure 15–26**). Adenylyl cyclase is a large, multipass transmembrane protein with its catalytic domain on the cytosolic side of the plasma membrane. There are at least eight isoforms in mammals, most of which are regulated by both G proteins and Ca²⁺.

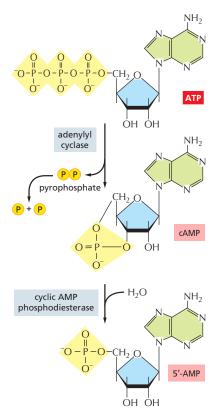

Many extracellular signals work by increasing cAMP concentrations inside the cell. These signals activate GPCRs that are coupled to a **stimulatory G protein** (G_s). The activated α subunit of G_s binds and thereby activates adenylyl cyclase. Other extracellular signals, acting through different GPCRs, reduce cAMP levels by activating an **inhibitory G protein** (G_i), which then inhibits adenylyl cyclase.

Both G_s and G_i are targets for medically important bacterial toxins. *Cholera toxin*, which is produced by the bacterium that causes cholera, is an enzyme that catalyzes the transfer of ADP ribose from intracellular NAD⁺ to the α subunit of G_s . This ADP ribosylation alters the α subunit so that it can no longer hydrolyze its bound GTP, causing it to remain in an active state that stimulates adenylyl cyclase indefinitely. The resulting prolonged elevation in cAMP concentration within intestinal epithelial cells causes a large efflux of Cl⁻ and water into the gut, thereby causing the severe diarrhea that characterizes cholera. *Pertussis toxin*, which is made by the bacterium that causes pertussis (whooping cough), catalyzes the ADP ribosylation of the α subunit of G_i , preventing the protein from interacting with receptors; as a result, the G protein remains in the inactive GDP-bound state and is unable to regulate its target proteins. These two toxins are widely used in experiments to determine whether a cell's GPCR-dependent response to a signal is mediated by G_s or by G_i .

Some of the responses mediated by a G_s -stimulated increase in cAMP concentration are listed in Table 15–1. As the table shows, different cell types respond differently to an increase in cAMP concentration. Some cell types, such as fat cells, activate adenylyl cyclase in response to multiple hormones, all of which thereby

Figure 15–26 The synthesis and degradation of cyclic AMP. In a reaction catalyzed by the enzyme adenylyl cyclase, cyclic AMP (cAMP) is synthesized from ATP through a cyclization reaction that removes two phosphate groups as pyrophosphate (PP); a pyrophosphatase drives this synthesis by hydrolyzing the released pyrophosphate to phosphate. Cyclic AMP is short-lived (unstable) in the cell because it is hydrolyzed by specific phosphodiesterases to form 5'-AMP, as indicated.

Figure 15-25 An increase in cyclic AMP in response to an extracellular signal. This Aplysia sensory nerve cell in culture is responding to the neurotransmitter serotonin, which acts through a GPCR to cause a rapid rise in the intracellular concentration of cAMP. To monitor the cAMP level, the cell has been loaded with a fluorescent protein that changes its fluorescence when it binds cAMP. Blue indicates a low level of cAMP. vellow an intermediate level, and red a high level. (A) In the resting cell, the cAMP level is about 5×10^{-8} M. (B) Twenty seconds after the addition of serotonin to the culture medium, the intracellular level of cAMF has increased to more than $10^{-6} \,\mathrm{M}$ in the relevant parts of the cell, an increase of more than twentyfold. (From B.J. Bacskai et al., Science 260:222-226, 1993. With permission from AAAS.)

TABLE 15–1 Some Hormone-induced Cell Responses Mediated by Cyclic AMP					
Target tissue	Hormone	Major response			
Thyroid gland	Thyroid-stimulating hormone (TSH)	Thyroid hormone synthesis and secretion			
Adrenal cortex	Adrenocorticotrophic hormone (ACTH)	Cortisol secretion			
Ovary	Luteinizing hormone (LH)	Progesterone secretion			
Muscle	Epinephrine	Glycogen breakdown			
Bone	Parathyroid hormone	Bone resorption			
Heart	Epinephrine	Increase in heart rate and force of contraction			
Liver	Glucagon	Glycogen breakdown			
Kidney	Vasopressin	Water resorption			
Fat	Epinephrine, ACTH, glucagon, TSH	Triglyceride breakdown			

stimulate the breakdown of triglyceride (the storage form of fat) to fatty acids. Individuals with genetic defects in the G_s α subunit show decreased responses to certain hormones, resulting in metabolic abnormalities, abnormal bone development, and mental retardation.

Cyclic-AMP-dependent Protein Kinase (PKA) Mediates Most of the Effects of Cyclic AMP

In most animal cells, cAMP exerts its effects mainly by activating **cyclic-AMP-dependent protein kinase (protein kinase A; PKA)**. This kinase phosphorylates specific serines or threonines on selected target proteins, including intracellular signaling proteins and effector proteins, thereby regulating their activity. The target proteins differ from one cell type to another, which explains why the effects of cAMP vary so markedly depending on the cell type (see Table 15–1).

In the inactive state, PKA consists of a complex of two catalytic subunits and two regulatory subunits. The binding of cAMP to the regulatory subunits alters their conformation, causing them to dissociate from the complex. The released catalytic subunits are thereby activated to phosphorylate specific target proteins (Figure 15–27). The regulatory subunits of PKA are important for localizing the kinase inside the cell: special *A-kinase anchoring proteins* (*AKAPs*) bind both to the regulatory subunits and to a component of the cytoskeleton or a membrane of an organelle, thereby tethering the enzyme complex to a particular subcellular compartment. Some AKAPs also bind other signaling proteins, forming a signaling complex. An AKAP located around the nucleus of heart muscle cells,

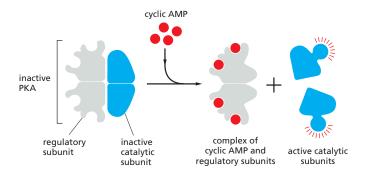

Figure 15–27 The activation of cyclic-AMP-dependent protein kinase (PKA). The binding of cAMP to the regulatory subunits of the PKA tetramer induces a conformational change, causing these subunits to dissociate from the catalytic subunits, thereby activating the kinase activity of the catalytic subunits. The release of the catalytic subunits requires the binding of more than two cAMP molecules to the regulatory subunits in the tetramer. This requirement greatly sharpens the response of the kinase to changes in cAMP concentration, as discussed earlier (see Figure 15–17).

MBOC7_ptr_ch15_873-948.indd 896 08/12/21 12:23 PM

for example, binds both PKA and a phosphodiesterase that hydrolyzes cAMP. In unstimulated cells, the phosphodiesterase keeps the local cAMP concentration low, so that the bound PKA is inactive; in stimulated cells, cAMP concentration rapidly rises, overwhelming the phosphodiesterase and activating the PKA. Among the target proteins that PKA phosphorylates and activates in these cells is the adjacent phosphodiesterase, which rapidly lowers the cAMP concentration again. This negative feedback arrangement converts what might otherwise be a prolonged PKA response into a brief, local pulse of PKA activity.

Whereas some responses mediated by cAMP occur within seconds (see Figure 15–25), others depend on changes in the transcription of specific genes and take hours to develop fully. In cells that secrete the peptide hormone *somatostatin*, for example, cAMP activates the gene that encodes this hormone. The regulatory region of the somatostatin gene contains a short *cis*-regulatory sequence, called the *cyclic AMP response element* (*CRE*), which is also found in the regulatory region of many other genes activated by cAMP. A specific transcription regulator called **CRE-binding** (**CREB**) **protein** recognizes this sequence. When PKA is activated by cAMP, it phosphorylates CREB on a single serine; phosphorylated CREB then recruits a transcription coactivator called *CREB-binding protein* (*CBP*), which stimulates the transcription of the target genes (**Figure 15–28**). Thus, CREB can transform a short cAMP signal into a long-term change in a cell, a process that, in the brain, is thought to play an important part in some forms of learning and memory.

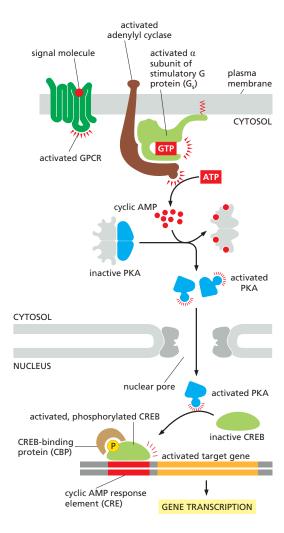

Figure 15-28 How a rise in intracellular cyclic AMP concentration can alter gene transcription. The binding of an extracellular signal molecule to its GPCR activates adenylyl cyclase via G_s and thereby increases cAMP concentration in the cytosol. This rise activates PKA, and the released catalytic subunits of PKA can then enter the nucleus, where they phosphorylate the transcription regulatory protein CREB. Once phosphorylated, CREB recruits the coactivator CBP, which stimulates gene transcription. In some cases, the inactive CREB protein is bound to the cyclic AMP response element (CRE) in DNA before it is phosphorylated (not shown). See Movie 15.2.

Smooth muscle	Acetylcholine	Muscle contraction		
Blood platelets	Thrombin	Platelet aggregation		

Some G Proteins Signal Via Phospholipids

Many GPCRs exert their effects through G proteins that activate the plasma-membrane-bound enzyme **phospholipase** C- β (PLC β). Table 15-2 lists some examples of responses activated in this way. The phospholipase acts on a phosphorylated inositol phospholipid (a phosphoinositide) called **phosphatidylinositol** 4,5-bisphosphate [PI(4,5)P₂], which is present in small amounts in the inner half of the plasma membrane lipid bilayer (Figure 15-29). Receptors that activate this **inositol phospholipid signaling pathway** do so primarily through a G protein called G_q, which activates phospholipase C- β in much the same way that G_s activates adenylyl cyclase. The activated phospholipase then cleaves the PI(4,5)P₂ to generate two products: **inositol** 1,4,5-trisphosphate (IP₃) and **diacylglycerol**. At this step, the signaling pathway splits into two branches.

 IP_3 is a water-soluble molecule that leaves the plasma membrane and diffuses through the cytosol to the endoplasmic reticulum (ER), where it binds IP_3 receptors in the ER membrane. The IP_3 receptor is a large transmembrane Ca^{2+} channel that is closed in the absence of IP_3 . IP_3 binding triggers a conformational change that exposes a high-affinity Ca^{2+} -binding site. Although the cytosolic Ca^{2+} concentration in the unstimulated cell is low ($\sim 10^{-7}$ M), it is sufficient to promote Ca^{2+} binding to some IP_3 receptors. The simultaneous binding of IP_3 and Ca^{2+} to an IP_3 receptor opens the receptor Ca^{2+} channel. Ca^{2+} stored in the ER is released and binds to other IP_3 -bound receptors to cause widespread channel opening. As

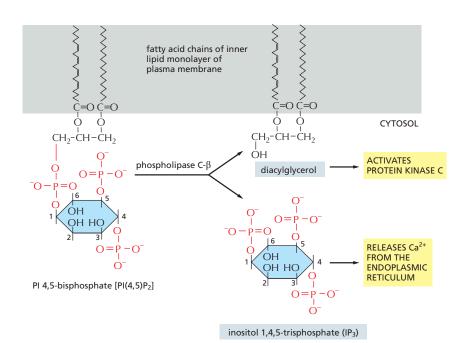

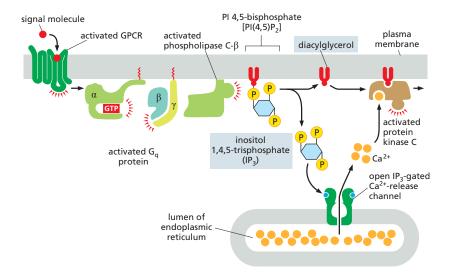

Figure 15-29 The hydrolysis of PI(4,5)P₂ by phospholipase C-β. Two second messengers are produced directly from the hydrolysis of PI(4,5)P2: inositol 1,4,5-trisphosphate (IP3), which diffuses through the cytosol and releases Ca2 from the endoplasmic reticulum, and diacylglycerol, which remains in the membrane and helps to activate protein kinase C (PKC; see Figure 15-30). There are several classes of phospholipase C: these include the β class, which is activated by GPCRs; as we see later, the v class is activated by a class of enzymecoupled receptors called receptor tyrosine kinases (RTKs).

MBOC7_ptr_ch15_873-948.indd 898 08/12/21 12:23 PM

a result, the concentration of cytosolic Ca^{2+} rises 10- to 20-fold (Figure 15–30). The increase in cytosolic Ca^{2+} propagates the signal by influencing the activity of Ca^{2+} -sensitive intracellular proteins, as we describe shortly.

At the same time that the IP_3 produced by the hydrolysis of $PI(4,5)P_2$ is increasing the concentration of Ca^{2+} in the cytosol, the other cleavage product of the $PI(4,5)P_2$, diacylglycerol, is exerting different effects. It also acts as a second messenger, but it remains embedded in the plasma membrane, where it has several potential signaling roles. One of its major functions is to activate a protein kinase called **protein kinase C (PKC)**, so named because it is Ca^{2+} -dependent. The initial rise in cytosolic Ca^{2+} induced by IP_3 alters the PKC so that it translocates from the cytosol to the cytoplasmic face of the plasma membrane. There it is activated by the combination of Ca^{2+} , diacylglycerol, and the negatively charged membrane phospholipid phosphatidylserine (see Figure 15–30). Once activated, PKC phosphorylates target proteins that vary depending on the cell type. The principles are the same as discussed earlier for PKA, although most of the target proteins are different.

Diacylglycerol can be further cleaved to release arachidonic acid, which can either act as a signal in its own right or be used in the synthesis of other small lipid signal molecules called *eicosanoids*. Most vertebrate cell types make eicosanoids, including *prostaglandins*, which have many biological activities. They participate in pain and inflammatory responses, for example, and many anti-inflammatory drugs (such as aspirin, ibuprofen, and cortisone) act in part by inhibiting their synthesis.

Ca²⁺ Functions as a Ubiquitous Intracellular Mediator

Many extracellular signals, and not just those that work via G proteins, trigger an increase in cytosolic Ca^{2+} concentration. In muscle cells, Ca^{2+} triggers contraction, and in many secretory cells, including nerve cells, it triggers secretion. Ca^{2+} has numerous other functions in a variety of cell types. Ca^{2+} is such an effective signaling mediator because its concentration in the cytosol is normally very low ($\sim 10^{-7}$ M), whereas its concentration in the extracellular fluid ($\sim 10^{-3}$ M) and in the lumen of the ER [and sarcoplasmic reticulum (SR) in muscle] is high. Thus, there is a large gradient tending to drive Ca^{2+} into the cytosol across both the plasma membrane and the ER or SR membrane. When a signal transiently opens Ca^{2+} channels in these membranes, Ca^{2+} rushes into the cytosol, and the resulting increase in the local Ca^{2+} concentration activates Ca^{2+} -responsive proteins in the cell.

Some stimuli, including membrane depolarization, membrane stretch, and certain extracellular signals, activate Ca^{2+} channels in the plasma membrane, resulting in Ca^{2+} influx from outside the cell. Other signals, including the GPCR-mediated

Figure 15-30 How GPCRs increase cytosolic Ca2+ and activate protein kinase C. The activated GPCR stimulates the plasma-membrane-bound phospholipase C-β (PLCβ) via a G protein called $G_q.$ The α subunit and $\beta\gamma$ complex of G_a are both involved in this activation. Two second messengers are produced when PI(4,5)P2 is hydrolyzed by activated PLC. Inositol 1,4,5-trisphosphate (IP₃) diffuses through the cytosol and releases ${\rm Ca^{2+}}$ from the ER by binding to and opening IP₃-gated Ca²⁺-release channels (IP3 receptors) in the ER membrane (opening of these channels also requires binding of Ca²⁺, not shown). The large electrochemical gradient for Ca2+ across this membrane causes Ca2+ to escape into the cytosol when the release channels are opened. Diacylglycerol remains in the plasma membrane and, together with phosphatidylserine (not shown) and Ca²⁺. helps to activate protein kinase C (PKC), which is recruited from the cytosol to the cytosolic face of the plasma membrane. Of the 10 or more distinct isoforms of PKC in humans, at least 4 are activated by diacylglycerol (Movie 15.3).

MBOC7_ptr_ch15_873-948.indd 899 08/12/21 12:23 PM

signals described earlier, act primarily through IP_3 receptors to stimulate Ca^{2+} release from intracellular stores in the ER (see Figure 15–30). The ER membrane also contains a second type of regulated Ca^{2+} channel called the **ryanodine receptor** (so called because it is sensitive to the plant alkaloid ryanodine), which opens in response to rising Ca^{2+} levels and thereby amplifies the Ca^{2+} signal.

Several mechanisms rapidly terminate the Ca^{2+} signal and are also responsible for keeping the concentration of Ca^{2+} in the cytosol low in resting cells. Most important, there are Ca^{2+} -pumps in the plasma membrane and the ER membrane that use the energy of ATP hydrolysis to pump Ca^{2+} out of the cytosol. Cells such as muscle and nerve cells, which make extensive use of Ca^{2+} signaling, have an additional Ca^{2+} transporter (an Na^+ -driven Ca^{2+} exchanger) in their plasma membrane that couples the efflux of Ca^{2+} to the influx of Na^+ .

Feedback Generates Ca²⁺ Waves and Oscillations

The IP₃ receptors and ryanodine receptors of the ER membrane have an important feature: they are both stimulated by low to moderate cytoplasmic Ca^{2+} concentrations. This Ca^{2+} -induced calcium release (CICR) results in positive feedback, which has a major impact on the properties of the Ca^{2+} signal. The importance of this feedback is seen clearly in studies with Ca^{2+} -sensitive fluorescent indicators, such as *aequorin* or *fura-2*, which allow researchers to monitor cytosolic Ca^{2+} in individual cells under a microscope (Figure 15–31 and Movie 15.4).

When cells carrying a Ca²⁺ indicator are treated with a small amount of an extracellular signal molecule that stimulates a small increase in the concentration of cytosolic $\overline{\text{IP}_3}$, tiny bursts of Ca^{2+} are seen in one or more discrete regions of the cell. These Ca²⁺ puffs or sparks reflect the local opening of small numbers of IP₃ receptors in the ER membrane that have bound both IP₃ and Ca²⁺, the concentrations of which are too low to bind to all of these receptors. Because various Ca²⁺-binding proteins and Ca²⁺-pumps restrict the diffusion of Ca²⁺, the Ca²⁺ signal often remains localized to the site where the Ca²⁺ entered the cytosol. If the extracellular signal is stronger, however, IP3 rises to a higher concentration and binds many of its receptors, although the low Ca²⁺ concentration still limits the activation of these receptors to some extent. Nevertheless, a local burst of Ca²⁺ release can now spread more easily to neighboring IP₃-bound receptors and activate them, resulting in a regenerative wave of Ca²⁺ release that moves through the cytosol (Figure 15-32), much like the spreading of an action potential along the membrane of an axon (see Figure 11-33). The presence of Ca²⁺-stimulated ryanodine receptors in the ER membrane further enhances the positive feedback.

In addition to being regulated by positive feedback, IP $_3$ receptors and ryanodine receptors are also regulated by negative feedback, in that they are inhibited by high Ca $^{2+}$ concentrations. Thus, the rise in Ca $^{2+}$ in a stimulated cell leads eventually to inhibition of Ca $^{2+}$ release. Because Ca $^{2+}$ -pumps remove the Ca $^{2+}$, the Ca $^{2+}$ concentration in the cytosol falls (see Figure 15–32). The decline in Ca $^{2+}$ eventually relieves the negative feedback, allowing cytosolic Ca $^{2+}$ to rise again. As in other cases of delayed negative feedback (see Figure 15–19), this sequence of events leads to oscillations in the Ca $^{2+}$ concentration, which persist as long as cell-surface receptors are activated. The frequency of the oscillations reflects the

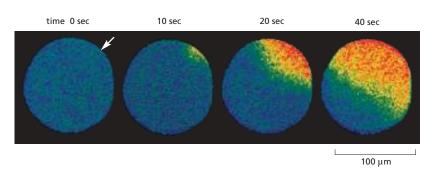

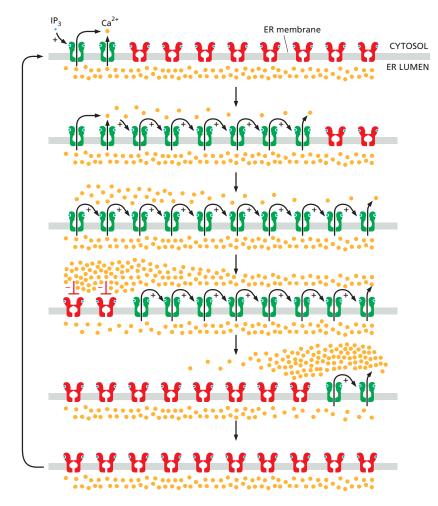

Figure 15-31 The fertilization of an egg by a sperm triggers a wave of cytosolic Ca2+. This sea star egg was injected with a Ca²⁺-sensitive fluorescent dve before it was fertilized. A wave of cytosolic Ca2+ (red and yellow), caused by Ca2+ release from the ER, sweeps across the egg from the site of sperm entry (arrow). This Ca²⁺ wave changes the egg cell surface, preventing the entry of other sperm, and it also initiates embryonic development (Movie 15.5). The initial increase in Ca²⁺ is thought to be caused by a sperm-specific form of PLC (PLCζ) that the sperm brings into the egg cytoplasm when it fuses with the egg; the PLC ζ cleaves PI(4,5)P₂ to produce IP3, which releases Ca2 from the egg ER. The released Ca²⁺ stimulates further Ca2+ release from the ER, producing the spreading wave, as we explain in Figure 15-32. (Courtesy of Stephen Stricker.)

MBOC7_ptr_ch15_873-948.indd 900 08/12/21 12:23 PM

strength of the extracellular stimulus (**Figure 15-33**). The frequency and amplitude of oscillations can also be modulated by other signaling mechanisms, such as phosphorylation, which influence the Ca^{2+} sensitivity of Ca^{2+} channels or affect other components in the signaling system.

The frequency of Ca²⁺ oscillations can be translated into a frequency-dependent cell response. In some cases, the frequency-dependent response itself is also oscillatory: in hormone-secreting pituitary cells, for example, stimulation by an extracellular signal induces repeated Ca²⁺ spikes, each of which

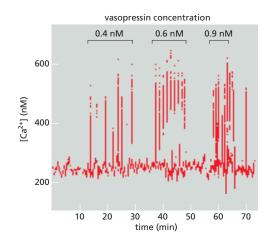

Figure 15-32 Positive and negative feedback produce cytosolic Ca2+ waves and oscillations. This diagram shows IP3 receptors on a portion of the ER membrane: active receptors are shown in green, inactive receptors in red, Ca2+ in orange, and IP3 in blue. When cytosolic IP3 rises to high levels in response to a strong extracellular signal, it occupies most IP3 receptors on the ER membrane. A few IP3-bound receptors are then activated by the low amount of cytosolic Ca²⁺ that is present in the unstimulated cell. The local release of Ca2+ by an activated receptor cluster (top) promotes the opening of nearby IP3 receptors (and ryanodine receptors, not shown), resulting in more Ca²⁺ release. This positive feedback (indicated by positive signs) produces a regenerative wave of Ca²⁺ release that spreads across the cell (see Figure 15-31). These waves of Ca²⁺ release move more quickly across the cell than would be possible by simple diffusion. Also, unlike a diffusing burst of Ca2+ ions, which will become more dilute as it spreads, the regenerative wave produces a high Ca2+ concentration across the entire cell. When it reaches high concentrations, Ca2inactivates IP3 receptors and ryanodine receptors (middle; indicated by red negative signs), shutting down the Ca2+ release. Ca²⁺-pumps reduce the local cytosolic Ca²⁺ concentration to its low resting levels. The result is a cytosolic Ca2+ pulse: positive feedback drives a rapid rise in cytosolic Ca²⁺, and negative feedback sends it back down again. The Ca²⁺ channels remain refractory to further stimulation for some period of time, delaying the generation of another Ca2 spike (bottom). Eventually, however, the negative feedback wears off, allowing IP3 to trigger another Ca²⁺ wave. The end result is repeated Ca²⁺ oscillations (see Figure 15-33). Under some conditions, these oscillations can be seen as repeating narrow waves of Ca2+ moving across the cell.

Figure 15-33 Vasopressin-induced cytosolic Ca2+ oscillations in a liver cell. The cell was loaded with the Ca²⁺sensitive protein aequorin and then exposed to increasing concentrations of the peptide signal molecule vasopressin, which activates a GPCR and thereby PLCB (see Table 15-2). Note that the frequency of the Ca2+ spikes increases with an increasing concentration of vasopressin but that the amplitude of the spikes is not affected. Each spike lasts about 7 seconds. (Adapted from N.M. Woods et al., Nature 319:600-602, published 1986 by Nature Publishing Group. Reproduced with permission of SNCSC.)

MBOC7_ptr_ch15_873-948.indd 901 08/12/21 12:23 PM

is associated with a burst of hormone secretion. In other cases, the frequency-dependent response is non-oscillatory: in some types of cells, for instance, one frequency of Ca^{2+} spikes activates the transcription of one set of genes, while a higher frequency activates the transcription of a different set. How do cells sense the frequency of Ca^{2+} spikes and change their response accordingly? The mechanism presumably depends on Ca^{2+} -sensitive proteins that change their activity as a function of Ca^{2+} -spike frequency. A protein kinase that acts as a molecular memory device seems to have this remarkable property, as we discuss next.

Ca²⁺/Calmodulin-dependent Protein Kinases Mediate Many Responses to Ca²⁺ Signals

Various Ca^{2+} -binding proteins help to relay the cytosolic Ca^{2+} signal. The most important is **calmodulin**, which is found in all eukaryotic cells and can constitute as much as 1% of a cell's total protein mass. Calmodulin functions as a multipurpose intracellular Ca^{2+} receptor, governing many Ca^{2+} -regulated processes. It consists of a highly conserved, single polypeptide chain with four high-affinity Ca^{2+} -binding sites (**Figure 15–34A**). When it binds to Ca^{2+} , it undergoes an activating conformational change. Because two or more Ca^{2+} ions must bind before calmodulin adopts its active conformation, the protein displays a sigmoidal response to increasing concentrations of Ca^{2+} (see Figure 15–17).

The allosteric activation of calmodulin by Ca^{2+} is analogous to the activation of PKA by cyclic AMP, except that the active Ca^{2+} /calmodulin complex has no

The allosteric activation of calmodulin by Ca^{2+} is analogous to the activation of PKA by cyclic AMP, except that the active Ca^{2+} /calmodulin complex has no enzymatic activity itself but instead acts by binding to and activating other proteins. In some cases, calmodulin serves as a permanent regulatory subunit of an enzyme complex, but usually the binding of Ca^{2+} instead enables calmodulin to bind to various target proteins in the cell to alter their activity.

When Ca^{2+} /calmodulin binds to its target protein, the calmodulin further changes its conformation, the nature of which depends on the specific target protein (**Figure 15–34B**). Among the many targets calmodulin regulates are enzymes and membrane transport proteins. As one example, Ca^{2+} /calmodulin binds to and activates the plasma membrane Ca^{2+} -pump that uses ATP hydrolysis to pump Ca^{2+} out of cells. Thus, whenever the concentration of Ca^{2+} in the cytosol rises, the pump is activated, which helps to return the cytosolic Ca^{2+} level to resting levels.

Many effects of Ca²⁺, however, are more indirect and are mediated by protein phosphorylations catalyzed by a family of protein kinases called Ca²⁺/calmodulin-dependent kinases (CaM-kinases). Some CaM-kinases phosphorylate transcription regulators, such as the CREB protein (see Figure 15–28), and in this way activate or inhibit the transcription of specific genes.

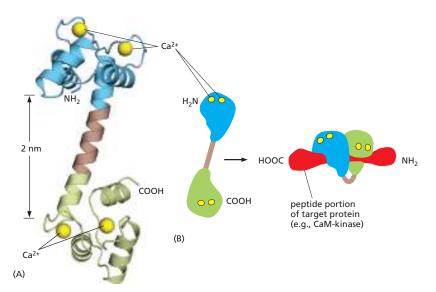

Figure 15-34 The structure of Ca²⁺/ calmodulin. (A) The molecule has a dumbbell shape, with two globular ends, which can bind to many different target proteins. The globular ends are connected by a long, exposed α helix, which allows the protein to adopt a number of different conformations, depending on the target protein it interacts with. Each globular head has two Ca²⁺-binding sites (Movie 15.6). (B) Shown is the major structural change that occurs in Ca2+/calmodulin when it binds to a target protein (in this example, a peptide that consists of the Ca²⁺/ calmodulin-binding domain of a Ca2+/ calmodulin-dependent protein kinase). Note that the Ca²⁺/calmodulin has folded to surround the peptide. When it binds to other targets, it can adopt different conformations. (A, PDB code: 1CLL; B, PDB codes: 1CDL and 2BBM.)

MBOC7_ptr_ch15_873-948.indd 902 08/12/21 12:23 PM

One of the best-studied CaM-kinase is **CaM-kinase II**, which is found in most animal cells but is especially enriched in the nervous system. It constitutes up to 2% of the total protein mass in some regions of the brain, and it is highly concentrated in synapses. CaM-kinase II has several remarkable properties. To begin with, it has a spectacular quaternary structure: twelve copies of the enzyme are assembled into a stacked pair of rings, with kinase domains on the outside linked to a central hub (**Figure 15–35**). This structure helps the enzyme function as a

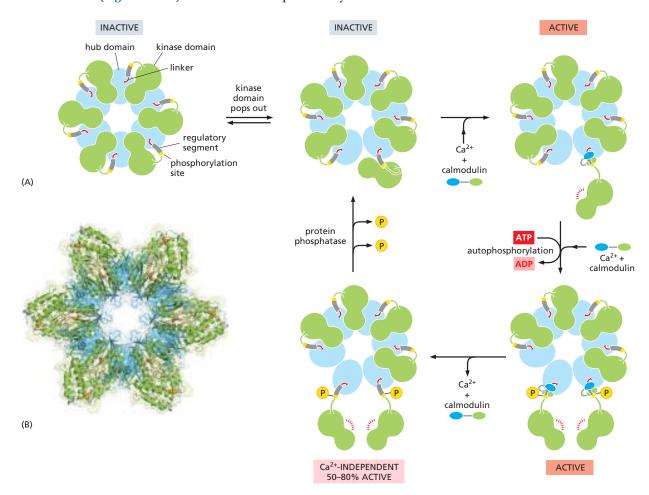

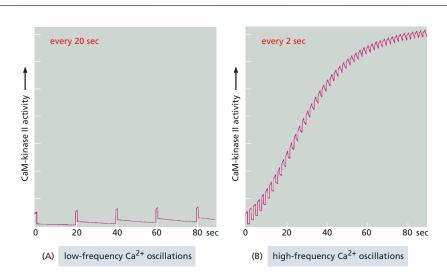

Figure 15–35 The stepwise activation of CaM-kinase II. (A) Each CaM-kinase II protein has two major domains: an amino-terminal kinase domain (green) and a carboxyl-terminal hub domain (blue), linked by a regulatory segment. Six CaM-kinase II proteins are assembled into a giant ring in which the hub domains interact tightly to produce a central structure that is surrounded by kinase domains. The complete enzyme contains two stacked rings, for a total of 12 kinase proteins, but only one ring is shown here for clarity. When the enzyme is inactive, the ring exists in a dynamic equilibrium between two states. The first (upper left) is a compact state, in which the kinase domains interact with the hub domains, so that the regulatory segments are buried in the kinase active sites and thereby block catalytic activity. In the second inactive state (upper middle), a kinase domain has popped out and is linked to its hub domain by its regulatory segment, which continues to inhibit the kinase domain but is now accessible to Ca²⁺/calmodulin. If present, Ca²⁺/calmodulin will bind the regulatory segment and prevent it from inhibiting the kinase, thereby locking the kinase in an active state (upper right). If the adjacent kinase domain also pops out from the hub, it will also be activated by Ca²⁺/calmodulin, and the two kinase domains will then phosphorylate each other on their regulatory segments (lower right). This autophosphorylation further activates the enzyme. It also prolongs the activity of the enzyme in two ways. First, it traps the bound Ca²⁺/calmodulin so that it does not dissociate from the enzyme until cytosolic Ca²⁺ levels return to basal values for at least 10 seconds (not shown). Second, it converts the enzyme to a Ca²⁺-independent form, so that the kinase remains active even after the Ca²⁺/calmodulin dissociates from it (lower left). This activity continues until the action of a protein phosphatase overrides the autophosphorylation activity of CaM-kinase II. (B) This model of the enzyme is based o

The remarkable dodecameric structure of the enzyme allows it to achieve a broad range of intermediate activity states in response to different Ca^{2+} oscillation frequencies: higher frequencies tend to cause more subunits in the enzyme to reach the phosphorylated active state (see Figure 15–36). The behavior of CaM-kinase II is also controlled by the length of the linker segment between the kinase and hub domains. The linker is longer in some isoforms of the enzyme; in these isoforms, the kinase domains tend to pop out of the ring more frequently, making it more sensitive to Ca^{2+} . These and other mechanisms allow the cell to tailor the responsiveness of the enzyme to the needs of different types of neurons. (A, adapted from L.H. Chao et al., Cell 146:732–745, 2011; B, PDB code: 3SOA.)

MBOC7_ptr_ch15_873-948.indd 903 08/12/21 12:23 PM

molecular memory device, switching to an active state when exposed to Ca^{2+} calmodulin and then remaining active even after the Ca^{2+} signal has decayed. This is because adjacent kinase subunits can phosphorylate each other (a process called *autophosphorylation*) when Ca^{2+} /calmodulin activates them (Figure 15–35). Once a kinase subunit is autophosphorylated, it remains active even in the absence of Ca^{2+} , thereby prolonging the duration of the kinase activity beyond that of the initial activating Ca^{2+} signal. The enzyme maintains this activity until a protein phosphatase removes the autophosphorylation and shuts the kinase off. CaM-kinase II activation can thereby serve as a memory trace of a prior Ca^{2+} pulse, and it seems to have a role in some types of memory and learning in the vertebrate brain. Mutant mice that lack a brain-specific form of the enzyme have specific defects in their ability to remember where things are.

Another remarkable property of CaM-kinase II is that the enzyme can use its intrinsic memory mechanism to decode the frequency of Ca^{2+} oscillations. When CaM-kinase II is exposed to both a protein phosphatase and repetitive pulses of Ca^{2+} /calmodulin at different frequencies that mimic those observed in stimulated cells, the enzyme's activity increases steeply as a function of pulse frequency (**Figure 15–36**). This property is thought to be especially important at a nerve cell synapse, where changes in intracellular Ca^{2+} levels in a postsynaptic cell as a result of neural activity can lead to long-term changes in the subsequent effectiveness of that synapse (discussed in Chapter 11).

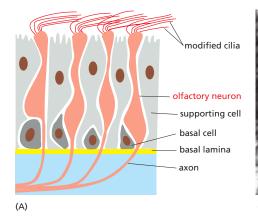

Some G Proteins Directly Regulate Ion Channels

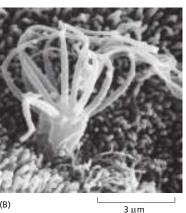

G proteins do not act exclusively by regulating the activity of membrane-bound enzymes that alter the concentration of cyclic AMP or Ca^{2+} in the cytosol. The α subunit of one type of G protein (called G_{12}), for example, activates a guanine nucleotide exchange factor that activates a monomeric GTPase of the *Rho family* (discussed later and in Chapter 16), which regulates the actin cytoskeleton.

In some other cases, G proteins directly activate or inactivate ion channels in the plasma membrane of the target cell, thereby altering the membrane's ion permeability, and hence its electrical excitability. As an example, acetylcholine released by the vagus nerve reduces the heart rate (see Figure 15–5B). This effect is mediated by a special class of acetylcholine receptors that activate the G_i protein discussed earlier. Once activated, the α subunit of G_i inhibits adenylyl cyclase (as described previously), while the $\beta\gamma$ subunits bind to K^+ channels in the plasma membrane of the heart muscle cell and open them. The opening of these K^+ channels makes it harder to depolarize the cell and thereby contributes to the inhibitory effect of acetylcholine on the heart. (These acetylcholine receptors, which can be activated by the fungal alkaloid muscarine, are called

Figure 15-36 CaM-kinase II as a frequency decoder of Ca2+ oscillations. (A) At low frequencies of Ca²⁺ spikes, the enzyme becomes inactive after each spike, as the autophosphorylation induced by Ca2+/calmodulin binding does not maintain the enzyme's activity long enough for the enzyme to remain active until the next Ca2+ spike arrives. (B) At higher spike frequencies, however, the enzyme fails to inactivate completely between Ca²⁺ spikes. so its activity ratchets up with each spike. If the spike frequency is high enough, this progressive increase in enzyme activity will continue until the enzyme is autophosphorylated on all subunits and is therefore maximally activated. Although not shown, once enough of its subunits are autophosphorylated, the enzyme can be maintained in a highly active state even with a relatively low frequency of Ca2+ spikes—a form of cell memory. The binding of Ca²⁺/calmodulin to the enzyme is enhanced by the CaM-kinase II autophosphorylation (an additional form of positive feedback), helping to generate a more switchlike response to repeated Ca²⁺ spikes, (From P.I. Hanson et al., Neuron 12:943-956, 1994. With permission from Elsevier.)

MBOC7_ptr_ch15_873-948.indd 904 08/12/21 12:23 PM

muscarinic acetylcholine receptors to distinguish them from the very different *nicotinic acetylcholine receptors*, which are ion-channel-coupled receptors on skeletal muscle and nerve cells that can be activated by the binding of nicotine, as well as by acetylcholine.)

Other G proteins regulate the activity of ion channels less directly, either by stimulating channel phosphorylation (by PKA, PKC, or CaM-kinase, for example) or by causing the production or destruction of cyclic nucleotides that directly activate or inactivate ion channels. These *cyclic-nucleotide-gated ion channels* have a crucial role in both smell (olfaction) and vision, as we now discuss.

Smell and Vision Depend on GPCRs That Regulate Ion Channels

Humans can distinguish more than 10,000 distinct smells, which they detect using specialized olfactory receptor neurons in the lining of the nose. These cells use specific GPCRs called **olfactory receptors** to recognize odors; the receptors are displayed on the surface of the modified cilia that extend from each olfactory neuron (**Figure 15–37**). The receptors act by increasing cAMP; when stimulated by odorant binding, they activate an olfactory-specific G protein (known as G_{olf}), which in turn activates adenylyl cyclase. The resulting increase in cAMP opens *cyclic-AMP-gated cation channels*, thereby allowing an influx of Na⁺, which depolarizes the plasma membrane of the olfactory receptor neuron and initiates a nerve impulse that travels along its axon to the brain.

There are about 1000 different olfactory receptors in a mouse and about 350 in a human, each encoded by a different gene and each recognizing a different set of odorants. Each olfactory receptor neuron produces only one of these receptors; the neuron responds to a specific set of odorants by means of the specific receptor it displays, and each odorant activates its own characteristic set of olfactory receptor neurons. The same receptor also helps direct the elongating axon of each developing olfactory neuron to the specific target neurons that it will connect to in the brain. A different set of GPCRs acts in a similar way in some vertebrates to mediate responses to *pheromones*, chemical signals detected in a different part of the nose that are used in communication between members of the same species. Humans, however, are thought to lack functional pheromone receptors.

Vertebrate vision employs a similarly elaborate, highly sensitive, signal-detection mechanism that uses cyclic-nucleotide-gated cation channels, but the crucial cyclic nucleotide is **cyclic GMP** (**Figure 15–38**) rather than cAMP. As with cAMP, continual rapid synthesis (by *guanylyl cyclase*) and rapid degradation (by *cyclic GMP phosphodiesterase*) control the concentration of cyclic GMP. However, the light-activated GPCR in this system does not stimulate guanylyl cyclase and raise cyclic GMP levels; instead, it stimulates cyclic GMP phosphodiesterase, resulting in decreased cyclic GMP levels and thus decreased cation channel opening.

The visual signaling system has been especially well studied in **rod photore-ceptors (rods)** in the vertebrate retina. Rods are responsible for noncolor vision

Figure 15-37 Olfactory receptor neurons. (A) A simplified drawing of a section of olfactory epithelium in the nose. Olfactory receptor neurons possess modified cilia, which project from the surface of the epithelium and contain the olfactory receptors, as well as the signal transduction machinery. The axon, which extends from the opposite end of the receptor neuron, convevs electrical signals to the brain when an odorant activates the cell to produce an action potential. In rodents, at least, the basal cells act as stem cells, producing new receptor neurons throughout life, to replace the neurons that die. (B) A scanning electron micrograph of the cilia on the surface of a human olfactory neuron. (B, from E.E. Morrison and R.M. Costanzo, J. Comp. Neurol. 297:1-13, 1990. Figure 15-38 Cyclic GMP.

MBOC7 ptr ch15 873-948.indd 905 08/12/21 12:23 PM

in dim light, whereas **cone photoreceptors (cones)** are responsible for color vision in bright light. Both types of photoreceptors are highly specialized cells with outer and inner segments, a cell body, and a synaptic region where the photoreceptor passes a chemical signal to a retinal neuron (**Figure 15–39**). After a network of retinal neurons processes the signals, the axons of a subset of the neurons transmit the signals to the brain.

The phototransduction apparatus is in the outer segment of the rod, which contains a stack of *discs*, each formed by a closed sac of membrane that is densely packed with a photosensitive GPCR called **rhodopsin**. The plasma membrane surrounding the outer segment contains *cyclic-GMP-gated cation channels*. Cyclic GMP bound to these channels keeps them open in the dark. Light-induced activation of rhodopsin molecules in the disc membrane decreases the cytosolic cyclic GMP concentration and closes the cation channels in the plasma membrane (**Figure 15–40**). Thus, light causes hyperpolarization (a more negative membrane potential—discussed in Chapter 11), which inhibits synaptic signaling.

Rhodopsin is a member of the GPCR family, but the extracellular signal that activates it is not a molecule but a photon of light. Each rhodopsin molecule contains a covalently attached chromophore, 11-cis retinal, which isomerizes almost instantaneously to all-trans retinal when it absorbs a single photon. The isomerization alters the shape of the retinal, forcing a conformational change in the rhodopsin protein. The activated rhodopsin molecule then alters the conformation of the G protein transducin (G_t), causing the transducin α subunit to activate transducin cyclic GMP phosphodiesterase. The phosphodiesterase then hydrolyzes cytosolic cyclic GMP, causing its concentration to fall. As a result, the amount of cyclic GMP bound to the plasma membrane cation channels declines, allowing more of these channels to close. In this way, the signal passes quickly from the disc membrane to the plasma membrane, and a light signal is converted into an electrical one, through a hyperpolarization of the plasma membrane.

Rods use several negative feedback loops to allow the cells to revert quickly to a resting, dark state in the aftermath of a flash of light—a requirement for perceiving the shortness of the flash. A rhodopsin-specific protein kinase called *rhodopsin kinase* (*RK*) phosphorylates the cytosolic tail of activated rhodopsin on multiple serines, partially inhibiting the ability of the rhodopsin to activate transducin. An inhibitory protein called *arrestin* (discussed later) then binds to the phosphorylated rhodopsin, further inhibiting rhodopsin's activity. Mice or humans with a mutation that inactivates the gene encoding RK have a prolonged light response.

At the same time as arrestin shuts off rhodopsin, an RGS protein (discussed earlier) binds to activated transducin, stimulating the transducin to hydrolyze its bound GTP to GDP, which returns transducin to its inactive state. In addition, the cation channels that close in response to light are permeable to ${\rm Ca^{2^+}}$, as well as to Na⁺, so that when they close, the normal influx of ${\rm Ca^{2^+}}$ is inhibited, causing the ${\rm Ca^{2^+}}$ concentration in the cytosol to fall. The decrease in ${\rm Ca^{2^+}}$ concentration stimulates guanylyl cyclase to replenish the cyclic GMP, rapidly returning its level to where it was before the light was switched on. A specific ${\rm Ca^{2^+}}$ -sensitive protein mediates the activation of guanylyl cyclase in response to the fall in ${\rm Ca^{2^+}}$ levels. In contrast to calmodulin, this protein is inactive when ${\rm Ca^{2^+}}$ is bound to it and active when it is ${\rm Ca^{2^+}}$ -free. It therefore stimulates the cyclase when ${\rm Ca^{2^+}}$ levels fall after a light response.

Negative feedback mechanisms do more than just return the rod to its resting state after a transient light flash; they also help the rod *adapt*, by stepping down the response when the rod is exposed to light continually. Adaptation, as we discussed earlier, allows the receptor cell to function as a sensitive detector of *changes* in stimulus intensity over an enormously wide range of baseline levels of stimulation. It is why we can see faint stars in a dark sky or a camera flash in bright sunlight.

The various heterotrimeric G proteins we have discussed in this chapter fall into four major families, as summarized in **Table 15–3**.

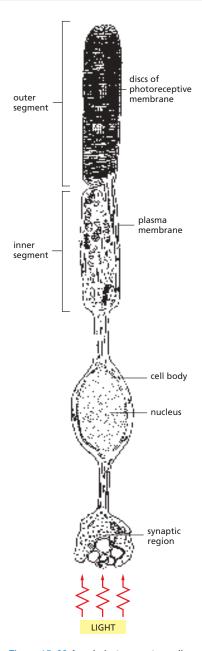

Figure 15–39 A rod photoreceptor cell. There are about 1000 discs in the outer segment. The disc membranes are not connected to the plasma membrane. The inner and outer segments are specialized parts of a *primary cilium* (discussed in Chapter 16). A primary cilium extends from the surface of most vertebrate cells, where it serves as a signaling compartment.

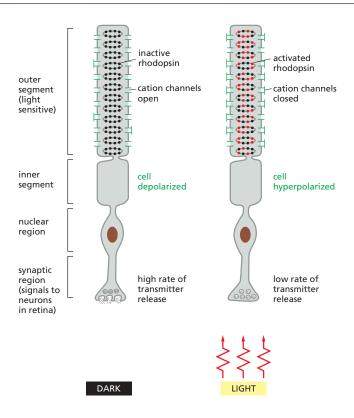

Figure 15-40 The response of a rod photoreceptor cell to light. Rhodopsin molecules in the outer-segment discs absorb photons. Photon absorption closes cation channels in the plasma membrane, which hyperpolarizes the membrane and reduces the rate of neurotransmitter release from the synaptic region. Because the neurotransmitter inhibits many of the postsynaptic retinal neurons in the absence of light, illumination serves to free the neurons from inhibition and thus, in effect, excites them. The neural connections of the retina lie between the light source and the outer segment, and so light must pass through the synapses and rod cell nucleus to reach the light sensors.

TABLE 15–3 Four Major Families of Heterotrimeric G Proteins*				
Family	Some family members	Subunits that mediate action	Some functions	
I	Gs	α	Activates adenylyl cyclase; activates Ca ²⁺ channels	
	G _{olf}	α	Activates adenylyl cyclase in olfactory sensory neurons	
II	G _i	α	Inhibits adenylyl cyclase	
		βγ	Activates K ⁺ channels	
	G _o	βγ	Activates K ⁺ channels; inactivates Ca ²⁺ channels	
		α and $\beta\gamma$	Activates phospholipase C-β	
	G _t (transducin)	α	Activates cyclic GMP phosphodiesterase in vertebrate rod photoreceptors	
III	Gq	α	Activates phospholipase C-β	
IV	G _{12/13}	α	Activates Rho family monomeric GTPases (via Rho GEF) to regulate the actin cytoskeleton	

^{*}Families are determined by amino acid sequence relatedness of the α subunits. Only selected examples are included. About 20 α subunits and at least 6 β subunits and 11 γ subunits have been described in humans.

MBOC7_ptr_ch15_873-948.indd 907 08/12/21 12:23 PM

smooth muscle cells

Nitric Oxide Gas Can Mediate Signaling Between Cells

Small signaling molecules like cyclic nucleotides and Ca^{2+} are hydrophilic small molecules that act within the cell where they are produced. Some small signaling molecules, however, are hydrophobic enough to cross the plasma membrane and thereby affect nearby cells. An important and remarkable example is the gas **nitric oxide (NO)**, which acts as a signaling molecule in many tissues of both animals and plants.

In mammals, one of NO's many functions is to relax smooth muscle in the walls of blood vessels. The neurotransmitter acetylcholine stimulates NO synthesis by activating a GPCR on the membranes of the endothelial cells that line the interior of the vessel. The activated receptor triggers IP₃ synthesis and Ca²⁺ release (see Figure 15–30), leading to stimulation of an enzyme that synthesizes NO. Because dissolved NO passes readily across membranes, it diffuses out of the cell where it is produced and into neighboring smooth muscle cells, where it causes muscle relaxation and thereby vessel dilation (Figure 15–41). It acts only locally because it has a short half-life—about 5–10 seconds—in the extracellular space before oxygen and water convert it to nitrates and nitrites.

The effect of NO on blood vessels provides an explanation for the mechanism of action of nitroglycerine, which has been used for about 100 years to treat people with angina (pain resulting from inadequate blood flow to the heart muscle). The nitroglycerine is converted to NO, which relaxes blood vessels. This reduces the workload on the heart and, as a consequence, reduces the oxygen requirement of the heart muscle.

NO is made by the deamination of the amino acid arginine, catalyzed by enzymes called **NO synthases (NOS**; see Figure 15–41). The NOS in endothelial cells is called *eNOS*, while that in nerve and muscle cells is called *nNOS*. Both eNOS and nNOS are stimulated by an increase in cytosolic Ca^{2+} . Macrophages, by contrast, make yet another NOS, called inducible NOS (*iNOS*), that is constitutively active but synthesized only when the cells are activated, usually in response to an infection.

In some target cells, including smooth muscle cells, NO binds reversibly to iron in the active site of guanylyl cyclase, stimulating synthesis of cyclic GMP. NO

basal lamina

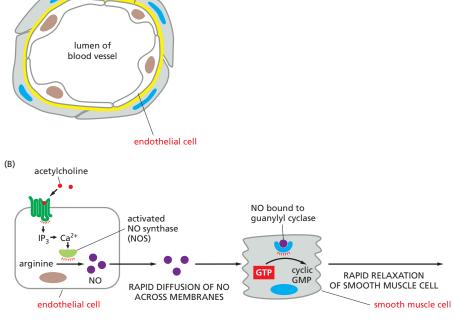

Figure 15-41 The role of nitric oxide (NO) in smooth muscle relaxation in a blood vessel wall. (A) Drawing of a cross section of a small blood vessel, showing the endothelial cells lining the lumen, the smooth muscle cells around them, and the basal lamina separating the two. (B) The neurotransmitter acetylcholine stimulates blood vessel dilation by activating a GPCR-the muscarinic acetylcholine receptor - on the surface of endothelial cells. This receptor activates a G protein, Gq, thereby stimulating IP3 synthesis and Ca2+ release from the ER by the mechanisms illustrated in Figure 15-30. Increased Ca²⁺ activates nitric oxide synthase, causing the endothelial cells to produce NO from arginine. The NO diffuses out of the endothelial cells and into the neighboring smooth muscle cells, where it activates guanylyl cyclase to produce cyclic GMP. The cyclic GMP triggers a response that causes the smooth muscle cells to relax, increasing blood flow through the vessel.

MBOC7_ptr_ch15_873-948.indd 908 08/12/21 12:23 PM

can increase cyclic GMP in the cytosol within seconds, because the normal rate of turnover of cyclic GMP is high: rapid degradation to GMP by a phosphodiesterase constantly balances the production of cyclic GMP by guanylyl cyclase. The drug Viagra and its relatives inhibit the cyclic GMP phosphodiesterase in the penis, thereby increasing the amount of time that cyclic GMP levels remain elevated in the smooth muscle cells of penile blood vessels after NO production is induced by local nerve terminals. The cyclic GMP, in turn, keeps the blood vessels relaxed and thereby the penis erect. NO can also signal cells independently of cyclic GMP. It can, for example, alter the activity of an intracellular protein by covalently nitrosylating thiol (–SH) groups on specific cysteines in the protein.

Second Messengers and Enzymatic Cascades Amplify Signals

Despite the differences in molecular details, the different intracellular signaling pathways that GPCRs trigger share certain features and general principles. They depend on relay chains of intracellular signaling proteins and second messengers. These relay chains provide numerous opportunities for amplifying the responses to extracellular signals. In the rod visual transduction cascade, for example, a single activated rhodopsin molecule catalyzes the activation of about 500 transducin molecules per second. Each activated transducin molecule activates a molecule of cyclic GMP phosphodiesterase, resulting in the hydrolysis of more than 10^5 cyclic GMP molecules. The resulting drop in the concentration of cyclic GMP in turn transiently closes hundreds of cation channels in the plasma membrane (Figure 15–42). Thus, a rod cell can respond to even a single photon of light in a way that is highly reproducible in its timing and magnitude.

Likewise, when an extracellular signal molecule binds to a receptor that indirectly activates adenylyl cyclase via G_s , each receptor protein may activate many molecules of G_s protein, each of which can activate a cyclase molecule. Each cyclase molecule, in turn, can catalyze the conversion of a large number of ATP molecules to cAMP molecules. A similar amplification operates in the IP_3 signaling pathway. In these ways, a nanomolar $(10^{-9} \, \text{M})$ change in the concentration of an extracellular signal can induce micromolar $(10^{-6} \, \text{M})$ changes in the concentration of a second messenger such as cAMP or Ca^{2+} . Because these messengers function as allosteric effectors to activate specific enzymes or ion channels, a single extracellular signal molecule can alter many thousands of protein molecules within the target cell.

In signaling systems like those involved in smell and vision, any amplifying cascade of stimulatory signals requires counterbalancing mechanisms at every step of the cascade to restore the system to its resting state when stimulation ceases. As emphasized earlier, the response to stimulation in these systems can be rapid only if the inactivating mechanisms are also rapid. Cells therefore have efficient mechanisms for rapidly degrading (and resynthesizing) cyclic nucleotides and for buffering and removing cytosolic ${\rm Ca^{2+}}$, as well as for inactivating the responding enzymes and ion channels once they have been activated. This is not only essential for turning a response off but is also important for establishing the resting state from which a response begins.

Each protein in the signaling relay chain can be a separate target for regulation, including the receptor itself, as we discuss next.

GPCR Desensitization Depends on Receptor Phosphorylation

As discussed earlier, when target cells are exposed to an extracellular signal for a prolonged period, they can become *desensitized*, or *adapted*, in several different ways. An important class of adaptation mechanisms depends on alteration of the quantity or condition of the receptor molecules themselves.

For GPCRs, there are three general modes of adaptation, all centered on inactivation of the receptor (see Figure 15–21C, D, and E): (1) In *receptor inactivation*, they become altered so that they can no longer interact with G proteins. (2) In *receptor sequestration*, they are temporarily moved to the interior of the cell

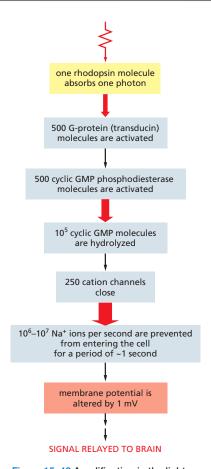

Figure 15–42 Amplification in the light-induced catalytic cascade in vertebrate rods. The *red arrows* indicate the steps where amplification occurs, with the thickness of the arrow roughly indicating the magnitude of the amplification.

MBOC7_ptr_ch15_873-948.indd 909 08/12/21 12:23 PM

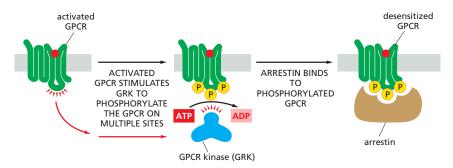

Figure 15–43 The roles of GPCR kinases (GRKs) and arrestins in GPCR desensitization. A GRK phosphorylates only activated receptors because it is the activated GPCR that turns on the GRK. The binding of an arrestin to the phosphorylated receptor prevents the receptor from binding to its G protein and also directs its endocytosis (not shown). Mice deficient in one form of arrestin fail to desensitize in response to morphine, for example, attesting to the importance of arrestins for desensitization.

(internalized) so that they no longer have access to their ligand. (3) In *receptor destruction*, they are destroyed in lysosomes after internalization. In each case, the desensitization of the GPCRs depends on their phosphorylation by PKA, PKC, or a member of the family of GPCR kinases (GRKs), which includes the rhodopsin kinase involved in rod photoreceptor desensitization discussed earlier. The GRKs phosphorylate multiple serines and threonines on a GPCR, but they do so only after ligand binding has activated the receptor, because it is the activated receptor that allosterically activates the GRK. As with rhodopsin, once a receptor has been phosphorylated by a GRK, it binds with high affinity to a member of the arrestin family of proteins (Figure 15–43).

The bound arrestin can contribute to the desensitization process in at least two ways. First, it prevents the activated receptor from interacting with G proteins. Second, it serves as an adaptor protein to help couple the receptor to the clathrin-dependent endocytosis machinery (discussed in Chapter 13), inducing receptor-mediated endocytosis. The fate of the internalized GPCR-arrestin complex depends on other proteins in the complex. In some cases, the internalized receptor is dephosphorylated and recycled back to the plasma membrane for reuse; in others, it is degraded in lysosomes.

Receptor endocytosis does not necessarily stop the receptor from signaling. In some cases, the bound arrestin recruits other signaling proteins to relay the signal onward from the internalized GPCRs along new pathways.

Summary

GPCRs can indirectly activate or inactivate either plasma-membrane-bound enzymes or ion channels via G proteins. When an activated receptor stimulates a G protein, the G protein undergoes a conformational change that activates its α subunit, thereby triggering release of a $\beta\gamma$ complex. Either component can then directly regulate the activity of target proteins in the plasma membrane. Some GPCRs either activate or inactivate adenylyl cyclase, thereby altering the intracellular concentration of the second messenger cyclic AMP. Others activate a phosphoinositide-specific phospholipase C (PLC β), which generates two second messengers. One is inositol 1,4,5-trisphosphate (IP $_3$), which releases Ca $^{2+}$ from the ER and thereby increases the concentration of Ca $^{2+}$ in the cytosol. The other is diacylglycerol, which remains in the plasma membrane and helps activate protein kinase C (PKC). An increase in cytosolic cyclic AMP or Ca $^{2+}$ levels affects cells mainly by stimulating cAMP-dependent protein kinase (PKA) and Ca $^{2+}$ /calmodulin-dependent kinases (CaM-kinases), respectively.

PKC, PKA, and CaM-kinases phosphorylate specific target proteins and thereby alter the activity of the proteins. Each type of cell has its own characteristic set of target proteins that is regulated in these ways, enabling the cell to make its own

MBOC7_ptr_ch15_873-948.indd 910 08/12/21 12:23 PM

distinctive response to the second messengers. The intracellular signaling cascades activated by GPCRs greatly amplify the responses, so that many thousands of target protein molecules are changed for each molecule of extracellular signaling ligand bound to its receptor. The responses mediated by GPCRs are rapidly turned off when the extracellular signal is removed, and activated GPCRs are inactivated by phosphorylation and association with arrestins.

SIGNALING THROUGH ENZYME-COUPLED RECEPTORS

Like GPCRs, enzyme-coupled receptors are transmembrane proteins with their ligand-binding domain on the outer surface of the plasma membrane. Instead of having a cytosolic domain that associates with a heterotrimeric G protein, however, their cytosolic domain either has intrinsic enzyme activity or associates directly with an enzyme. Whereas a GPCR has seven transmembrane segments, each subunit of an enzyme-coupled receptor typically has only one. GPCRs and enzyme-coupled receptors often activate some of the same signaling pathways. In this section, we describe some of the important features of signaling by enzyme-coupled receptors, with an emphasis on the most common class of these proteins, the receptor tyrosine kinases.

Activated Receptor Tyrosine Kinases (RTKs) Phosphorylate Themselves

Many extracellular signal proteins act through **receptor tyrosine kinases (RTKs)**. These include many secreted and cell-surface-bound proteins that control cell behavior in developing and adult animals. Some of these signal proteins and their RTKs are listed in **Table 15-4**.

There are about 60 human RTKs, which can be classified into about 20 structural subfamilies, each dedicated to its complementary family of protein ligands. Figure 15–44 shows the basic structural features of a number of the families that operate in mammals. In all cases, the binding of the signal protein to the ligand-binding domain on the extracellular side of the receptor activates the tyrosine kinase domain on the cytosolic side. This leads to phosphorylation of tyrosine

TABLE 15-4 Some Extracellular Signal Proteins That Act Via RTKs				
Signal protein family	Receptor family	Some representative responses		
Epidermal growth factor (EGF)	EGF receptors	Stimulates cell survival, growth, proliferation, or differentiation of various cell types; acts as inductive signal in development		
Insulin	Insulin receptor	Stimulates carbohydrate utilization and protein synthesis		
Insulin-like growth factor (IGF1)	IGF receptor-1	Stimulates cell growth and survival in many cell types		
Nerve growth factor (NGF)	Trk receptors	Stimulates survival and growth of some neurons		
Platelet-derived growth factor (PDGF)	PDGF receptors	Stimulates survival, growth, proliferation, and migration of various cell types		
Macrophage-colony-stimulating factor (MCSF)	MCSF receptor	Stimulates monocyte/macrophage proliferation and differentiation		
Fibroblast growth factor (FGF)	FGF receptors	Stimulates proliferation of various cell types; inhibits differentiation of some precursor cells; acts as inductive signal in development		
Vascular endothelial growth factor (VEGF)	VEGF receptors	Stimulates angiogenesis		
Ephrin	Eph receptors	Stimulates angiogenesis; guides cell and axon migration		

MBOC7_ptr_ch15_873-948.indd 911 08/12/21 12:23 PM

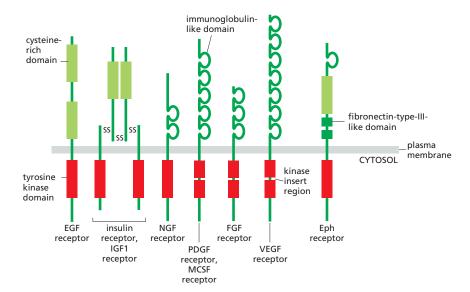

Figure 15–44 Some subfamilies of RTKs. Only one or two members of each subfamily are indicated. Note that in some cases, the tyrosine kinase domain is interrupted by a kinase insert region that is an extra segment emerging from the folded kinase domain. The functions of most of the cysteine-rich, immunoglobulin-like, and fibronectin-type-III-like domains are not known. Some of the ligands for the receptors shown are listed in Table 15–4, along with some representative responses that they mediate.

side chains on the cytosolic part of the receptor, creating phosphotyrosine docking sites for various intracellular signaling proteins that relay the signal.

How does the binding of an extracellular ligand activate the kinase domain on the other side of the plasma membrane? For a GPCR, ligand binding is thought to change the relative orientation of several of the transmembrane α helices, thereby shifting the position of the cytoplasmic loops relative to one another. It is unlikely, however, that a conformational change could propagate across the lipid bilayer through a single transmembrane α helix. Instead, the mechanism of RTK activation depends on ligand-stimulated changes in the interaction of two receptors, bringing the two cytoplasmic kinase domains together and thereby promoting their activation (Figure 15–45).

The cytoplasmic kinase domains of RTKs are dimerized and activated by a variety of mechanisms. In many cases, such as the receptor for *platelet-derived growth*

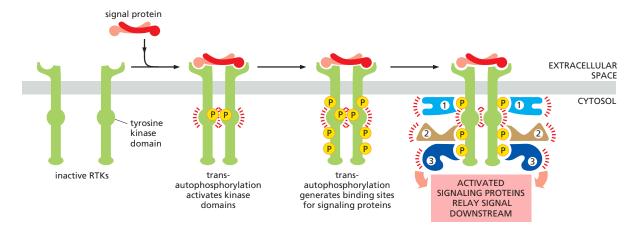

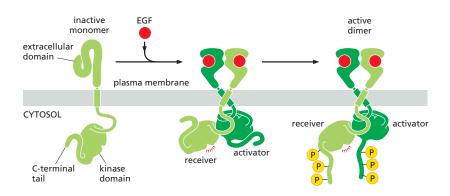

Figure 15–45 Activation of RTKs by dimerization. In the absence of extracellular signals, many RTKs exist as monomers in which the internal kinase domain is inactive. Binding of ligand brings two monomers together to form a dimer. The close proximity in the dimer leads the two kinase domains to phosphorylate each other, which has two effects. First, phosphorylation at some tyrosines in the kinase domains promotes the complete activation of the domains. Second, phosphorylation at tyrosines in other parts of the receptors generates docking sites for intracellular signaling proteins, resulting in the formation of large signaling complexes that can then broadcast signals along multiple signaling pathways.

Mechanisms of activation vary widely among different RTK family members. In some cases (as shown here), the ligand itself is a dimer and brings two receptors together by binding them simultaneously. In other cases, two ligands can bind independently on two receptors to promote receptor dimerization. Some RTKs exist normally as a dimer (see Figure 15–44), and ligand binding causes a conformational change that brings the two internal kinase domains closer together. Although many RTKs are activated by transautophosphorylation as shown here, there are some important exceptions, including the EGF receptor illustrated in Figure 15–46.

MBOC7_ptr_ch15_873-948.indd 912 08/12/21 12:23 PM

factor (PDGF), dimerization of the external receptor domain simply brings two kinase domains close to each other in a stable orientation that allows them to phosphorylate each other on specific tyrosines in the kinase active sites, thereby promoting conformational changes that fully activate both kinase domains. Some RTKs, including the insulin receptor, exist as dimers in the absence of ligand (see Figure 15–44), and ligand binding re-orients the extracellular domains to bring the internal kinase domains into a closer position to promote kinase activation. In other cases, such as the receptor for *epidermal growth factor* (*EGF*), the kinase is not activated by phosphorylation but by conformational changes brought about by interactions between the two kinase domains outside their active sites (**Figure 15–46**).

Phosphorylated Tyrosines on RTKs Serve as Docking Sites for Intracellular Signaling Proteins

Once the kinase domains of an RTK dimer are activated, they phosphorylate multiple additional sites in the cytosolic parts of the receptors, typically in disordered regions outside the kinase domain (see Figure 15–45). This phosphorylation creates high-affinity docking sites for specific intracellular signaling proteins. Each signaling protein binds to a particular phosphorylated site on the activated receptors because it contains a specific phosphotyrosine-binding domain that recognizes surrounding features of the polypeptide chain in addition to the phosphotyrosine.

Once bound to the activated RTK, a signaling protein may become phosphorylated on tyrosines and thereby activated. In many cases, however, the binding alone may be sufficient to activate the docked signaling protein, by either inducing a conformational change in the protein or simply bringing it near the protein that is next in the signaling pathway. Thus, receptor phosphorylation serves as a switch to trigger the assembly of an intracellular signaling complex, which can then relay the signal onward, often along multiple routes, to various destinations in the cell. Because different RTKs bind different combinations of these signaling proteins, they activate different responses.

Some RTKs use additional docking proteins to enlarge the signaling complex at activated receptors. Insulin receptor signaling, for example, depends on a specialized adaptor protein called *insulin receptor substrate-1* (*IRS1*). IRS1 binds to specific phosphorylated tyrosines on the activated receptor and is then phosphorylated at multiple sites, thereby creating many more docking sites than could be accommodated on the receptor alone (see Figure 15–11).

Proteins with SH2 Domains Bind to Phosphorylated Tyrosines

A whole menagerie of intracellular signaling proteins can bind to the phosphotyrosines on activated RTKs (or on docking proteins such as IRS1). They help to relay the signal onward, mainly through chains of protein-protein interactions mediated by modular interaction domains, as discussed earlier (see Figure 15-11). Some of the docked proteins are enzymes, such as **phospholipase C-\gamma (PLC\gamma)**, which functions in the same way as phospholipase C- β —activating the inositol

Figure 15-46 Activation of the EGF receptor kinase. In the absence of ligand, the EGF receptor exists primarily as an inactive monomer. EGF binding results in a conformational change that promotes dimerization of the external domains. The receptor kinase domain, unlike that of many RTKs, is not activated by transautophosphorylation. Instead, dimerization orients the internal kinase domains into an asymmetrical dimer, in which one kinase domain (the activator) pushes against the other kinase domain (the receiver), thereby causing an activating conformational change in the receiver. The active receiver domain then phosphorylates multiple tyrosines in the C-terminal tails of both receptors, generating docking sites for intracellular signaling proteins (see Figure 15-45).

Note that protein kinase activity is generated only in the receiver kinase domain; the activator kinase domain remains in an inactive conformation. In fact, some members of the EGF receptor family contain kinase domains that are missing key residues in their active site and are therefore inactive. These pseudokinase receptors can still dimerize with and activate EGF receptors containing an active kinase receiver domain.

MBOC7_ptr_ch15_873-948.indd 913 08/12/21 12:23 PM

phospholipid signaling pathway discussed earlier in connection with GPCRs (see Figures 15–29 and 15–30). Through this pathway, RTKs can increase cytosolic Ca²⁺ levels and activate PKC. Another enzyme that docks on these receptors is the cytoplasmic tyrosine kinase *Src*, which phosphorylates other signaling proteins on tyrosines (discussed in Chapter 3). Yet another is *phosphoinositide 3-kinase* (*PI 3-kinase*), which phosphorylates lipids rather than proteins; as we discuss later, the phosphorylated lipids then serve as docking sites to attract various signaling proteins to the plasma membrane.

The intracellular signaling proteins that bind to phosphotyrosines have varied structures and functions. However, they usually share highly conserved phosphotyrosine-binding domains, which can be either **SH2 domains** (for *Src homology 2*) or, less commonly, *PTB domains* (for *phosphotyrosine-binding*). By recognizing specific phosphorylated tyrosines, these small interaction domains enable the proteins that contain them to bind to activated RTKs, as well as to many other intracellular signaling proteins that have been transiently phosphorylated on tyrosines (**Figure 15–47**). Many signaling proteins also contain other interaction domains that allow them to interact specifically with other proteins as part of the signaling process. These domains include the *SH3 domain*, which binds to proline-rich motifs in intracellular proteins (see Figures 15–11 and 15–12).

Not all proteins that bind to activated RTKs via SH2 domains help to relay the signal onward. Some act to decrease the signaling process, providing negative feedback. One example is the *c-Cbl protein*, which can dock on some activated receptors and catalyze their ubiquitylation, covalently adding one or more ubiquitin molecules to specific sites on the receptor. This promotes the endocytosis and degradation of the receptors in lysosomes—an example of receptor destruction (see Figure 15–21E). Endocytic proteins that contain *ubiquitin-interaction motifs*

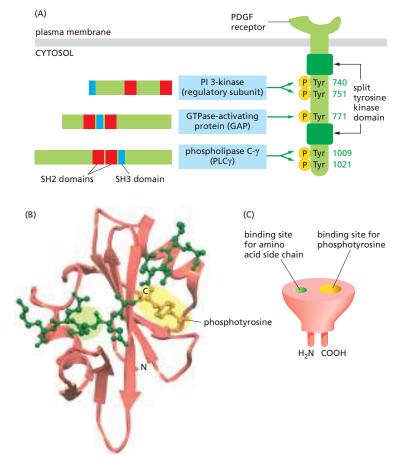

Figure 15–47 The binding of SH2containing intracellular signaling proteins to an activated RTK.

(A) Drawing based on an activated receptor for platelet-derived growth factor (PDGF); for simplicity, only one monomer of the dimer is shown, and the PDGF ligand is omitted. Five phosphotyrosines are shown, three in the kinase insert region and two on the C-terminal tail: these form three docking sites, each of which binds a different signaling protein as indicated. The numbers on the right indicate the positions of the tyrosines in the polypeptide chain. The functions of these phosphotyrosines were determined by mutation of specific tyrosines. Mutation of tyrosines 1009 and 1021, for example, prevents the binding and activation of PLC γ , so that receptor activation no longer stimulates the inositol phospholipid signaling pathway. The locations of the SH2 (red) and SH3 (blue) domains in the primary structures of the three signaling proteins are indicated. Additional phosphotyrosine docking sites on this receptor are not shown, including those that bind the cytoplasmic tyrosine kinase Src and two adaptor proteins. It is unclear how many signaling proteins can bind simultaneously to a single RTK. (B) The three-dimensional structure of an SH2 domain, as determined by x-ray crystallography. The binding pocket for phosphotyrosine is shaded in yellow on the right, and a pocket for binding a specific amino acid side chain (valine, in this case) is shaded in green on the left. The RTK polypeptide segment that binds the SH2 domain is shown in green. (C) The SH2 domain is a compact, "plug-in" module, which can be inserted in disordered regions of a protein without disturbing the protein's folding or function (discussed in Chapter 3). Because each domain has distinct sites for recognizing phosphotyrosine and for recognizing a particular amino acid side chain, different SH2 domains recognize phosphotyrosine in the context of different flanking amino acid sequences. (B, PDB code: 2SRC.)

MBOC7_ptr_ch15_873-948.indd 914 08/12/21 12:23 PM

(*UIMs*) recognize the ubiquitylated RTKs and direct them into clathrin-coated vesicles and, ultimately, into lysosomes (discussed in Chapter 13). Mutations that inactivate c-Cbl-dependent RTK down-regulation cause prolonged RTK signaling and thereby promote the development of cancer.

As is the case for GPCRs, ligand-induced endocytosis of RTKs does not always decrease signaling. In some cases, activated RTKs are endocytosed with their bound signaling proteins and continue to signal from endosomes or other intracellular compartments. This mechanism, for example, allows *nerve growth factor* (*NGF*) to bind to its specific RTK (called TrkA) at the end of a long nerve cell axon and signal to the cell body of the same cell a long distance away. The signaling endocytic vesicles containing activated TrkA, with NGF bound on the lumenal side and signaling proteins docked on the cytosolic side, are transported along the axon to the cell body, where they signal the cell to survive.

Some signaling proteins are composed almost entirely of SH2 and SH3 domains and function as *adaptors* to couple tyrosine-phosphorylated proteins to other proteins that do not have their own SH2 domains (see Figures 15–11 and 15–12). Adaptor proteins of this type help to couple activated RTKs to the important signaling protein *Ras*, a monomeric GTPase that, in turn, can activate various downstream signaling pathways, as we now discuss.

The Monomeric GTPase Ras Mediates Signaling by Most RTKs

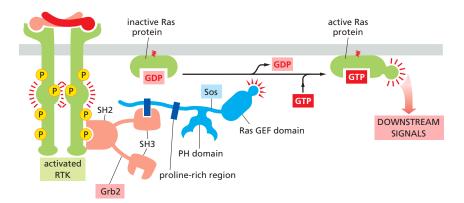

The **Ras superfamily** consists of various families of monomeric GTPases, but only the Ras and Rho families relay signals from cell-surface receptors (**Table 15–5**). By interacting with different intracellular signaling proteins, a single Ras or Rho family member can coordinately spread the signal along several distinct downstream signaling pathways.

There are three major, closely related Ras proteins in humans: H-, K-, and N-Ras (see Table 15–5). Although they have subtly different functions, they are thought to work in the same way, and we will refer to them simply as **Ras**. Like many monomeric GTPases, Ras contains one or more covalently attached lipid groups that help anchor the protein to the cytoplasmic face of the plasma membrane, from where it relays signals to other parts of the cell. Ras is often required, for example, when RTKs signal to the nucleus to stimulate cell proliferation or differentiation, both of which require changes in gene expression. If Ras function is inhibited by various experimental approaches, the cell proliferation or differentiation responses normally induced by the activated RTKs do not occur. Conversely,

TABLE 15–5 The Ras Superfamily of Monomeric GTPases			
Family	Some family members	Some functions	
Ras	H-Ras, K-Ras, N-Ras	Relay signals from RTKs	
	Rheb	Activates mTOR to stimulate cell growth	
	Rap1	Activated by a cyclic-AMP-dependent GEF; influences cell adhesion by activating integrins	
Rho*	Rho, Rac, Cdc42	Relay signals from surface receptors to the cytoskeleton and elsewhere	
ARF*	ARF1-ARF6	Regulate assembly of protein coats on intracellular vesicles	
Rab*	Rab1-60	Regulate intracellular vesicle traffic	
Ran*	Ran	Regulates mitotic spindle assembly and nuclear transport of RNAs and proteins	
*The Rho family is discussed in Chanter 16, the ARE and Rah proteins in Chanter 13, and Ran			

*The Rho family is discussed in Chapter 16, the ARF and Rab proteins in Chapter 13, and Ran in Chapters 12 and 17. The three-dimensional structure of Ras is shown in Figure 3–64.

MBOC7_ptr_ch15_873-948.indd 915 08/12/21 12:23 PM

a specific phosphorylated tyrosine on the activated receptor by means of an SH2 domain and recruits the Ras GEF Sos by means of an interaction between its

Ras. The Grb2 adaptor protein recognizes

Figure 15-48 How an RTK activates

SH3 domains and proline-rich regions in Sos. Sos also contains a PH domain that recognizes specific phospholipids but is not used here (see Figure 15-11). The Ras GEF domain of Sos stimulates the inactive Ras protein to replace its bound GDP by GTP, which activates Ras to relay the signal downstream.

30% of human tumors express hyperactive mutant forms of Ras, which contribute to the uncontrolled proliferation of the cancer cells.

Like other GTP-binding proteins, Ras functions as a molecular switch, cycling between two distinct conformational states-active when GTP is bound and inactive when GDP is bound (Movie 15.7). As discussed earlier for monomeric GTPases in general, two classes of signaling proteins regulate Ras activity by influencing its transition between active and inactive states (see Figure 15-8). Ras guanine nucleotide exchange factors (Ras GEFs) stimulate the dissociation of GDP and the subsequent binding of GTP from the cytosol, thereby activating Ras. Ras GTPase-activating proteins (Ras GAPs) increase the rate of hydrolysis of bound GTP by Ras, thereby inactivating Ras. Hyperactive mutant forms of Ras are resistant to Ras GAPs and are therefore locked in the GTP-bound active state, which is why they promote the development of cancer.

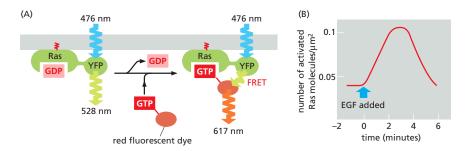

How do RTKs normally activate Ras? In principle, they could either activate a Ras GEF or inhibit a Ras GAP. Even though some GAPs bind directly (via their SH2 domains) to activated RTKs (see Figure 15-47A), it is the indirect coupling of the activated receptor to a Ras GEF that drives Ras into its active state. The loss of function of a Ras GEF has a similar effect to the loss of function of Ras itself. Activation of the other Ras superfamily proteins, including those of the Rho family, also occurs through the activation of GEFs. The particular GEF determines in which membrane the GTPase is activated, and, by acting as a scaffold, it can also determine which downstream proteins the GTPase activates.

The GEF that mediates Ras activation by RTKs was discovered by genetic studies of eye development in Drosophila, where an RTK called Sevenless (Sev) is required for the formation of a photoreceptor cell called R7. Genetic screens for components of this signaling pathway led to the discovery of a Ras GEF called Son-of-sevenless (Sos). Further genetic screens uncovered another protein, now called Grb2, which is an adaptor protein that links the Sev receptor to the Sos protein; the SH2 domain of the Grb2 adaptor binds to the activated receptor, while one or both of its SH3 domains bind to Sos. Sos then promotes Ras activation. Biochemical and cell biological studies have shown that Grb2 and Sos also link activated RTKs to Ras in mammalian cells, revealing that this mechanism in RTK signaling has been highly conserved in evolution (Figure 15-48). Once activated, Ras activates various other signaling proteins to relay the signal downstream.

Ras Activates a MAP Kinase Signaling Module

Both the tyrosine phosphorylations and the activation of Ras triggered by activated RTKs are usually short-lived (Figure 15-49). Tyrosine-specific protein phosphatases reverse the phosphorylations, and Ras GAPs induce activated Ras to inactivate itself by hydrolyzing its bound GTP to GDP. To stimulate cells to proliferate or differentiate, these short-lived signaling events must be converted into longer-lasting ones that can sustain the signal and relay it downstream to the nucleus to alter the pattern of gene expression. One of the key mechanisms used for this purpose is a system of proteins called the mitogen-activated protein kinase

MBOC7 ptr ch15 873-948.indd 916 08/12/21 12:23 PM

module (MAP kinase module) (Figure 15–50). The three components of this system form a functional signaling module that has been remarkably well conserved during evolution and is used, with variations, in many different signaling contexts.

The three components are all protein kinases, which mainly phosphory-late serines and threonines. The final kinase in the series is called simply MAP kinase (MAPK). The next one upstream from this is MAP kinase kinase (MAPKK): it phosphorylates and thereby activates MAP kinase. Next above that, receiving an activating signal directly from Ras, is MAP kinase kinase kinase (MAPKKK): it phosphorylates and thereby activates MAPKK. In the mammalian **Ras-MAP-kinase signaling pathway**, these three kinases are known by shorter names: Raf (= MAPKKK), Mek (= MAPKK), and Erk (= MAPKK).

Once activated, the MAP kinase relays the signal downstream by phosphorylating various proteins in the cell, including transcription regulators and other protein kinases (see Figure 15–50). Erk, for example, enters the nucleus and phosphorylates one or more components of a transcription regulatory complex. This activates the transcription of a set of *immediate early genes*, so named because they turn on within minutes after an RTK receives an extracellular signal, even if protein synthesis is experimentally blocked with drugs. Some of these genes encode other transcription regulators that turn on other genes, a process that requires both protein synthesis and more time. In this way, the Ras–MAP-kinase signaling pathway conveys signals from the cell surface to the nucleus and alters the pattern of gene expression. Among the genes activated by this pathway are some that stimulate cell proliferation, such as the genes encoding G_1 cyclins (discussed in Chapter 17).

MAP kinase activation lasts for different amounts of time, depending on the extracellular signal. When EGF activates its receptors in a neural precursor cell line, for example, Erk MAP kinase activity peaks at 5 minutes and rapidly declines,

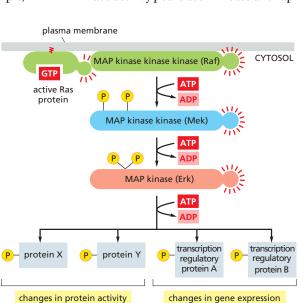

Figure 15-49 Transient activation of Ras revealed by single-molecule fluorescence resonance energy transfer (FRET). (A) Schematic drawing of the experimental strategy. Cells of a human cancer cell line were genetically engineered to express a Ras protein that was covalently linked to yellow fluorescent protein (YFP). GTP that was labeled with a red fluorescent dve was microiniected into some of the cells. The cells were then stimulated with the extracellular signal protein EGF, and single fluorescent molecules of Ras-YFP at the inner surface of the plasma membrane were measured by video fluorescence microscopy in individual cells. When a fluorescent Ras-YFP molecule becomes activated, it exchanges unlabeled GDP for fluorescently labeled GTP; the energy emitted by the YFP now activates the fluorescent GTP to emit red light (called fluorescence resonance energy transfer, or FRET; see Figure 9-22). Thus, the activation of single Ras molecules can be followed by the emission of red fluorescence from a previously yellow-green fluorescent spot at the plasma membrane. As shown in (B), activated Ras molecules could be detected after about 30 seconds of EGF stimulation. The red signal peaked at about 3 minutes and then decreased to baseline by 6 minutes. As Ras GAP was found to be recruited to the same spots at the plasma membrane as Ras, it presumably plays a major part in rapidly shutting off the Ras signal. (Modified from H. Murakoshi et al., Proc. Natl. Acad. Sci. USA 101:7317-7322, 2004. Copyright 2004 National Academy of Sciences, USA. With permission from National Academy of Sciences.)

Figure 15–50 The MAP kinase module activated by Ras. The three-component module begins with a MAP kinase kinase kinase called *Raf.* Ras recruits Raf to the plasma membrane and helps activate it. Raf then activates the MAP kinase kinase *Mek*, which then activates the MAP kinase *Erk.* Erk in turn phosphorylates a variety of downstream proteins, including other protein kinases, as well as transcription regulators in the nucleus. The resulting changes in protein activities and gene expression cause complex changes in cell behavior (Movie 15.8).

MBOC7_ptr_ch15_873-948.indd 917 08/12/21 12:23 PM

and the cells later go on to divide. By contrast, when NGF activates its receptors on the same cells, Erk activity remains high for many hours, and the cells stop proliferating and differentiate into neurons.

Many intracellular mechanisms influence the duration and other features of the signaling response, including positive and negative feedback loops, which can combine to give responses that are either graded or switchlike and either brief or long lasting. In an example illustrated earlier, in Figure 15–20, MAP kinase activates a complex positive feedback loop to produce an all-or-none, irreversible response when frog oocytes are stimulated to mature by a brief exposure to the hormone progesterone. In many cells, MAP kinases activate a negative feedback loop by increasing the concentration of a protein phosphatase that removes the phosphates from MAP kinase. The increase in the phosphatase results from both an increase in the transcription of the phosphatase gene and the stabilization of the phosphatase protein against degradation. In the Ras–MAP-kinase pathway shown in Figure 15–50, Erk also phosphorylates and inactivates Raf, providing another negative feedback loop that helps shut off the MAP kinase module.

Scaffold Proteins Reduce Cross-Talk Between Different MAP Kinase Modules

Three-component MAP kinase signaling modules operate in all eukaryotic cells, with different modules mediating different responses in the same cell. In budding yeast, for example, one MAP kinase module mediates the response to mating pheromone, another the response to starvation, and yet another the response to osmotic shock. Some of these MAP kinase modules use one or more of the same kinases and yet manage to activate different downstream proteins and hence different responses. As discussed earlier, one way in which cells avoid cross-talk between the different parallel signaling pathways and ensure that each response is specific is to use scaffold proteins (see Figure 15–10A). In budding yeast cells, such scaffolds bind all or some of the kinases in each MAP kinase module to form a complex and thereby help to ensure response specificity (Figure 15–51).

Mammalian cells also use this scaffold strategy to prevent cross-talk between different MAP kinase modules. At least five parallel MAP kinase modules can operate in a mammalian cell. These modules make use of at least 12 MAP kinases, 7 MAPKKs, and 7 MAPKKKs. Two of these modules (terminating in MAP kinases called JNK and p38) are activated by different kinds of cell stresses, such as ultraviolet (UV) irradiation, heat shock, and osmotic stress; others mediate responses to signals from other cells.

Although the scaffold strategy provides precision and avoids cross-talk, it reduces the opportunities for amplification and spreading of the signal to different parts of the cell, which require at least some of the components to be diffusible. It

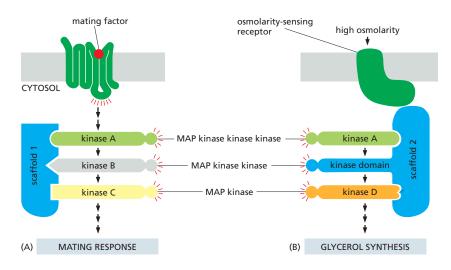

Figure 15-51 The organization of two MAP kinase modules by scaffold proteins in budding yeast. Budding veast have at least six three-component MAP kinase modules involved in a variety of biological processes, including the two responses illustrated here—a mating response and the response to high osmolarity. (A) The mating response is triggered when a mating factor secreted by a yeast of opposite mating type binds to a GPCR. This activates a G protein, the βγ complex of which indirectly activates the MAPKKK (kinase A), which then relays the response onward. Once activated, the MAP kinase (kinase C) phosphorylates and thereby activates several downstream proteins that mediate the mating response, in which the yeast cell stops dividing and prepares for fusion. The three kinases in this module are bound to scaffold protein 1. (B) In a second response, a yeast cell exposed to a high-osmolarity environment is induced to synthesize glycerol to increase its internal osmolarity. This response is mediated by an osmolarity-sensing receptor protein and a different MAP kinase module bound to a second scaffold protein. (Note that the kinase domain of scaffold 2 provides the MAPKK activity of this module.) Although both pathways use the same MAPKKK (kinase A, green), there is no cross-talk between them because the kinases in each module are bound to different scaffold proteins, and the osmolarity-sensing receptor is bound to the same scaffold protein as the particular kinase it activates.

MBOC7_ptr_ch15_873-948.indd 918 08/12/21 12:23 PM

is unclear to what extent the individual components of MAP kinase modules can dissociate from the scaffold during the activation process to permit amplification.

Rho Family GTPases Functionally Couple Cell-Surface Receptors to the Cytoskeleton

Besides the Ras proteins, the other class of Ras superfamily GTPases that relays signals from cell-surface receptors is the large **Rho family** (see Table 15–5). Rho family monomeric GTPases regulate both the actin and microtubule cytoskeletons, controlling cell shape, polarity, motility, and adhesion (discussed in Chapter 16); they also regulate cell-cycle progression, gene transcription, and membrane transport. They play a key part in the guidance of cell migration and nerve axon outgrowth, mediating cytoskeletal responses to the activation of a special class of guidance receptors. We focus on this aspect of Rho family function here.

The three best-characterized family members are **Rho** itself, **Rac**, and **Cdc42**, each of which affects multiple downstream target proteins. In the same way as for Ras, GEFs activate and GAPs inactivate the Rho family GTPases; there are more than 80 Rho GEFs and more than 70 Rho GAPs in humans. Some of the GEFs and GAPs are specific for one particular family member, whereas others are less specific. Unlike Ras, which is membrane-associated even when inactive (with GDP bound), inactive Rho family GTPases are often bound to *guanine nucleotide dissociation inhibitors* (*GDIs*) in the cytosol, which prevent the GTPases from interacting with their Rho GEFs at the plasma membrane.

Signaling by extracellular signaling proteins of the **ephrin** family provides an example of how RTKs can activate a Rho GTPase. Ephrins bind and thereby activate members of the *Eph* family of RTKs (see Figure 15–44). One member of the Eph family is found on the surface of motor neurons and helps guide the migrating tip of the axon (called a *growth cone*) to its muscle target. The binding of a cell-surface *ephrin* protein activates the Eph receptor, causing the growth cones to collapse, thereby repelling them from inappropriate paths and keeping them on track. The response depends on a Rho GEF called *ephexin*, which is stably associated with the cytosolic tail of the Eph receptor. When ephrin binding activates the Eph receptor, the receptor activates a cytoplasmic tyrosine kinase that phosphorylates ephexin on a tyrosine, enhancing the ability of ephexin to activate the Rho protein RhoA. The activated RhoA (RhoA-GTP) then regulates various downstream target proteins, including some effector proteins that control the actin cytoskeleton, causing the growth cone to collapse (**Figure 15–52**).

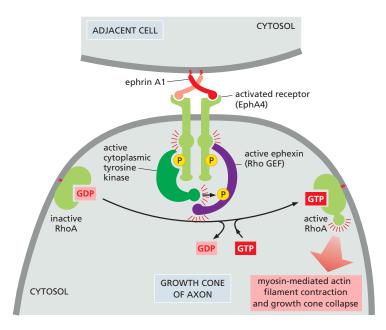

Figure 15–52 Growth cone collapse mediated by the Rho family GTPase RhoA. The binding of ephrin A1 proteins on an adjacent cell activates EphA4 RTKs on the growth cone. The resulting phosphotyrosines on the activated Eph receptors recruit and activate a cytoplasmic tyrosine kinase to phosphorylate the receptor-associated Rho GEF ephexin on a tyrosine. This enhances the ability of the ephexin to activate membrane-bound RhoA, which stimulates the myosin-dependent contraction of the actin cytoskeleton, thereby causing the growth cone to collapse.

MBOC7_ptr_ch15_873-948.indd 919 08/12/21 12:23 PM

Having considered how RTKs use GEFs and monomeric GTPases to relay signals into the cell, we now consider a second major RTK signaling strategy that depends on a different intracellular relay mechanism.

PI 3-Kinase Produces Lipid Docking Sites in the Plasma Membrane

As mentioned earlier (see Figure 15–47A), one of the proteins that binds to the intracellular tail of RTK molecules is the plasma-membrane-bound enzyme **phosphoinositide 3-kinase (PI 3-kinase)**. This kinase principally phosphorylates inositol phospholipids rather than proteins, and both RTKs and GPCRs can activate it. It plays a central part in promoting cell survival and growth.

Phosphatidylinositol (PI) is unusual among membrane lipids because it can undergo reversible phosphorylation at multiple sites on its inositol head group to generate a variety of phosphorylated PI lipids called **phosphoinositides**. When activated, PI 3-kinase catalyzes phosphorylation at the 3 position of the inositol ring to generate several phosphoinositides (**Figure 15–53**). The production of $PI(3,4,5)P_3$ matters most because it can serve as a docking site for various intracellular signaling proteins, which assemble into signaling complexes that relay the signal into the cell from the cytosolic face of the plasma membrane (see Figure 15–10C).

Notice the difference between this use of phosphoinositides and their use described earlier, in which PI(4,5)P₂ is cleaved by PLC β (in the case of GPCRs) or PLC γ (in the case of RTKs) to generate soluble IP₃ and membrane-bound diacylglycerol (see Figures 15–29 and 15–30). By contrast, PI(3,4,5)P₃ is not cleaved by either PLC. It is made from PI(4,5)P₂ and then remains in the plasma membrane until specific *phosphoinositide phosphatases* dephosphorylate it. Prominent among these is the *PTEN* phosphatase, which dephosphorylates the 3 position of the inositol ring. Mutations in PTEN are found in many cancers: by prolonging signaling by PI 3-kinase, they promote uncontrolled cell growth.

There are various types of PI 3-kinases. Those activated by RTKs and GPCRs belong to class I. These are heterodimers composed of a common catalytic subunit and different regulatory subunits. RTKs activate *class Ia PI 3-kinases*, in which the regulatory subunit is an adaptor protein that binds to two phosphotyrosines

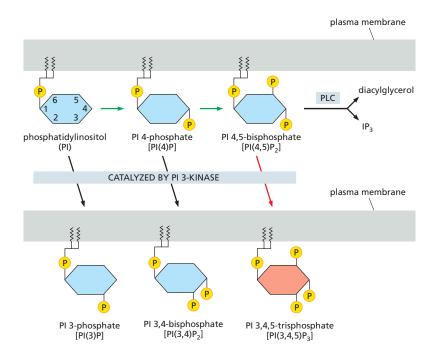

Figure 15-53 The generation of phosphoinositide docking sites by PI 3-kinase. PI 3-kinase phosphorylates the inositol ring on carbon atom 3 to generate the phosphoinositides shown at the bottom of the figure (diverting them away from the pathway leading to IP3 and diacylglycerol; see Figure 15-29). The most important phosphorvlation (indicated by the red arrow) is of PI(4,5)P₂ to PI(3,4,5)P₃, which can serve as a docking site for signaling proteins with PI(3,4,5)P₃-binding PH domains. Other inositol phospholipid kinases (not shown) catalyze the phosphorylations indicated by the green arrows.

MBOC7_ptr_ch15_873-948.indd 920 08/12/21 12:23 PM

on activated RTKs through its two SH2 domains (see Figure 15–47A). GPCRs activate class Ib PI 3-kinases, which have a regulatory subunit that binds to the $\beta\gamma$ complex of an activated heterotrimeric G protein (G_q) when GPCRs are activated by their extracellular ligand. The direct binding of activated Ras can also activate the common class I catalytic subunit.

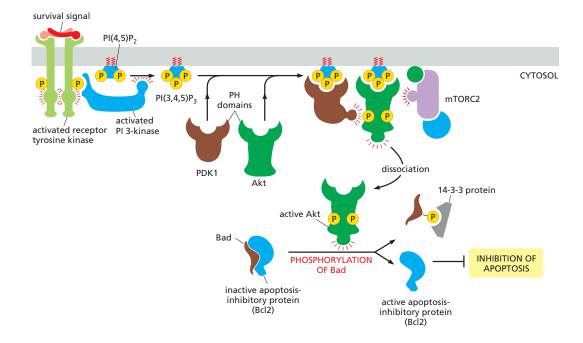

Intracellular signaling proteins bind to $PI(3,4,5)P_3$ produced by activated PI 3-kinase via a specific interaction domain, such as a **pleckstrin homology (PH) domain**, first identified in the platelet protein pleckstrin. PH domains function mainly as protein-protein interaction domains, and it is only a small subset of them that bind to $PI(3,4,5)P_3$; at least some of these also recognize a specific membrane-bound protein as well as the $PI(3,4,5)P_3$, which greatly increases the specificity of the binding and helps explain why the signaling proteins with $PI(3,4,5)P_3$ -binding PH domains do not all dock at all $PI(3,4,5)P_3$ sites. PH domains occur in about 200 human proteins, including the Ras GEF Sos discussed earlier (see Figure 15–48).

One especially important PH-domain-containing protein is the serine/threonine protein kinase *Akt*. The *PI-3-kinase–Akt signaling pathway* is the major pathway activated by the hormone *insulin*. It also plays a key part in promoting the survival and growth of many cell types in both invertebrates and vertebrates, as we now discuss.

The PI-3-Kinase–Akt Signaling Pathway Stimulates Animal Cells to Survive and Grow

As discussed earlier, extracellular signals are usually required for animal cells to grow and divide, as well as to survive (see Figure 15–4). Members of the *insulin-like growth factor (IGF)* family of signal proteins, for example, stimulate many types of animal cells to survive and grow. Like insulin, they bind to specific RTKs (see Figure 15–44), which activate PI 3-kinase to produce PI(3,4,5)P₃. The PI(3,4,5)P₃ recruits two protein kinases to the plasma membrane via their PH domains—Akt (also called *protein kinase B*, or *PKB*) and *phosphoinositide-dependent protein kinase 1 (PDK1)*—and this leads to the activation of Akt (Figure 15–54). Once activated, Akt phosphorylates various target proteins at the plasma membrane, as well as in the cytosol and nucleus. The effect on most of the known targets is to inactivate them, but the targets are such that these actions of Akt all conspire

Figure 15-54 One way in which signaling through PI 3-kinase can promote cell survival. An extracellular survival signal activates an RTK, which recruits and activates PI 3-kinase. The PI 3-kinase produces PI(3,4,5)P₃, which serves as a docking site for two serine/threonine kinases with PH domains-Akt and the phosphoinositide-dependent kinase PDK1 - and brings them into proximity at the plasma membrane. The Akt is phosphorylated on a serine by a third membrane-associated kinase (mTOR in complex 2, or mTORC2), which alters the conformation of the Akt so that it can be phosphorylated on a threonine by PDK1. which activates the Akt. The activated Akt now dissociates from the plasma membrane and phosphorylates various target proteins, including the Bad protein. When unphosphorylated, Bad holds the apoptosis-inhibitory Bcl2 in an inactive state (Bad and Bcl2 are both members of a family of proteins that regulates apoptosis, as discussed in Chapter 18). Once phosphorylated, Bad releases Bcl2, which now can block apoptosis and thereby promote cell survival. The phosphorylated Bad binds to a ubiquitous cytosolic protein called 14-3-3, which keeps the protein out of action, as shown.

MBOC7_ptr_ch15_873-948.indd 921 08/12/21 12:23 PM

to enhance cell survival and growth, as illustrated for one cell survival pathway in Figure 15–54.

The control of cell growth by the **PI-3-kinase-Akt pathway** depends in part on a protein kinase called **TOR**, named as the target of *rapamycin*, a bacterial toxin that inactivates some forms of the kinase and is used clinically as both an immunosuppressant and anticancer drug. In mammalian cells, it is called **mTOR** and exists in cells in two functionally distinct multiprotein complexes. *mTOR complex 1 (mTORC1)* contains the protein *raptor*; this complex is sensitive to rapamycin, and it stimulates cell growth. *mTOR complex 2 (mTORC2)* contains the protein *rictor* and is insensitive to rapamycin; it helps to promote cell survival by activating Akt (see Figure 15–54) and also regulates the actin cytoskeleton via Rho family GTPases.

mTORC1 is a key regulator of cell physiology, which integrates inputs from multiple sources. The two best understood activators of mTORC1 are extracellular signal proteins referred to as *growth factors* and nutrients such as amino acids, both of which activate mTORC1 and thereby promote cell growth. The complex signaling network that governs mTORC1 activity includes examples of many of the classes of signaling molecules we have discussed in this chapter (Figure 15–55). We discuss in Chapter 17 how activated mTORC1 stimulates cell growth (see Figure 17–61).

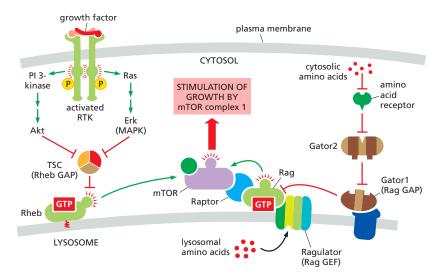

Figure 15-55 Activation of mTOR complex 1 (mTORC1) by growth factors and amino acids. mTORC1 activity depends on binding to the GTP-bound forms of two Ras-related GTPases, Rag and Rheb. In the presence of abundant cytosolic amino acids, Rag-GTP recruits mTORC1 to the surface of lysosomes. Full activation of mTORC1 then requires interaction with Rheb-GTP, which is activated in response to growth factor signaling. In both cases, enhanced GTP binding is driven primarily by inhibition of specific GTPase-activating proteins (GAPs). In the case of Rag, the GAP is a protein complex called Gator1, which is anchored on the lysosome and is regulated by a series of inhibitory interactions: cytosolic amino acids bind receptor proteins, thereby removing their inhibitory effect on Gator2, which is then free to inhibit the GAP activity of Gator1 - resulting in Rag activation and binding to mTORC1. The interaction of Rag with the lysosome depends on a large protein complex, the Ragulator, that serves as an activating GEF for Rag; this GEF activity is stimulated by amino acids in the lysosome, further promoting mTORC1 activation. On the left side of the diagram are the mechanisms leading to activation of the Rheb GTPase by growth factors. As described earlier in the chapter, activation of RTKs by growth factor binding initiates various signaling pathways, including activation of PI 3-kinase (see Figure 15-54) and the GTPase Ras (see Figure 15-48), resulting in activation of the protein kinases Akt and Erk, respectively. One target of these kinases is a trimeric protein complex called TSC, which is a GAP for Rheb. Its phosphorylation inhibits TSC, allowing Rheb-GTP to accumulate and stimulate mTORC1.

TSC is short for *tuberous sclerosis complex*. Mutations in the genes that encode two of its three subunits, Tsc1 and Tsc2, cause the genetic disease *tuberous sclerosis*, which is associated with benign tumors that contain abnormally large cells.

MBOC7_ptr_ch15_873-948.indd 922 08/12/21 12:23 PM

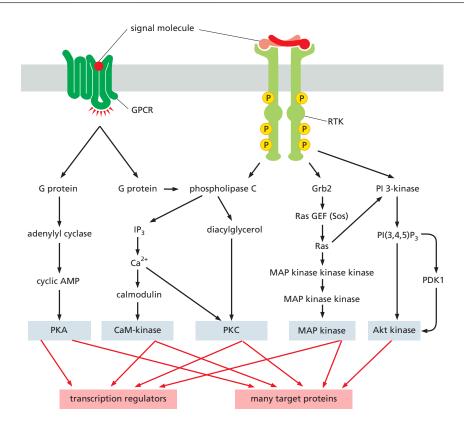

Figure 15–56 Five parallel intracellular signaling pathways activated by GPCRs, RTKs, or both. In this simplified example, the five kinases (shaded gray) at the end of each signaling pathway phosphorylate target proteins (shaded red), many of which are phosphorylated by more than one of the kinases. The phospholipase C activated by the two types of receptors is different: GPCRs activate PLC β , whereas RTKs activate PLC γ (not shown). Although not shown, some GPCRs can also activate Ras, but they do so independently of Grb2, via a Ras GEF that is activated by Ca²⁺ and diacylglycerol.

RTKs and GPCRs Activate Overlapping Signaling Pathways

As mentioned earlier, RTKs and GPCRs activate some of the same intracellular signaling pathways. Both, for example, can activate the inositol phospholipid pathway triggered by phospholipase C. Moreover, even when they activate different pathways, the different pathways can converge on the same target proteins. Figure 15–56 illustrates both of these types of signaling overlaps: it summarizes five parallel intracellular signaling pathways that we have discussed so far—one triggered by GPCRs, two triggered by RTKs, and two triggered by both kinds of receptors. Interactions among these pathways allow different extracellular signal molecules to modulate and coordinate each other's effects.

Some Enzyme-coupled Receptors Associate with Cytoplasmic Tyrosine Kinases

Many cell-surface receptors depend on tyrosine phosphorylation for their activity and yet lack a tyrosine kinase domain. These receptors act through **cytoplasmic tyrosine kinases**, which are associated with the receptors and phosphorylate various target proteins, often including the receptors themselves, when the receptors bind their ligand. These **tyrosine-kinase-associated receptors** thus function in much the same way as RTKs, except that their kinase domain is encoded by a separate gene and is noncovalently associated with the receptor polypeptide chain. A variety of receptor classes belong in this category, including the receptors for antigen and interleukins on lymphocytes (discussed in Chapter 24), integrins (discussed in Chapter 19), and receptors for various cytokines and some hormones. As with RTKs, many of these receptors depend on dimerization for their activation.

Some of these receptors work with members of the largest family of mammalian cytoplasmic tyrosine kinases, the **Src family**, which includes *Src*, *Yes*, *Fgr*, *Fyn*,

MBOC7_ptr_ch15_873-948.indd 923 08/12/21 12:23 PM

Lck, Lyn, Hck, and Blk. These protein kinases all contain SH2 and SH3 domains and are located on the cytoplasmic side of the plasma membrane, held there partly by their interaction with transmembrane receptor proteins and partly by covalently attached lipid chains (discussed in Chapter 3). Different family members are associated with different receptors and phosphorylate overlapping but distinct sets of intracellular signaling proteins. Lyn, Fyn, and Lck, for example, are each associated with different sets of receptors on lymphocytes. In each case, the kinase is activated when an extracellular ligand binds to the appropriate receptor protein. Src itself, as well as several other family members, can also bind to activated RTKs; in these cases, the receptor and cytoplasmic kinases mutually stimulate each other's catalytic activity, thereby strengthening and prolonging the signal (see Figure 15–52). There are even some G proteins (G_s and G_i) that can activate Src, which is one way that the activation of GPCRs can lead to tyrosine phosphorylation of intracellular signaling proteins and effector proteins.

Another type of cytoplasmic tyrosine kinase associates with *integrins*, the main receptors that cells use to bind to the extracellular matrix (discussed in Chapter 19). The binding of matrix components to integrins activates intracellular signaling pathways that influence the behavior of the cell. When integrins cluster at sites of contact with the extracellular matrix, they help trigger the assembly of cell-matrix junctions called *focal adhesions*. Among the many proteins recruited into these junctions is the cytoplasmic tyrosine kinase called *focal adhesion* kinase (FAK), which binds to the cytosolic tail of one of the integrin subunits with the assistance of other proteins. The clustered FAK molecules phosphorylate each other, creating phosphotyrosine docking sites where the Src kinase can bind. Src and FAK then phosphorylate each other and other proteins that assemble in the junction, including many of the signaling proteins used by RTKs. In this way, the two tyrosine kinases signal to the cell that it has adhered to a suitable substratum, where the cell can now survive, grow, divide, migrate, and so on.

The largest and most diverse class of receptors that rely on cytoplasmic tyrosine kinases is the *cytokine receptors*, which we consider next.

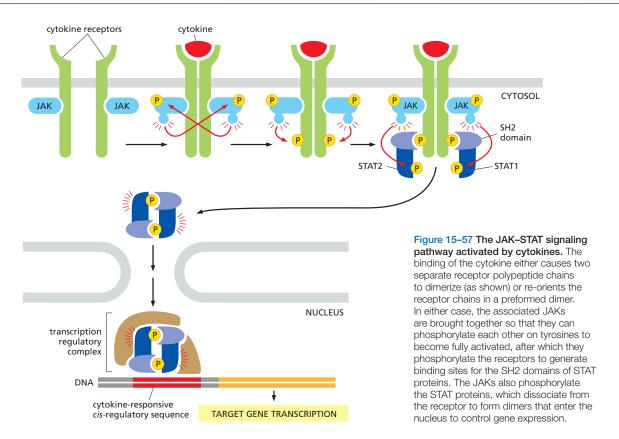

Cytokine Receptors Activate the JAK-STAT Signaling Pathway

The large family of **cytokine receptors** includes receptors for many kinds of local mediators (collectively called *cytokines*), as well as receptors for some hormones, such as *growth hormone* and *prolactin* (Movie 15.9). These receptors are stably associated with cytoplasmic tyrosine kinases called **Janus kinases** (JAKs; after the two-faced Roman god), which phosphorylate and activate transcription regulators called STATs (signal transducers and activators of transcription). STAT proteins are located in the cytosol and are referred to as *latent transcription regulators* because they migrate into the nucleus and regulate gene transcription only after they are activated.

Although many intracellular signaling pathways lead from cell-surface receptors to the nucleus, where they alter gene transcription (see Figure 15–56), the JAK-STAT signaling pathway provides one of the more direct routes. Cytokine receptors are dimers or trimers and are stably associated with one or two of the four known JAKs (JAK1, JAK2, JAK3, and Tyk2). Cytokine binding alters the arrangement so as to bring two JAKs into close proximity so that they phosphorylate each other, thereby increasing the activity of their tyrosine kinase domains. The JAKs then phosphorylate tyrosines on the cytoplasmic tails of cytokine receptors, creating phosphotyrosine docking sites for STATs (Figure 15–57). Some adaptor proteins can also bind to some of these sites and couple cytokine receptors to the Ras–MAP-kinase signaling pathway discussed earlier, but these will not be discussed here.

There are at least six STATs in mammals. Each has an SH2 domain that performs two functions. First, it mediates the binding of the STAT protein to a phosphotyrosine docking site on an activated cytokine receptor. Once bound, the JAKs phosphorylate the STAT on tyrosines, causing the STAT to dissociate from the receptor. Second, the SH2 domain on the released STAT now mediates its binding to a phosphotyrosine on another STAT molecule, forming either a STAT homodimer

MBOC7_ptr_ch15_873-948.indd 924 08/12/21 12:23 PM

or a heterodimer. The STAT dimer then translocates to the nucleus, where, in combination with other transcription regulators, it binds to a specific *cis*-regulatory sequence in various genes and stimulates their transcription (see Figure 15–57). In response to the hormone prolactin, for example, which stimulates breast cells to produce milk, activated STAT5 stimulates the transcription of genes that encode milk proteins. **Table 15–6** lists some of the more than 30 cytokines and hormones that activate the JAK-STAT pathway by binding to cytokine receptors.

Negative feedback regulates the responses mediated by the JAK-STAT pathway. In addition to activating genes that encode proteins mediating the cytokine-induced response, the STAT dimers can also activate genes that encode inhibitory proteins that help shut off the response. Some of these proteins bind to and inactivate phosphorylated JAKs and their associated phosphorylated

TABLE 15–6 Some Extracellular Signal Proteins That Act Through Cytokine Receptors and the JAK–STAT Signaling Pathway					
Signal protein	Receptor-associated JAKs	STATs activated	Some responses		
Interferon-γ (IFNγ)	JAK1 and JAK2	STAT1	Activates macrophages		
Interferon-α (IFNα)	Tyk2 and JAK2	STAT1 and STAT2	Increases cell resistance to viral infection		
Erythropoietin	JAK2	STAT5	Stimulates production of erythrocytes		
Prolactin	JAK1 and JAK2	STAT5	Stimulates milk production		
Growth hormone	JAK2	STAT1 and STAT5	Stimulates growth by inducing IGF1 production		
Granulocyte–macrophage- colony-stimulating factor (GMCSF)	JAK2	STAT5	Stimulates production of granulocytes and macrophages		

MBOC7_ptr_ch15_873-948.indd 925 08/12/21 12:23 PM

receptors; others bind to phosphorylated STAT dimers and prevent them from binding to their DNA targets. Such negative feedback mechanisms, however, are not enough on their own to turn off the response. Inactivation of the activated JAKs and STATs requires dephosphorylation of their phosphotyrosines.

Extracellular Signal Proteins of the TGFβ Superfamily Act Through Receptor Serine/Threonine Kinases and Smads

The transforming growth factor- β (TGF β) superfamily consists of a large number (33 in humans) of structurally related, secreted, dimeric proteins. They act either as hormones or, more commonly, as local mediators to regulate a wide range of biological functions in all animals. During development, they regulate pattern formation and influence various cell behaviors, including proliferation, specification and differentiation, extracellular matrix production, and cell death. In adults, they are involved in tissue repair and in immune regulation, as well as in many other processes. The superfamily consists of the TGF β /activin family and the larger bone morphogenetic protein (BMP) family.

All of these proteins act through receptors that are single-pass transmembrane proteins with a serine/threonine kinase domain on the cytosolic side of the plasma membrane. There are two classes of these **receptor serine/threonine kinases**—*type I* and *type II*. Signaling begins when a TGF β dimer interacts with the extracellular domains of two type-I receptors and two type-II receptors, bringing the kinase domains together so that the type-II receptors can phosphorylate and activate the type-I receptors, forming an active tetrameric receptor complex.

Once activated, the receptor complex uses a strategy for rapidly relaying the signal to the nucleus that is very similar to the JAK-STAT strategy used by cytokine receptors. The activated type-I receptor directly binds and phosphorylates a latent transcription regulator of the **Smad family** (named after the first two proteins identified, Sma in *Caenorhabditis elegans* and Mad in *Drosophila*). Activated TGFβ/activin receptors phosphorylate Smad2 or Smad3, while activated BMP receptors phosphorylate Smad1, Smad5, or Smad8. Once one of these *receptor-activated Smads* (*R-Smads*) has been phosphorylated, it binds to Smad4 (called a *co-Smad*), which can form a complex with any of the five R-Smads. The Smad complex then translocates into the nucleus, where it associates with other transcription regulators and controls the transcription of specific target genes (**Figure 15–58**). Because the partner proteins in the nucleus vary depending on the cell type and state of the cell, the genes affected vary.

Activated $TGF\beta$ receptors and their bound ligand are endocytosed by two distinct routes, one leading to further activation and the other leading to inactivation. The activation route depends on clathrin-coated vesicles and leads to early endosomes (discussed in Chapter 13), where most of the Smad activation occurs. An anchoring protein called SARA (for Smad anchor for receptor activation) has an important role in this pathway; it is concentrated in early endosomes and binds to both activated $TGF\beta$ receptors and Smads, increasing the efficiency of receptor-mediated Smad phosphorylation. The inactivation route depends on caveolae (discussed in Chapter 13) and leads to receptor ubiquitylation and degradation in proteasomes.

During the signaling response, the Smads shuttle continually between the cytoplasm and the nucleus: they are dephosphorylated in the nucleus and exported to the cytoplasm, where they can be rephosphorylated by activated receptors. In this way, the effect exerted on the target genes reflects both the concentration of the extracellular signal and the time the signal continues to act on the cell-surface receptors (often several hours). Cells exposed to a morphogen at high concentration, or for a long time, or both, will switch on one set of genes, whereas cells receiving a lower or more transient exposure will switch on another set.

As in other signaling systems, negative feedback regulates the Smad pathway. Among the target genes activated by Smad complexes are those that encode *inhibitory Smads*, either Smad6 or Smad7. Smad7 (and possibly Smad6) binds to the cytosolic tail of the activated receptor and inhibits its signaling ability in at least three ways: (1) it competes with R-Smads for binding sites on the receptor,

MBOC7_ptr_ch15_873-948.indd 926 08/12/21 12:23 PM

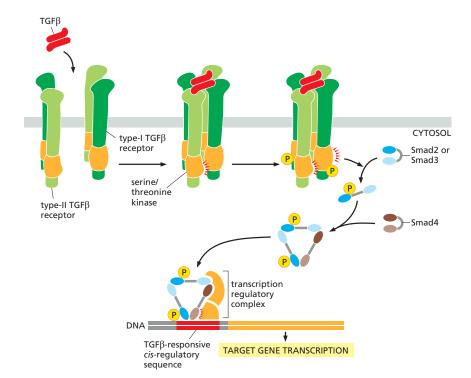

Figure 15-58 The Smad-dependent signaling pathway activated by TGFB. The $\mathsf{TGF}\beta$ dimer promotes the assembly of a tetrameric receptor complex containing two copies each of the type-I and type-II receptors. The type-II receptors phosphorylate specific sites on the type-I receptors, thereby activating their kinase domains and leading to phosphorylation of R-Smads such as Smad2 and Smad3. Smads open up to expose a binding surface when they are phosphorylated, leading to the formation of a trimeric Smad complex containing two R-Smads and the co-Smad, Smad4. The phosphorylated Smad complex enters the nucleus and collaborates with other transcription regulators to control the transcription of specific target genes.

decreasing R-Smad phosphorylation; (2) it recruits a ubiquitin ligase called *Smurf*, which ubiquitylates the receptor, leading to receptor internalization and degradation (it is because Smurfs also ubiquitylate and promote the degradation of Smads that they are called *Smad ubiquitylation regulatory factors*, or Smurfs); and (3) it recruits a protein phosphatase that dephosphorylates and inactivates the receptor. In addition, the inhibitory Smads bind to the co-Smad, Smad4, and inhibit it, either by preventing its binding to R-Smads or by promoting its ubiquitylation and degradation.

Summary

There are various classes of enzyme-coupled receptors, the most common of which are receptor tyrosine kinases (RTKs), tyrosine-kinase-associated receptors, and receptor serine/threonine kinases.

Ligand binding to RTKs causes their dimerization, which leads to activation of their kinase domains. These activated kinase domains phosphorylate multiple tyrosines on the receptors, producing a set of phosphotyrosines that serve as docking sites for a set of intracellular signaling proteins, which bind via their SH2 (or PTB) domains. One such signaling protein serves as an adaptor to couple some activated receptors to a Ras GEF (Sos), which activates the monomeric GTPase Ras; Ras, in turn, activates a three-component MAP kinase signaling module, which relays the signal to the nucleus by phosphorylating transcription regulators. Another important signaling protein that can dock on activated RTKs is PI 3-kinase, which phosphorylates specific phosphoinositides to produce lipid docking sites in the plasma membrane for signaling proteins with phosphoinositide-binding PH domains, including the serine/threonine protein kinase Akt, which plays a key part in the control of cell survival and cell growth. Many receptor classes, including some RTKs, activate Rho family monomeric GTPases, which functionally couple the receptors to the cytoskeleton.

Tyrosine-kinase-associated receptors depend on various cytoplasmic tyrosine kinases for their action. These kinases include members of the Src family, which associate with many kinds of receptors, and the focal adhesion kinase (FAK), which associates with integrins at focal adhesions. The cytoplasmic tyrosine kinases then phosphorylate a variety of signaling proteins to relay the signal onward. The largest

MBOC7_ptr_ch15_873-948.indd 927 08/12/21 12:23 PM

family of tyrosine-kinase-associated receptors is the cytokine receptor family. When stimulated by ligand binding, these receptors activate JAK cytoplasmic tyrosine kinases, which phosphorylate STATs. The STATs then dimerize, translocate to the nucleus, and activate the transcription of specific genes. Receptor serine/threonine kinases, which are activated by signal proteins of the TGF β superfamily, act similarly: they directly phosphorylate and activate Smads, which then oligomerize with another Smad, translocate to the nucleus, and regulate gene transcription.

ALTERNATIVE SIGNALING ROUTES IN GENE REGULATION

Major changes in the behavior of a cell tend to depend on changes in the expression of numerous genes. Thus, many extracellular signaling molecules carry out their effects, in whole or in part, by initiating signaling pathways that change the activities of transcription regulators. There are numerous examples of gene regulation in both GPCR and enzyme-coupled receptor pathways (see Figures 15–28 and 15–50). In this section, we describe some of the less common signaling mechanisms by which gene expression can be controlled by extracellular signals. We begin with several pathways that depend on *regulated proteolysis* to control the activity and location of latent *transcription regulators*. We then turn to a class of extracellular signal molecules that do not employ cell-surface receptors but enter the cell and interact directly with transcription regulators to perform their functions. Finally, we briefly discuss some of the mechanisms by which gene expression is controlled by the *circadian rhythm*: the daily cycle of light and dark.

The Receptor Notch Is a Latent Transcription Regulator

Signaling through the **Notch** protein is used widely in animal development. As discussed in Chapter 21, it has a general role in controlling cell-fate choices and regulating pattern formation during the development of most tissues, as well as in the continual cell renewal in tissues such as the lining of the gut. It is best known, however, for its role in the production of *Drosophila* neural cells, which usually arise as isolated single cells within an epithelial sheet of precursor cells. During this process, when a precursor cell commits to becoming a neural cell, it signals to its immediate neighbors not to do the same; the inhibited cells develop into epidermal cells instead. This process, called *lateral inhibition*, depends on a contact-dependent signaling mechanism that is activated by a single-pass transmembrane signal protein called **Delta**, displayed on the surface of the future neural cell. By binding to its receptor, the Notch protein, on a neighboring cell, Delta signals to the neighbor not to become neural (**Figure 15–59**). When this signaling process is defective, a huge excess of neural cells is produced at the expense of epidermal cells, which is lethal.

Notch is a single-pass transmembrane protein that requires proteolytic processing to function. It acts as a latent transcription regulator and provides the

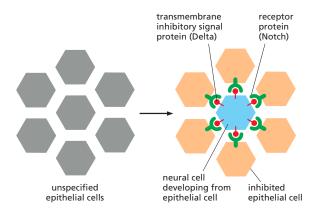

Figure 15-59 Lateral inhibition mediated by Notch and Delta during neural cell development in Drosophila. When individual cells in the epithelium begin to develop as neural cells, they signal to their neighbors not to do the same. This inhibitory, contact-dependent signaling is mediated by the ligand Delta, which appears on the surface of the future neural cell and binds to Notch protein on the neighboring cells. In many tissues, all the cells in a cluster initially express both Delta and Notch, and a competition occurs, with one cell emerging as winner, expressing Delta strongly and inhibiting its neighbors from doing likewise. In other cases, additional factors interact with Delta or Notch to make some cells susceptible to the lateral inhibition signal and others unresponsive to it.

MBOC7_ptr_ch15_873-948.indd 928 08/12/21 12:23 PM

simplest and most direct signaling pathway known from a cell-surface receptor to the nucleus. When activated by the binding of Delta on another cell, a plasma-membrane-bound protease cleaves off the cytoplasmic tail of Notch, and the released tail translocates into the nucleus to activate the transcription of a set of Notch-response genes. The Notch tail fragment acts by binding to a DNA-binding protein, converting it from a transcription repressor into a transcription activator.

Notch undergoes three successive proteolytic cleavage steps, but only the last two depend on Delta binding. As part of its normal biosynthesis, it is cleaved in the Golgi apparatus to form a heterodimer, which is then transported to the cell surface as the mature receptor. The binding of Delta to Notch induces a second cleavage in the extracellular domain, mediated by an extracellular protease. A final cleavage quickly follows, cutting free the cytoplasmic tail of the activated Notch (Figure 15–60). Note that, unlike most receptors, the activation of Notch is irreversible; once activated by ligand binding, the protein cannot be used again.

This final cleavage of the Notch tail occurs just within the transmembrane segment, and it is mediated by a protease complex called γ -secretase, which is also

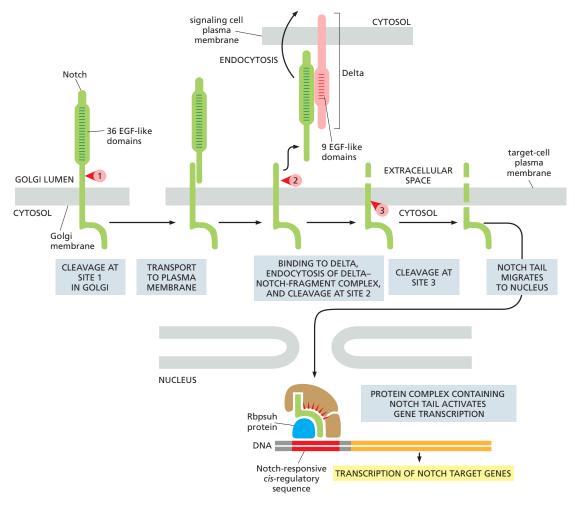

Figure 15–60 The processing and activation of Notch by proteolytic cleavage. The *numbered red arrowheads* indicate the sites of proteolytic cleavage. The first proteolytic processing step occurs within the *trans* Golgi network to generate mature heterodimeric Notch, which is then displayed on the cell surface. The binding to Delta on a neighboring cell triggers the next two proteolytic steps: the complex of Delta and the Notch fragment to which it is bound is endocytosed by the Delta-expressing cell, exposing the extracellular cleavage site in the transmembrane Notch subunit. Note that Notch and Delta interact through their repeated EGF-like domains. The released Notch tail migrates into the nucleus, where it binds to the Rbpsuh protein, which it converts from a transcription repressor to a transcription activator.

MBOC7_ptr_ch15_873-948.indd 929 08/12/21 12:23 PM

responsible for the intramembrane cleavage of various other single-pass transmembrane proteins. One of its essential subunits is *Presenilin*, so called because mutations in the gene encoding it are a frequent cause of early-onset familial Alzheimer's disease, a form of presenile dementia. The protease complex is thought to contribute to this and other forms of Alzheimer's disease by generating extracellular peptide fragments from a transmembrane neuronal protein; the fragments accumulate in excessive amounts and form aggregates of misfolded protein called amyloid plaques, which may injure nerve cells and contribute to their degeneration and loss.

Wnt Proteins Activate Frizzled and Thereby Inhibit β -Catenin Degradation

Wnt proteins are secreted signal molecules that control various aspects of animal development. They were discovered independently in flies and in mice: in *Drosophila*, the *Wingless* (*Wg*) gene originally came to light because of its role in wing development, while in mice, the *Int1* gene was found because it promoted the formation of breast tumors when activated by the integration of a virus next to it. Both of these genes encode Wnt proteins. There are 19 Wnts in humans, each having distinct, but often overlapping, functions.

What are unusual extracellular signaling proteins in that they are covalently attached to a fatty acid chain after their synthesis in the endoplasmic reticulum. What are therefore hydrophobic molecules that tend to associate with cell membranes and do not diffuse rapidly in the extracellular environment. They are thought to act primarily as local (paracrine) signaling molecules (see Figure 15–2B).

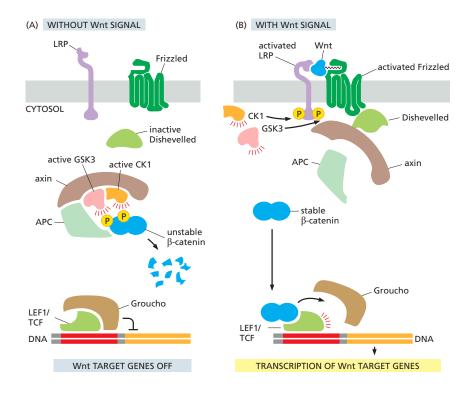

Which have been implicated in several signaling pathways. The best understood, and our primary focus here, is the Wnt/ β -catenin pathway (also known as the *canonical Wnt pathway*), which centers on a protein called β -catenin. β -catenin is an intriguing example of a signaling protein with two seemingly unconnected functions in the same cell. A portion of the cell's β -catenin is located at cell-cell junctions and thereby contributes to the control of cell-cell adhesion; this function is discussed in Chapter 19 and does not concern us here. Wnt signaling acts primarily on cytoplasmic β -catenin, a latent transcription regulator that is degraded rapidly in unstimulated cells but stabilized by Wnt signaling.

In the absence of Wnt signaling, cytoplasmic β -catenin is degraded by a process that depends on a large protein $degradation\ complex$, which binds β -catenin, keeps it out of the nucleus, and promotes its destruction. The complex contains at least four other proteins, including a protein kinase called $casein\ kinase\ 1\ (CK1)$, which phosphorylates the β -catenin on a serine, priming it for further phosphorylation by another protein kinase called $glycogen\ synthase\ kinase\ 3\ (GSK3)$. This final phosphorylation marks the protein for ubiquitylation and rapid degradation in proteasomes. Two scaffold proteins called $axin\$ and $Adenomatous\ polyposis\ coli\ (APC)$ hold the protein complex together (Figure 15–61A). APC gets its name from the finding that the gene encoding it is often mutated in a type of benign tumor (an adenoma) of the colon; the tumor projects into the lumen as a polyp and can eventually become malignant. (This APC should not be confused with the anaphase-promoting complex, or APC/C, that plays a central part in selective protein degradation during the cell cycle—discussed in Chapter 17.)

Wnt proteins regulate β -catenin proteolysis by interacting with two cell-surface co-receptors, **Frizzled** and **LDL-receptor-related protein (LRP)**. Frizzled is a seven-pass transmembrane protein that resembles GPCRs in structure but does not generally work through the activation of G proteins. LRP is a relatively simple single-pass transmembrane protein. Frizzled contains an extracellular domain that binds with high affinity to Wnt, due in part to a hydrophobic pocket on the receptor domain that interacts with the lipid modification on Wnt; this lipid is therefore required for Wnt signaling. LRP interacts with a different site on Wnt. Thus, as in so many other signaling pathways, the Wnt ligand drives formation of a co-receptor dimer.

Formation of the activated receptor complex promotes phosphorylation of the LRP receptor by the two protein kinases, CK1 and GSK3. Receptor activation also leads to recruitment of the scaffold protein **Dishevelled**. Axin is brought to the

MBOC7_ptr_ch15_873-948.indd 930 08/12/21 12:23 PM

receptor complex and inactivated, thereby disrupting the β -catenin degradation complex in the cytoplasm. In this way, the phosphorylation and degradation of β -catenin are prevented, enabling β -catenin to accumulate and translocate to the nucleus, where it alters the pattern of gene transcription (Figure 15–61B).

In the absence of Wnt signaling, Wnt-responsive genes are kept silent by an inhibitory complex of transcription regulators. The complex includes proteins of the *LEF1/TCF* family bound to a co-repressor protein of the *Groucho* family (see Figure 15–61A). In response to a Wnt signal, β -catenin enters the nucleus and binds to the LEF1/TCF proteins, displacing Groucho. The β -catenin now functions as a coactivator, inducing the transcription of the Wnt target genes (see Figure 15–61B). Thus, as in the case of Notch signaling, Wnt/ β -catenin signaling triggers a switch from transcriptional repression to transcriptional activation.

Among the genes activated by β -catenin is Myc, which encodes a protein (Myc) that is an important regulator of cell growth and proliferation (discussed in Chapter 17). Mutations of the Apc gene occur in 80% of human colon cancers (discussed in Chapter 20). These mutations inhibit the protein's ability to bind β -catenin, so that β -catenin accumulates in the nucleus and stimulates the transcription of c-Myc and other Wnt target genes, even in the absence of Wnt signaling. The resulting uncontrolled cell growth and proliferation promote the development of cancer.

The Wnt signaling pathway shown in Figure 15–61 is supplemented with additional regulatory inputs that fine-tune the strength of the Wnt signal. Some Wnt-stimulated genes, for example, suppress the Wnt signal, resulting in negative feedback. One of these genes encodes a secreted enzyme called Notum, which removes the fatty acid modification from Wnt, thereby inactivating it. Another Wnt-stimulated gene encodes a cell-surface transmembrane protein, Rnf43, which is a ubiquitin ligase that targets the Frizzled protein for degradation. This negative feedback mechanism can be suppressed by extracellular signaling molecules from other cells: a signaling protein called R-spondin, for example, binds to a GPCR called Lgr, which inactivates Rnf43, thereby enhancing the Wnt signal. Through these and a variety of other mechanisms, the localization and strength of the Wnt signal can be fine-tuned in different tissues.

Figure 15-61 The Wnt/β-catenin signaling pathway. (A) in the absence of a Wnt signal, β-catenin that is not bound to cell-cell adherens junctions (not showndiscussed in Chapter 19) interacts with a degradation complex containing APC, axin, GSK3, and CK1. In this complex, β-catenin is phosphorylated by CK1 and then by GSK3, triggering its ubiquitylation and degradation in proteasomes. Wntresponsive genes are kept inactive by the Groucho co-repressor protein bound to the transcription regulator LEF1/TCF. (B) Wnt binding to Frizzled and LRP brings the two co-receptors together, and the cvtosolic tail of LRP is phosphorylated by CK1 and GSK3. The scaffold protein Dishevelled is recruited to the activated Frizzled protein. Axin binds to Dishevelled and the phosphorylated LRP and is inactivated, resulting in disassembly of the degradation complex. The phosphorylation of β-catenin is thereby prevented, and unphosphorylated β-catenin accumulates and translocates to the nucleus, where it binds to LEF1/TCF, displaces the co-repressor Groucho, and acts as a coactivator to stimulate the transcription of Wnt target genes. The scaffold protein Dishevelled is required for the signaling pathway to operate; it binds to Frizzled and becomes phosphorylated (not shown), but its precise role is unknown.

MBOC7_ptr_ch15_873-948.indd 931 08/12/21 12:23 PM

Hedgehog Proteins Initiate a Complex Signaling Pathway in the Primary Cilium

Hedgehog proteins and Wnt proteins act in similar ways. Both are secreted signal molecules, which act as local mediators in many developing invertebrate and vertebrate tissues. Both proteins are modified by covalently attached lipids, and both trigger a switch from transcriptional repression to transcriptional activation. Excessive signaling along either pathway in adult cells can lead to cancer.

The first **Hedgehog protein** was discovered in *Drosophila*, where mutation of the *Hedgehog* gene produces a larva covered with spiky processes (denticles), like a hedgehog. At least three genes encode Hedgehog proteins in vertebrates—*Sonic, Desert,* and *Indian hedgehog.* The active forms of all Hedgehog proteins are covalently coupled to cholesterol, as well as to a fatty acid chain. The cholesterol is added during an unusual processing step in which a precursor protein cleaves itself to produce a smaller, cholesterol-containing signal protein.

The signaling proteins activated by Hedgehog were also first identified in *Drosophila* and are conserved in vertebrates and other animals. The vertebrate pathway, which we focus on here, provides a striking example of an important concept: the sensitivity and efficiency of a signaling system can be enhanced by concentrating its components in a small volume or compartment. Most of the signaling proteins of the vertebrate Hedgehog pathway are located within the **primary cilium**, a small membrane protrusion that is present in one copy on the surface of most vertebrate cell types. As we discuss in Chapter 16, the primary cilium contains a microtubule array along its central axis, but it is not motile like other microtubule-based cilia or flagella; instead, its microtubules are used as tracks for the transport of various signaling proteins to and from the tip. All the early signaling steps in the Hedgehog pathway occur in the cilium, and signaling is lost in cells with defects in primary cilium formation or function. Thus, the primary cilium serves as an antenna for the extracellular Hedgehog signal.

Hedgehog signaling begins at a cell-surface receptor called **Patched**, which employs a convoluted mechanism to activate a group of transcription regulators called *Gli proteins*, thereby increasing the expression of genes that drive changes in the target cell's proliferation or developmental fate. In the absence of Hedgehog ligand, the unoccupied Patched protein resides in the ciliary membrane and inhibits the activity of another transmembrane protein called **Smoothened**, which is located outside the cilium (**Figure 15–62A**). Smoothened is a GPCR-like protein that resembles the Wnt receptor Frizzled; like Frizzled, it has an external domain that serves as a lipid-binding activation domain, and its activation requires binding of this domain to cholesterol in the cell membrane. Patched, in contrast, is a large transmembrane protein that transports cholesterol out of the membrane. It has been proposed that Patched inhibits Smoothened by reducing the amount of cholesterol in the ciliary membrane, and Hedgehog inhibits Patched by blocking its cholesterol transport channel.

In cells lacking the Hedgehog signal, expression of Hedgehog-responsive genes is blocked by two mechanisms. First, an inhibitory protein called *SuFu* holds the Gli transcription regulators in an inactive state within the cilium. Second, one member of the family, Gli3, is proteolytically processed to form a smaller fragment that acts as a transcription repressor, helping to keep Hedgehog-responsive genes silent. This processing of the Gli3 protein depends on a signaling pathway that begins with a GPCR called Gpr161, which is found in the cilium membrane and stimulates adenylyl cyclase to produce cyclic AMP; cyclic AMP then stimulates PKA, which phosphorylates Gli3 to promote its partial processing into a transcription repressor (see Figure 15–62A).

The binding of Hedgehog to the Patched protein promotes the transport of Patched out of the cilium and removes its inhibitory effects on Smoothened, which moves into the cilium. Gpr161 is removed from the cilium, thereby reducing formation of the Gli3 transcription repressor. Inactive complexes of Gli proteins and SuFu are transported to the tip of the cilium, where the activated Smoothened

MBOC7_ptr_ch15_873-948.indd 932 08/12/21 12:23 PM

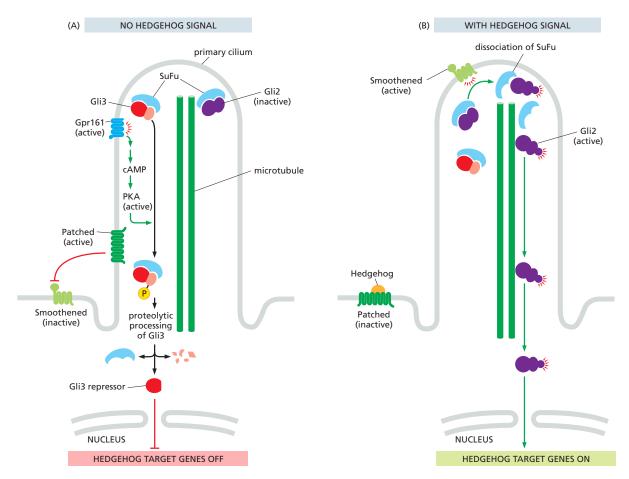

Figure 15-62 Vertebrate Hedgehog signaling in the primary cilium. (A) In the absence of Hedgehog, its receptor, Patched, is active in the cilium membrane and inhibits Smoothened, which is in the membrane adjacent to the cilium. Gli transcription regulators (primarily Gli2 and Gli3) are held in an inactive state by SuFu. In addition, an active GPCR (Gpr161) stimulates adenylyl cyclase, generating cyclic AMP that leads to PKA-dependent phosphorylation of the Gli3 protein. Phosphorylated Gli3 is processed to a transcription repressor, which accumulates in the nucleus to help keep Hedgehog target genes inactive. (B) Hedgehog binding to Patched removes the inhibition of Smoothened Smoothened translocates to the cilium, where it triggers the dissociation of SuFu-Gli2 complexes and the conversion of Gli2 to an active transcription regulator; activated Gli2 is then transported to the cytoplasm, from where it moves to the nucleus to stimulate expression of Hedgehog-responsive genes. Hedgehog also promotes removal of Gpr161 from the cilium (not shown), thereby reducing the processing of Gli3 to a transcription repressor.

promotes their dissociation and triggers modifications of Gli2 proteins, thereby converting them into active transcription regulators. Activated Gli2 proteins are transported out of the cilium along microtubule tracks to the cytoplasm, from where they diffuse to the nucleus to promote gene expression (Figure 15–62B). The result is a rise in the expression of numerous Hedgehog target genes.

Hedgehog signaling can promote cell proliferation, and excessive Hedgehog signaling can lead to cancer. Inactivating mutations in one of the two human *Patched* genes, for example, which lead to excessive Hedgehog signaling, occur frequently in *basal cell carcinoma* of the skin, the most common form of cancer in Caucasians. A small molecule called *cyclopamine*, made by a meadow lily, is being used to treat cancers associated with excessive Hedgehog signaling. It blocks Hedgehog signaling by binding tightly to Smoothened and inhibiting its activity. It was originally identified because it causes severe developmental defects in the progeny of sheep grazing on such lilies; these include the presence of a single central eye (a condition called *cyclopia*), which is also seen in mice that are deficient in Hedgehog signaling.

MBOC7_ptr_ch15_873-948.indd 933 08/12/21 12:23 PM

Many Inflammatory and Stress Signals Act Through an NFκB-dependent Signaling Pathway

The NFκB proteins are latent transcription regulators that are present in most animal cells and are central to many inflammatory and innate immune responses. These responses occur as a reaction to infection or injury and help protect stressed multicellular organisms and their cells (discussed in Chapter 24). An excessive or inappropriate inflammatory response in animals can also damage tissue and cause severe pain, and chronic inflammation can lead to cancer. NFκB proteins also have important roles during normal animal development: the *Drosophila* NFκB family member *Dorsal*, for example, has a crucial role in specifying the dorsal-ventral axis of the developing fly embryo (discussed in Chapter 22).

Various cell-surface receptors activate the NFkB signaling pathway in animal cells. Toll receptors in Drosophila and Toll-like receptors in vertebrates, for example, recognize pathogens and activate this pathway to trigger innate immune responses (discussed in Chapter 24). The receptors for tumor necrosis factor α (TNF α) and interleukin-1 (IL1), which are vertebrate cytokines especially important in inducing inflammatory responses, also activate this signaling pathway. The Toll, Toll-like, and IL1 receptors belong to the same family of proteins, whereas TNF receptors belong to a different family; all of them, however, act in similar ways to activate NFkB. When activated, they trigger a multiprotein ubiquitylation and phosphorylation cascade that releases NFkB from an inhibitory protein complex, so that it can translocate to the nucleus and turn on the transcription of hundreds of genes that participate in inflammatory and innate immune responses.

There are several NF κ B proteins in mammals, and they form a variety of homodimers and heterodimers, each of which activates its own characteristic set of genes. Inhibitory proteins called I κ B bind tightly to the dimers and hold them in an inactive state within the cytoplasm of unstimulated cells. The signals that release NF κ B dimers do so by triggering a signaling pathway that leads to the phosphorylation, ubiquitylation, and consequent degradation of the I κ B proteins (Figure 15–63).

Among the genes activated by the released NF κ B is the gene that encodes I κ B α . This activation leads to increased synthesis of I κ B α protein, which binds to NF κ B

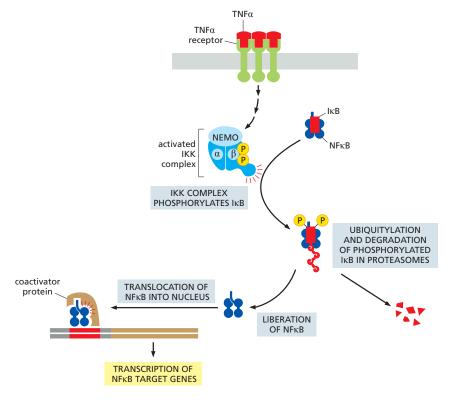

Figure 15-63 The activation of the NFkB pathway by TNF α . Both TNF α and its receptors are trimers. The binding of $\mathsf{TNF}\alpha$ causes a rearrangement of the clustered cytosolic tails of the receptors, which now recruit various signaling proteins. resulting in the activation of a protein kinase that phosphorylates and activates IkB kinase kinase (IKK). IKK is a heterotrimer composed of two kinase subunits (IKK α and IKKB) and a regulatory subunit called NEMO. IKKB then phosphorylates IκB on two serines, which marks the protein for ubiquitylation and degradation in proteasomes. The released NFkB translocates into the nucleus, where, in collaboration with a coactivator protein. it stimulates the transcription of its target genes.

MBOC7_ptr_ch15_873-948.indd 934 08/12/21 12:23 PM

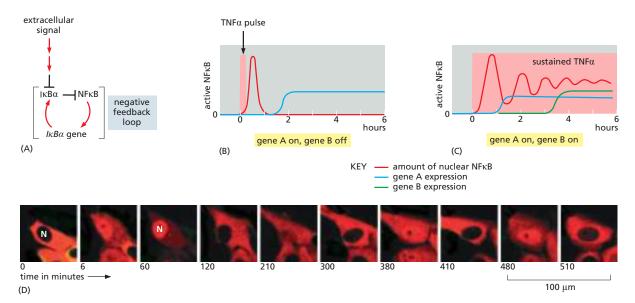

Figure 15–64 Negative feedback in the NFκB signaling pathway induces oscillations in NFκB activation. (A) Diagram showing how activated NFκB stimulates the transcription of the $I\kappa B\alpha$ gene, the protein product of which acts back in the cytoplasm to sequester and inhibit NFκB there. If the stimulus is persistent, the newly made $I\kappa B\alpha$ protein will then be ubiquitylated and degraded, liberating active NFκB again so that it can return to the nucleus and activate transcription (see Figure 15–63). (B) A short exposure to TNF α produces a single, short pulse of NFκB activation, beginning within minutes and ending by 1 hour. This response turns on the transcription of gene A but not gene B. (C) A sustained exposure to TNF α for the entire 6 hours of the experiment produces oscillations in NFκB activation that damp down over time. This response turns on the transcription of both genes A and B; gene B turns on only after several hours, indicating that gene B transcription requires prolonged activation of NFκB, for reasons that are not understood. (D) These time-lapse confocal fluorescence micrographs from a different study of TNF α stimulation show the oscillations of NFκB in a cultured cell, as indicated by the periodic movement into the nucleus (N) of a fusion protein composed of NFκB fused to a red fluorescent protein. In the cell at the center of the micrographs, NFκB is active and in the nucleus at 6, 60, 210, 380, and 480 minutes, but it is exclusively in the cytoplasm at 0, 120, 300, 410, and 510 minutes. (A–C, based on data from A. Hoffmann et al., Science 298:1241–1245, 2002, and adapted from A.Y. Ting and D. Endy, Science 298:1189–1190, 2002; D, from D.E. Nelson et al., Science 306: 704–708, 2004. All with permission from AAAS.)

and inactivates it, creating a negative feedback loop (Figure 15–64A). Experiments on TNF α -induced responses, as well as computer modeling studies of the responses, indicate that the negative feedback produces two types of NF κ B responses, depending on the duration of the TNF α stimulus. Importantly, the two types of responses induce different patterns of gene expression (Figure 15–64B, C, and D).

Thus far, we have focused on the mechanisms by which extracellular signal molecules use cell-surface receptors to initiate changes in gene expression. We now turn to a class of extracellular signals that bypasses the plasma membrane entirely and controls, in the most direct way possible, transcription regulators inside the cell.

Nuclear Receptors Are Ligand-modulated Transcription Regulators

Various small, hydrophobic signal molecules diffuse directly across the plasma membrane of target cells and bind to intracellular receptors that are transcription regulators. These signal molecules include steroid hormones, thyroid hormones, retinoids, and vitamin D. Although they differ greatly from one another in both chemical structure (Figure 15–65) and function, they all act by a similar mechanism. They bind to their respective intracellular receptor proteins and alter the ability of these proteins to control the transcription of specific genes. Thus, these proteins serve both as intracellular receptors and as intracellular effectors for the signal.

The receptors are all structurally related, being part of the very large **nuclear receptor superfamily**. Many family members have been identified by DNA sequencing only, and their ligands are not yet known; they are therefore referred

MBOC7_ptr_ch15_873-948.indd 935 08/12/21 12:24 PM

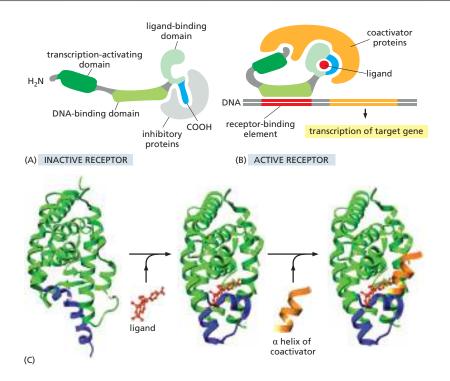

to as *orphan nuclear receptors*, and they make up large fractions of the nuclear receptors encoded in the genomes of humans, *Drosophila*, and the nematode *C. elegans*. Some mammalian nuclear receptors are regulated by intracellular metabolites rather than by secreted signal molecules; the *peroxisome proliferationactivated receptors* (*PPARs*), for example, bind intracellular lipid metabolites and regulate the transcription of genes involved in lipid metabolism and fat-cell differentiation. It seems likely that the nuclear receptors for hormones evolved from such receptors for intracellular metabolites, which might help explain their intracellular location.

Steroid hormones—which include cortisol, the steroid sex hormones, vitamin D (in vertebrates), and the molting hormone *ecdysone* (in insects)—are all made from cholesterol. *Cortisol* is produced in the cortex of the adrenal glands and influences the metabolism of many types of cells. The *steroid sex hormones* are made in the testes and ovaries and are responsible for the secondary sex characteristics that distinguish males from females. *Vitamin D* is synthesized in the skin in response to sunlight; after it has been converted to its active form in the liver or kidneys, it regulates Ca²⁺ metabolism, promoting Ca²⁺ uptake in the gut and reducing its excretion in the kidneys. The *thyroid hormones*, which are made from the amino acid tyrosine, act to increase the metabolic rate of many cell types, while the *retinoids*, such as retinoic acid, are made from vitamin A and have important roles as local mediators in vertebrate development. Although all of these signal molecules are relatively insoluble in water, they are made soluble for transport in the bloodstream and other extracellular fluids by binding to specific carrier proteins, from which they dissociate before entering a target cell (see Figure 15–3B).

The nuclear receptors bind to specific DNA sequences adjacent to the genes that the ligand regulates. Some of the receptors, such as those for cortisol, are located primarily in the cytosol and enter the nucleus only after ligand binding; others, such as the thyroid and retinoid receptors, are bound to DNA in the nucleus even in the absence of ligand. In either case, the inactive receptors are usually bound to inhibitory protein complexes. Ligand binding alters the conformation of the receptor protein, causing the inhibitory complex to dissociate and the receptor to bind coactivator proteins that stimulate gene transcription (Figure 15–66). In other cases, however, ligand binding to a nuclear receptor inhibits transcription: some thyroid hormone receptors, for example, act as transcription activators in the absence of their hormone and become transcription repressors when hormone binds.

Thus far, we have focused on the control of gene expression by extracellular signal molecules produced by other cells. We now turn to gene regulation by a more global environmental signal: the cycle of light and dark that results from Earth's rotation.

Figure 15–65 Some extracellular signal molecules that bind to intracellular receptors. Note that all of them are small and hydrophobic. The active, hydroxylated form of vitamin D_3 is shown. Estradiol and testosterone are steroid sex hormones.

heterodimers, but for simplicity we show them as monomers. (A) The receptors all have a related structure, which includes three major domains. An inactive receptor is bound to inhibitory proteins. (B) Typically, the binding of ligand to the receptor causes the ligand-binding domain of the receptor to clamp shut around the ligand. the inhibitory proteins to dissociate. and coactivator proteins to bind to the receptor's transcription-activating domain, thereby increasing gene transcription. In other cases, ligand binding has the opposite effect, causing co-repressor proteins to bind to the receptor, thereby decreasing transcription (not shown). (C) The structure of the ligand-binding domain of the retinoic acid receptor is shown in the absence (left) and presence (middle) of ligand (shown in red). When ligand binds, the blue α helix acts as a lid that snaps shut, trapping the ligand in place. The shift in the conformation of the receptor upon ligand binding also creates a binding site for a small α helix (orange) on the surface of coactivator proteins. (PDB codes: 6HN6, 2ZY0, and 2ZXZ.)

Figure 15-66 The activation of

nuclear receptors. All nuclear receptors

bind to DNA as either homodimers or

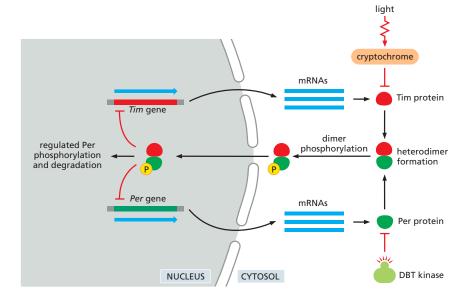

Circadian Clocks Use Negative Feedback Loops to Control Gene Expression

Life on Earth evolved in the presence of a daily cycle of day and night, and many present-day organisms possess an internal rhythm that regulates different behaviors at different times of day and night. These behaviors range from the cyclical change in metabolic enzyme activities of a bacterium to the elaborate sleep-wake cycles of humans. The intracellular oscillators that control such diurnal rhythms are called **circadian clocks**.

Having a circadian clock enables an organism to anticipate the regular daily changes in its environment and take appropriate action in advance. Of course, the internal clock cannot be perfectly accurate, and so it must be capable of being reset by external cues such as the light of day. Nonetheless, circadian clocks keep running even when the environmental cues (changes in light and dark) are removed, but the period of this free-running rhythm is generally a little less or more than 24 hours. External signals indicating the time of day cause small adjustments in the running of the clock, so as to keep the organism in synchrony with its environment. After more drastic shifts, circadian cycles become gradually reset (entrained) by the new cycle of light and dark, as anyone who has experienced jet lag can attest.

We might expect that the circadian clock would be a complex multicellular device, with different groups of cells responsible for different parts of the oscillation mechanism. Remarkably, however, in almost all multicellular organisms, including humans, the timekeepers are individual cells. Thus, our diurnal cycles of sleeping and waking, body temperature, and hormone release are controlled by a clock that operates in each member of a specialized group of brain cells in the suprachiasmatic nucleus (SCN) of the hypothalamus. Even if these cells are removed from the brain and dispersed in a culture dish, they will continue to oscillate individually, showing a cyclic pattern of gene expression with a period of approximately 24 hours. In the intact body, the SCN cells receive neural cues from the retina, entraining the SCN cells to the daily cycle of light and dark. SCN cells send information about the time of day to other brain areas, as well as the pineal gland, which relays the time signal to the rest of the body by releasing the hormone melatonin in time with the clock.

MBOC7_ptr_ch15_873-948.indd 937 08/12/21 12:24 PM

Although the SCN is the central regulator of the circadian rhythm in mammals, most of the other cells in the mammalian body also have circadian clocks, which have the ability to reset in response to light. Similarly, in *Drosophila*, many different types of cells have a similar circadian clock, which continues to cycle when isolated from the rest of the fly and can be reset by externally imposed light and dark cycles.

Circadian clocks are therefore a fundamental feature of many cells. Although we do not yet understand how these clocks work in detail, studies in a wide variety of organisms have revealed the basic principles and molecular components of some of them. A key principle is that circadian clocks generally depend on negative feedback loops. As discussed earlier, oscillations in the activity of an intracellular signaling protein can occur if that protein inhibits its own activity with a long delay (see Figure 15-19C and D). In Drosophila and many other animals, including humans, the heart of the circadian clock is a delayed negative feedback loop based on transcription regulators: accumulation of certain gene products switches off the transcription of their own genes, but with a delay, so that the cell oscillates between a state in which the products are present and transcription is switched off, and one in which the products are absent and transcription is switched on (Figure 15-67). The negative feedback underlying circadian rhythms is not always based on transcription regulators, however. In some cell types, the circadian clock is constructed of proteins that govern their own activities through post-translational mechanisms, as we discuss next.

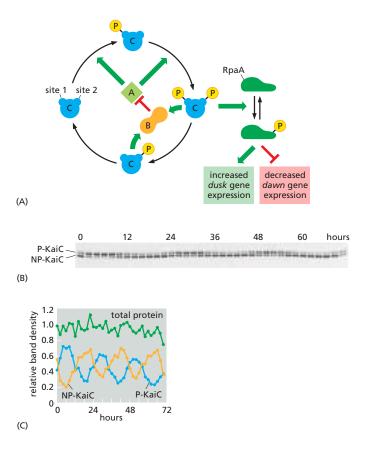

Three Purified Proteins Can Reconstitute a Cyanobacterial Circadian Clock in a Test Tube

The best understood circadian clock is found in the photosynthetic cyanobacterium *Synechococcus elongatus*. The core oscillator in this organism is remarkably simple, being composed of just three proteins—*KaiA*, *KaiB*, and *KaiC*. The central player is KaiC, a multifunctional enzyme that catalyzes its own phosphorylation and dephosphorylation in a 24-hour cycle: it gradually phosphorylates itself sequentially at two sites during the day and dephosphorylates itself during the night. This timing depends on interactions with the two other Kai proteins: KaiA binds to unphosphorylated KaiC in the morning and stimulates KaiC autophosphorylation, first at one site and then, with a lengthy delay, at the other. At nightfall, the second phosphorylation promotes the gradual binding of the third

Figure 15-67 Simplified outline of the mechanism of the circadian clock in Drosophila cells. A central feature of the clock is the periodic accumulation and decay of two transcription regulatory proteins, Tim (short for timeless, based on the phenotype when its gene is inactivated) and Per (short for period). The levels of mRNAs encoding these proteins increase gradually during the day and are translated in the cytoplasm, where the two proteins slowly associate to form a Tim-Per heterodimer. The heterodimer is transported into the nucleus, where it represses the Tim and Per genes, resulting in negative feedback that causes the levels of Tim and Per proteins to fall during the night. Decreased Per and Tim levels remove the negative feedback, allowing renewed expression of Tim and Per genes the following day. In addition to this transcriptional feedback, the clock depends on numerous other proteins that influence the period of the circadian oscillator through post-translational modifications. For example, a protein kinase called Doubletime (DBT) promotes the degradation of Per in the cytoplasm, thereby delaying the formation of the Tim-Per dimer. Once formed, the nuclear import of the dimer depends on phosphorylation and glycosylation of one or both proteins, introducing additional delays that further influence the timing of the clock

Entrainment (or resetting) of the clock occurs in response to new light-dark cycles. Although most *Drosophila* cells do not have true photoreceptors, light is sensed by intracellular flavoproteins called cryptochromes, which, in the presence of light, associate with the Tim protein and cause its degradation, thereby resetting the clock. (Adapted from J.C. Dunlap, *Science* 311:184–186, 2006.)

MBOC7_ptr_ch15_873-948.indd 938 08/12/21 12:24 PM

protein, KaiB, which blocks the stimulatory effect of KaiA and thereby allows KaiC to dephosphorylate itself, slowly bringing KaiC back to its dephosphorylated state during the night. This clock depends on a negative feedback loop: KaiC drives its own phosphorylation until, after a delay, it recruits an inhibitor, KaiB, that stimulates KaiC to dephosphorylate itself. Amazingly, when the three Kai proteins are purified and incubated in a test tube with ATP, the KaiC phosphorylation cycle occurs with roughly 24-hour timing for several days (Figure 15–68).

Circadian oscillations in KaiC phosphorylation lead to parallel rhythms in the expression of a large number of genes involved in controlling metabolic activities and cell division (see Figure 15–68). Many aspects of cell behavior are thereby synchronized with the circadian cycle.

Even in continual darkness, cyanobacterial cells generate free-running oscillations of KaiC phosphorylation with roughly 24-hour periods. Like other circadian clocks, the cyanobacterial clock is entrained by the environmental light-dark cycle. Light is thought to affect the clock indirectly: the activities of Kai proteins are influenced by changes in intracellular redox potential, which occur as a result of increased photosynthetic activity during the day.

Summary

Some signaling pathways that are especially important in animal development depend on proteolysis to control the activity and location of latent transcription regulators. Notch proteins are latent transcription regulators that are activated by cleavage when Delta proteins on another cell binds to them; the cleaved cytosolic tail of Notch migrates into the nucleus, where it stimulates the transcription of Notch-responsive genes. In the Wnt/ β -catenin signaling pathway, by contrast, the proteolysis of the latent transcription regulatory protein β -catenin is inhibited when a secreted Wnt protein binds to both a Frizzled and an LRP receptor protein;

Figure 15-68 The core circadian oscillator of cyanobacteria. (A) KaiC protein (C, blue) is a combined kinase and phosphatase that phosphorylates and dephosphorylates itself on two adjacent sites. In the absence of other proteins, the phosphatase activity is dominant, and the protein is mostly unphosphorylated. During the day, the binding of KaiA (A, green) to KaiC suppresses the phosphatase activity and promotes the kinase activity, leading to KaiC phosphorylation, first at site 1 and then, slowly, at site 2, resulting in diphosphorylated KaiC. This form of KaiC interacts with KaiB (B. orange). which blocks the stimulatory effects of KaiA, thereby reducing the rate of KaiC phosphorylation and allowing dephosphorylation at both sites to occur by the end of the night. KaiB then dissociates, allowing KaiA to promote KaiC phosphorylation again. Diphosphorylated KaiC increases in abundance during the day and peaks around dusk. It activates other proteins that phosphorylate a transcription regulator called RpaA (dark green), which then stimulates expression of certain genes that peak in early evening (the dusk genes) and inhibits expression of other genes that peak in the morning (the dawn genes). When KaiC dephosphorylation gradually occurs during the night, these effects are reversed: dusk genes are turned off and dawn genes are turned on. (B) In this experiment, the three Kai proteins were purified and mixed in a test tube with ATP (which is required for KaiC kinase activity). Every 2 hours over the next 3 days, the KaiC protein was analyzed by polyacrylamide-gel electrophoresis, in which the phosphorylated form of KaiC migrates more slowly (upper band. P-KaiC) than the nonphosphorvlated form (lower band, NP-KaiC). The three different phosphorylated forms of KaiC are not distinguished by this method. The phosphorvlation of KaiC oscillates with a roughly 24-hour period. (C) The amount of phosphorylated and unphosphorylated KaiC in the experiment in B is plotted on this graph, along with the amount of total protein. (B and C, from M. Nakajima et al., Science 308:414-415, 2005. With permission from AAAS.)

MBOC7_ptr_ch15_873-948.indd 939 08/12/21 12:24 PM

as a result, β -catenin accumulates in the nucleus and activates the transcription of Wnt target genes.

Hedgehog signaling also depends on activation of latent transcription regulators—members of the Gli protein family. In the absence of a signal, Gli3 is proteolytically cleaved to form a transcription repressor that keeps Hedgehog target genes silenced. The unoccupied Hedgehog receptor, Patched, also blocks activation of another Gli family member, Gli2. The binding of Hedgehog to Patched has two effects: it inhibits the proteolytic processing of Gli3, thereby removing its inhibitory effect on gene expression, and it also triggers activation of Gli2, further promoting target gene expression. Thus, in Notch, Wnt, and Hedgehog signaling, the extracellular signal triggers a switch from transcriptional repression to transcriptional activation.

Signaling through the latent transcription regulator NF κ B also depends on proteolysis. NF κ B proteins are normally held in an inactive state in the cytoplasm by inhibitory I κ B proteins. A variety of extracellular stimuli, including proinflammatory cytokines, trigger the degradation of I κ B, allowing NF κ B to translocate to the nucleus and activate the transcription of its target genes.

Some small, hydrophobic signal molecules, including steroid and thyroid hormones, diffuse across the plasma membrane of the target cell and activate intracellular receptor proteins that directly regulate the transcription of specific genes.

In many cell types, gene expression is governed by circadian clocks, in which delayed negative feedback produces 24-hour oscillations in the activities of transcription regulators, anticipating the cell's changing needs during the day and night.

SIGNALING IN PLANTS

In plants, as in animals, cells are in constant communication with one another. Plant cells communicate to coordinate their activities in response to the changing conditions of light, dark, and temperature, which guide the plant's cycle of growth, flowering, and fruiting. Plant cells also communicate to coordinate activities in their roots, stems, and leaves. In this final section, we consider how plant cells signal to one another and how they respond to light. Less is known about the receptors and intracellular signaling mechanisms involved in cell communication in plants than is known about that in animals, and we will concentrate mainly on how the receptors and intracellular signaling mechanisms differ from those used by animals.

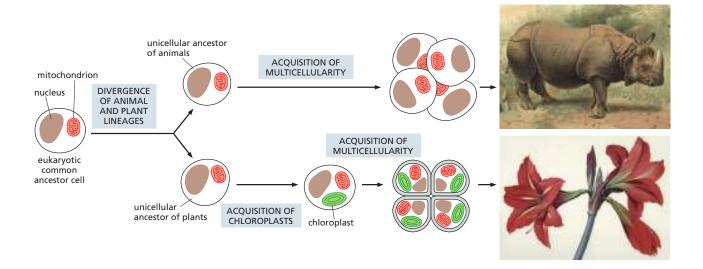

Multicellularity and Cell Communication Evolved Independently in Plants and Animals

Although plants and animals are both eukaryotes, they have evolved separately for more than a billion years. Their last common ancestor is thought to have been a unicellular eukaryote that had mitochondria but no chloroplasts; the plant lineage acquired chloroplasts after plants and animals diverged. The earliest fossils of multicellular animals and plants date from almost 600 million years ago. Thus, it seems that plants and animals evolved multicellularity independently, each starting from a different unicellular eukaryote, sometime between 1.6 and 0.6 billion years ago (Figure 15–69).

If multicellularity evolved independently in plants and animals, some of the molecules and mechanisms used for cell communication will have evolved separately and would be expected to be different. Indeed, whereas both plants and animals use nitric oxide, cyclic GMP, Ca^{2^+} , protein kinases, and small GTPases for signaling, modern flowering plants do not appear to contain homologs of the nuclear receptor family, JAK, STAT, TGF β , Notch, Wnt, or Hedgehog signaling pathways. Similarly, plants do not seem to use cyclic AMP for intracellular signaling. Nevertheless, the general strategies underlying signaling are similar in plants and animals. Both, for example, use enzyme-coupled cell-surface receptors, as we now discuss.

MBOC7_ptr_ch15_873-948.indd 940 08/12/21 12:24 PM

SIGNALING IN PLANTS 941

Receptor Serine/Threonine Kinases Are the Largest Class of Cell-Surface Receptors in Plants

Most cell-surface receptors in plants are enzyme-coupled. However, whereas the largest class of enzyme-coupled receptors in animals is the receptor tyrosine kinase (RTK) class, this type of receptor is extremely rare in plants. Instead, plants rely largely on a great diversity of transmembrane *receptor serine/threonine kinases*, which have a typical serine/threonine kinase cytoplasmic domain and an extracellular ligand-binding domain. The most abundant types of these receptors have a tandem array of extracellular leucine-rich repeat structures and are therefore called **leucine-rich repeat (LRR) receptor kinases**.

There are about 175 LRR receptor kinases encoded in the genome of the small flowering plant *Arabidopsis thaliana*. These include a protein called *Bri1*, which forms part of a cell-surface steroid hormone receptor. Plants synthesize a class of steroids that are called **brassinosteroids** because they were originally identified in the mustard family *Brassicaceae*, which includes *Arabidopsis*. These signal molecules regulate the growth and differentiation of plants throughout their life cycle. Binding of a brassinosteroid to a Bri1 cell-surface receptor kinase initiates an intracellular signaling cascade that uses a GSK3 protein kinase and a protein phosphatase to regulate the phosphorylation and degradation of specific transcription regulatory proteins in the nucleus, and thereby specific gene transcription. Mutant plants that are deficient in the Bri1 receptor kinase are insensitive to brassinosteroids and are therefore dwarfs.

The LRR receptor kinases are only one of many classes of transmembrane receptor serine/threonine kinases in plants. There are at least six additional families, each with its own characteristic set of extracellular domains. The *lectin receptor kinases*, for example, have extracellular domains that bind carbohydrate signal molecules. The *Arabidopsis* genome encodes more than 300 receptor serine/threonine kinases, which makes them the largest family of receptors known in plants. Many are involved in defense responses against pathogens.

Ethylene Blocks the Degradation of Specific Transcription Regulatory Proteins in the Nucleus

Various **plant growth regulators** (also called **plant hormones**) help to coordinate plant development. They include *ethylene, auxin, cytokinins, gibberellins,* and *abscisic acid,* as well as brassinosteroids. Growth regulators are all small molecules made by most plant cells. They diffuse readily through cell walls and can either act locally or be transported to influence cells further away. Each growth

Figure 15–69 The proposed divergence of plant and animal lineages from a common unicellular eukaryotic ancestor. The plant lineage acquired chloroplasts after the two lineages diverged. Both lineages independently gave rise to multicellular organisms—plants and animals. (Paintings courtesy of John Innes Foundation.)

MBOC7_ptr_ch15_873-948.indd 941 08/12/21 12:24 PM

regulator can have multiple effects. The specific effect depends on environmental conditions, the nutritional state of the plant, the responsiveness of the target cells, and which other growth regulators are acting.

Ethylene is an important example. This small gas molecule (Figure 15–70A) can influence plant development in various ways; it can, for example, promote fruit ripening, leaf abscission, and plant senescence. It also functions as a stress signal in response to wounding, infection, flooding, and so on. When the shoot of a germinating seedling, for instance, encounters an obstacle, ethylene promotes a complex response that allows the seedling to safely bypass the obstacle (Figure 15–70B and C).

Plants have various ethylene receptors, which are located in the endoplasmic reticulum and are all structurally related. They are dimeric, multipass transmembrane proteins, with a copper-containing ethylene-binding domain and a domain that interacts with a cytoplasmic protein called *CTR1*, which is closely related in amino acid sequence to the Raf MAP kinase kinase kinase discussed earlier (see Figure 15–50). Surprisingly, it is the empty receptors that are active and keep CTR1 active. By an unknown signaling mechanism, active CTR1 stimulates the ubiquitylation and degradation in proteasomes of a nuclear transcription regulator called *EIN3*, which is required for the transcription of ethylene-responsive genes. In this way, the empty but active receptors keep ethylene-response genes off. Ethylene binding inactivates the receptors, altering their conformation so that they no longer activate CTR1. The EIN3 protein is no longer ubiquitylated and degraded and can now activate the transcription of the large number of ethylene-responsive genes (Figure 15–71).

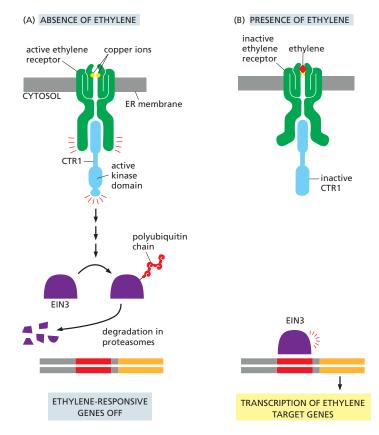

Figure 15–71 The ethylene signaling pathway. (A) In the absence of ethylene, the receptors and CTR1 are active, causing the ubiquitylation and destruction of EIN3, the transcription regulatory protein in the nucleus that is responsible for the transcription of ethylene-responsive genes. (B) The binding of ethylene inactivates the receptors and disrupts the activation of CTR1. The EIN3 protein is not degraded and can therefore activate the transcription of ethylene-responsive genes.

(A)

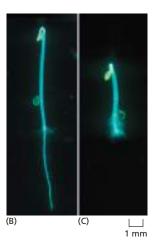

Figure 15-70 The ethylene-mediated triple response that occurs when the growing shoot of a germinating seedling encounters an obstacle underground. (A) The structure of ethylene. (B) In the absence of obstacles, the shoot grows upward and is long and thin. (C) If the shoot encounters an obstacle, such as a piece of gravel in the soil, the seedling responds to the encounter in three ways. First, it thickens its stem, which can then exert more force on the obstacle. Second, it shields the tip of the shoot (at top) by increasing the curvature of a specialized hook structure. Third, it reduces the shoot's tendency to grow away from the direction of gravity, so as to avoid the obstacle. (Courtesy of Melanie Webb.)

SIGNALING IN PLANTS 943

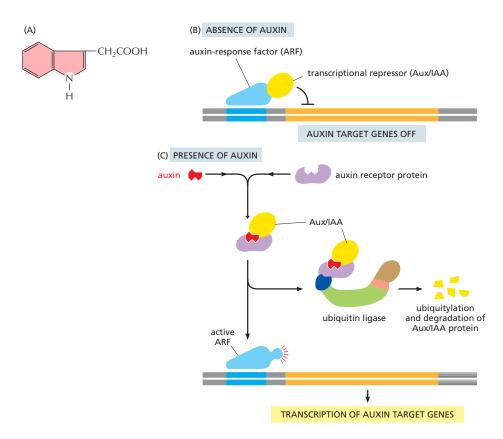

Regulated Positioning of Auxin Transporters Patterns Plant Growth

The plant hormone auxin (Figure 15–72A) binds to receptor proteins in the nucleus. It helps plants grow toward light, grow upward rather than branch out, and grow their roots downward. It also regulates organ initiation and positioning and helps plants flower and bear fruit. Like ethylene (and some of the animal signal molecules we have described in this chapter), auxin influences gene expression by controlling the degradation of transcription regulators. It works by stimulating the ubiquitylation and degradation of repressor proteins that block the transcription of auxin target genes in unstimulated cells (Figure 15–72B and C).

Auxin is unique in the way that it is transported. Unlike animal hormones, which are usually secreted by a specific endocrine gland and transported to target cells via the circulatory system, auxin has its own transport system. Specific plasmamembrane-bound *influx transporter proteins* and *efflux transporter proteins* move auxin into and out of plant cells, respectively. The efflux transporters can be distributed asymmetrically in the plasma membrane to make the efflux of auxin directional. A row of cells with their auxin efflux transporters confined to the basal plasma membrane, for example, will transport auxin from the top of the plant to the bottom.

In some regions of the plant, the localization of the auxin transporters, and therefore the direction of auxin flow, is highly dynamic and regulated. A cell can rapidly redistribute transporters by controlling the traffic of vesicles containing them. The auxin efflux transporters, for example, normally recycle between intracellular vesicles and the plasma membrane. A cell can redistribute these transporters on its surface by inhibiting their endocytosis in one domain of the plasma membrane, causing the transporters to accumulate there. One example occurs in the root, where gravity influences the direction of growth. The auxin efflux transporters are normally distributed symmetrically in the cap cells of the root. Within minutes of a change in the direction of the gravity vector, however, the efflux transporters redistribute to one side of the cells, so that auxin is pumped

Figure 15-72 The auxin signaling pathway. (A) The structure of auxin (indole-3-acetic acid). (B) In the absence of auxin, a transcription repressor protein (called Aux/IAA) binds and suppresses a transcription regulator (called auxinresponse factor; ARF), which is required for the transcription of auxin-responsive genes. (C) The auxin receptor proteins are located mainly in the nucleus. When activated by auxin binding, the receptorauxin complex recruits a ubiquitin ligase, which ubiquitylates the Aux/IAA protein, marking it for degradation in proteasomes ARF is now free to activate the transcription of auxin-responsive genes. There are many ARFs, Aux/IAA proteins, and auxin receptors that work as illustrated.

MBOC7_ptr_ch15_873-948.indd 943 08/12/21 12:24 PM

944 Chapter 15: Cell Signaling

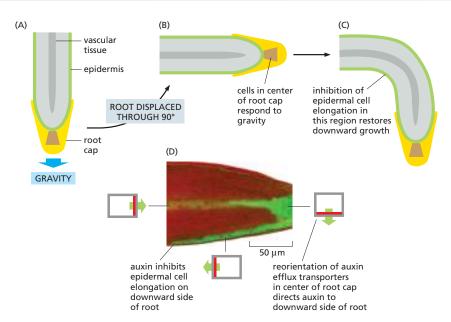

Figure 15–73 Auxin transport and root gravitropism. (A–C) Roots respond to a 90° change in the gravity vector and adjust their direction of growth so that they grow downward again. The cells that respond to gravity are in the center of the root cap, while it is the epidermal cells further back (on the lower side) that decrease their rate of elongation to restore downward growth. (D) The gravity-responsive cells in the root cap redistribute their auxin efflux transporters in response to the displacement of the root. This redirects the auxin flux mainly to the lower part of the displaced root, where it inhibits the elongation of the epidermal cells. The resulting asymmetrical distribution of auxin in the *Arabidopsis* root tip shown here is assessed indirectly, using an auxin-responsive reporter gene that encodes a protein fused to green fluorescent protein (GFP); the epidermal cells on the downward side of the root are green, whereas those on the upper side are not, reflecting the asymmetrical distribution of auxin. The distribution of auxin efflux transporters in the plasma membrane of cells in different regions of the root (shown as *gray rectangles*) is indicated in *red*, and the direction of auxin efflux is indicated by a *green arrow*. (D, photograph from T. Paciorek et al., *Nature* 435:1251–1256, published 2005 by Nature Publishing Group. Reproduced with permission of SNCSC.)

out toward the side of the root pointing downward. Because auxin inhibits root-cell elongation, this redirection of auxin transport causes the root tip to re-orient, so that it grows downward again (Figure 15–73).

Phytochromes Detect Red Light, and Cryptochromes Detect Blue Light

Plant development is greatly influenced by environmental conditions. Unlike animals, plants cannot move when conditions become unfavorable; they have to adapt or they die. The most important environmental influence on plants is light, which is their energy source and has a major role throughout their life cycle—from germination, through seedling development, to flowering and senescence. Plants have thus evolved a large set of light-sensitive proteins to monitor the quantity, quality, direction, and duration of light. These are usually referred to as *photoreceptors*. However, because the term photoreceptor is also used for light-sensitive cells in the animal retina (see Figure 15–39), we will use the term *photoprotein* instead.

All photoproteins sense light by means of a covalently attached light-absorbing chromophore, which changes its shape in response to light and then induces a change in the protein's conformation. The best-known plant photoproteins are the **phytochromes**, which are present in all plants and in some algae but are absent in animals. These are dimeric, cytoplasmic serine/threonine kinases, which respond differentially and reversibly to red and far-red light: whereas red light usually activates the kinase activity of the phytochrome, far-red light inactivates it. When activated by red light, the phytochrome is thought to phosphorylate itself

MBOC7_ptr_ch15_873-948.indd 944 08/12/21 12:24 PM

SIGNALING IN PLANTS 945

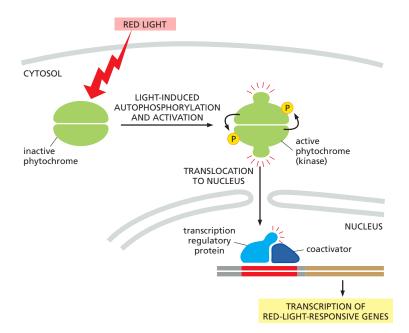

Figure 15–74 One way in which phytochromes mediate a light response in plant cells. When activated by red light, the phytochrome, which is a dimeric protein kinase, phosphorylates itself and then moves into the nucleus, where it activates transcription regulatory proteins to stimulate the transcription of red-light-responsive genes.

and then to phosphorylate one or more other proteins in the cell. In some light responses, the activated phytochrome translocates into the nucleus, where it activates transcription regulators to alter gene transcription (Figure 15–74). In other cases, the activated phytochrome activates a latent transcription regulator in the cytoplasm, which then translocates into the nucleus to regulate gene transcription. In still other cases, the activated phytochrome triggers signaling pathways in the cytosol that alter the cell's behavior without involving the nucleus.

Plants sense blue light using photoproteins of two other sorts, phototropin and cryptochromes. **Phototropin** is associated with the plasma membrane and is partly responsible for *phototropism*, the tendency of plants to grow toward light. Phototropism occurs by directional cell elongation, which is stimulated by auxin, but the links between phototropin and auxin are unknown.

Cryptochromes are flavoproteins that are sensitive to blue light. They are structurally related to blue-light-sensitive enzymes called *photolyases*, which are involved in the repair of ultraviolet-induced DNA damage in all organisms, except most mammals. Unlike phytochromes, cryptochromes are also found in animals, where they have an important role in circadian clocks (see Figure 15–67). Although cryptochromes are thought to have evolved from the photolyases, they do not have a role in DNA repair.

Summary

The mechanisms used to signal between cells in animals and in plants have both similarities and differences. Whereas animals rely heavily on GPCRs and RTKs, plants rely mainly on enzyme-coupled receptors of the receptor serine/threonine kinase type, especially those with extracellular leucine-rich repeats. Various plant hormones, or growth regulators, including ethylene and auxin, help coordinate plant development. Ethylene acts through intracellular receptors to stop the degradation of specific nuclear transcription regulators, which can then activate the transcription of ethylene-responsive genes. The receptors for some other plant hormones, including auxin, also regulate the degradation of specific transcription regulators, although the details vary. Auxin signaling is unusual in that it has its own highly regulated transport system, in which the dynamic positioning of plasmamembrane-bound auxin transporters controls the direction of auxin flow and thereby the direction of plant growth. Light has an important role in regulating plant development. These light responses are mediated by a variety of light-sensitive photoproteins, including phytochromes, which are responsive to red light, and cryptochromes and phototropin, which are sensitive to blue light.

MBOC7_ptr_ch15_873-948.indd 945 08/12/21 12:24 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **15–1** All second messengers are water soluble and diffuse freely through the cytosol.
- **15–2** In the regulation of molecular switches, protein kinases and guanine nucleotide exchange factors (GEFs) always turn proteins on, whereas protein phosphatases and GTPase-activating proteins (GAPs) always turn proteins off.
- **15–3** Most intracellular signaling pathways provide numerous opportunities for amplifying the responses to extracellular signals.
- **15–4** Binding of extracellular ligands to receptor tyrosine kinases (RTKs) activates the intracellular catalytic domain by propagating a conformational change across the lipid bilayer through a single transmembrane α helix.
- **15–5** Even though plants and animals independently evolved multicellularity, they use virtually all the same signaling proteins and second messengers for cell-cell communication.

Discuss the following problems.

- 15–6 Cells communicate in ways that resemble human communication. Decide which of the following forms of human communication are analogous to autocrine, paracrine, endocrine, and synaptic signaling by cells.
- A. A telephone conversation
- B. Talking to people at a cocktail party
- C. A radio announcement
- D. Talking to yourself
- **15–7** Suppose that the circulating concentration of hormone is 10^{-10} M and the $K_{\rm d}$ for binding to its receptor is 10^{-8} M. What fraction of the receptors will have hormone bound? If a meaningful physiological response occurs when 50% of the receptors have bound a hormone molecule, how much will the concentration of hormone have to rise to elicit a response? The fraction of receptors (R) bound to hormone (H) to form a receptor-hormone complex (R-H) is $[R-H]/([R] + [R-H]) = [R-H]/[R]_{TOT} = [H]/([H] + K_{\rm d})$.
- **15–8** How is it that different cells can respond in different ways to exactly the same signaling molecule even when they have identical receptors?
- **15–9** Why do you suppose that phosphorylation/dephosphorylation, as opposed to allosteric binding of small molecules, for example, has evolved to play such a prominent role in switching proteins on and off in signaling pathways?
- **15–10** Consider a signaling pathway that proceeds through three protein kinases that are sequentially activated by phosphorylation. In one case, the kinases are

held in a signaling complex by a scaffold protein; in the other, the kinases are freely diffusible (Figure Q15-1). Discuss the properties of these two types of organization in terms of signal amplification, speed, and potential for cross-talk between signaling pathways.

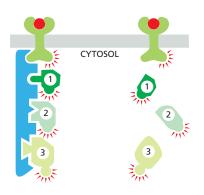

Figure Q15–1 A kinase cascade organized by a scaffold protein or composed of freely diffusing components (Problem 15–10).

15–11 Describe three ways in which a gradual increase in an extracellular signal can be sharpened by the target cell to produce an abrupt or nearly all-or-none response.

15–12 Why do signaling responses that involve changes in proteins already present in the cell occur in milliseconds to seconds, whereas responses that require changes in gene expression require minutes to hours?

15–13 Propose a specific type of mutation in the gene for the regulatory subunit of cyclic-AMP-dependent protein kinase (PKA) that could lead to a permanently active PKA.

15–14 Phosphorylase kinase integrates signals from the cyclic-AMP-dependent and Ca^{2+} -dependent signaling pathways that control glycogen breakdown in liver and muscle cells (**Figure Q15–2**). Phosphorylase kinase is composed of four subunits. One subunit is the protein kinase that catalyzes the addition of phosphate to glycogen phosphorylase to activate it for glycogen breakdown. The other three subunits are regulatory proteins that control the activity of the catalytic subunit. Two contain sites for phosphorylation by PKA, which is activated by cyclic AMP. The remaining subunit is calmodulin, which binds Ca^{2+} when the cytosolic Ca^{2+} concentration rises. The

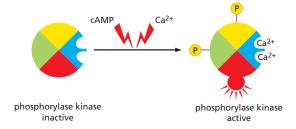

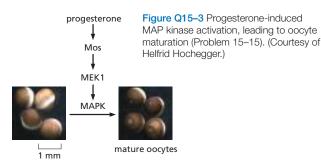

Figure Q15–2 Integration of cyclic-AMP-dependent and Ca²⁺-dependent signaling pathways by phosphorylase kinase in liver and muscle cells (Problem 15–14).

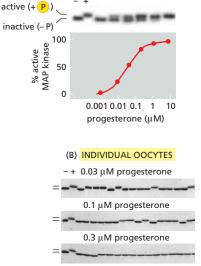

MBOC7_ptr_ch15_873-948.indd 946 08/12/21 12:24 PM

PROBLEMS 947

regulatory subunits control the equilibrium between the active and inactive conformations of the catalytic subunit, with each phosphate and Ca²⁺ nudging the equilibrium toward the active conformation. How does this arrangement allow phosphorylase kinase to serve its role as an integrator protein for the two pathways that stimulate glycogen breakdown?

15–15 Activation ("maturation") of frog oocytes is signaled through a MAP kinase signaling module. An increase in the hormone progesterone triggers the module by stimulating the translation of mRNA encoding Mos, which is the frog's MAP kinase kinase kinase (Figure Q15-3). Maturation is easy to score visually by the presence of a white spot in the middle of the brown surface of the oocyte (see Figure Q15-3). To determine the dose-response curve for progesterone-induced activation of MAP kinase, you place 16 oocytes in each of six plastic dishes and add various concentrations of progesterone. After an overnight incubation, you crush the oocytes, prepare an extract, and determine the state of MAP kinase phosphorylation (hence, activation) by SDS polyacrylamide-gel electrophoresis (Figure Q15-4A). This analysis shows a graded increase in MAP kinase activity with increasing concentrations of progesterone.

(A) POOLED OOCYTES

Figure Q15-4 Activation of frog oocytes (Problem 15-15) (A) Phosphorylation of MAP kinase in pooled oocytes. (B) Phosphorylation of MAP kinase in individual oocytes. MAP kinase was detected by immunoblottina usina a MAP-kinase-specific antibody. The first two lanes in each gel contain nonphosphorylated, inactive MAP kinase (-) and phosphorylated. active MAP kinase (+) respectively. (From J.E. Ferrell, Jr., and E.M. Machleder, Science 280:895-898, 1998. With permission from AAAS.)

Before you crushed the oocytes, you noticed that not all the oocytes in individual dishes had white spots. Had some oocytes undergone partial activation and not yet reached the white-spot stage? To answer this question, you repeat the experiment, but this time you analyze MAP kinase activation in individual oocytes. You are surprised to find that each oocyte has either a fully activated or a completely inactive MAP kinase (Figure Q15-4B). How can an all-or-none response in individual oocytes give rise to a graded response in the population?

15–16 The Wnt planar polarity signaling pathway normally ensures that each wing cell in *Drosophila* has a single hair. Overexpression of the *Frizzled* gene from a heat-shock promoter (hs-Fz) causes multiple hairs to grow from many cells (**Figure Q15–5A**). This phenotype is suppressed if hs-Fz is combined with a heterozygous deletion (Dsh^{Δ}) of the *Dishevelled* gene (**Figure Q15–5B**). Do these results allow you to order the action of Frizzled and Dishevelled in the signaling pathway? If so, what is the order? Explain your reasoning.

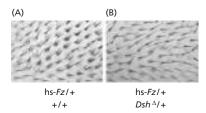

Figure Q15–5 Pattern of hair growth on wing cells in genetically different *Drosophila* (Problem 15–16). (From C.G. Winter et al., *Cell* 105:81–91, 2001. With permission from Elsevier.)

15–17 The last common ancestor to plants and animals was a unicellular eukaryote. Thus, it is thought that multicellularity and the attendant demands for cell communication arose independently in these two lineages. This evolutionary viewpoint accounts nicely for the vastly different mechanisms that plants and animals use for cell communication. Fungi use signaling mechanisms and components that are very similar to those used in animals. Which of the phylogenetic trees shown in Figure Q15–6 do these observations support?

The Cytoskeleton

CHAPTER

For cells to function properly, they must organize themselves in space and interact mechanically with each other and with their environment. They have to be correctly shaped, physically robust, and properly structured internally. Many have to change their shape and move from place to place. All cells have to be able to rearrange their internal components as they grow, divide, and adapt to changing circumstances. These spatial and mechanical functions depend on a remarkable system of filaments called the **cytoskeleton** (Figure 16–1).

The cytoskeleton's varied functions depend on the behavior of three main families of protein filaments-actin filaments, microtubules, and intermediate filaments. Each type of filament has distinct mechanical properties, dynamics, and biological roles, but all share certain fundamental features. Just as we require our ligaments, bones, and muscles to work together, so all three cytoskeletal filament systems must normally function collectively to give a cell its strength, its shape, and its ability to divide and move around.

In this chapter, we describe the function and evolutionary conservation of cellular filament systems. We explain the basic principles underlying filament assembly and disassembly and how other proteins interact with the filaments to alter their dynamics and direct their organization. Finally, we discuss how cytoskeletal systems work together with other cellular components to generate cell polarity, which is essential for many aspects of cell behavior and function.

FUNCTION AND DYNAMICS OF THE CYTOSKELETON

The three major cytoskeletal filaments are responsible for different aspects of the cell's spatial organization and mechanical properties. Actin filaments determine the shape of the cell's surface and are necessary for whole-cell locomotion; they also drive the pinching of one cell into two. Microtubules determine the positions of organelles, direct intracellular transport, and form the mitotic spindle that segregates chromosomes during cell division. Intermediate filaments provide mechanical strength. All of these cytoskeletal filaments interact with hundreds of accessory proteins that regulate and link the filaments to other cell components, as well as to each other. The accessory proteins are essential for the controlled assembly of the cytoskeletal filaments in particular locations, and they include the motor proteins, remarkable molecular machines that convert the energy of ATP hydrolysis into mechanical force that can either move organelles along the filaments or move the filaments themselves.

In this part of the chapter, we discuss the general features of the proteins that make up the filaments of the cytoskeleton. We focus on their ability to form intrinsically polarized and self-organized structures that are highly dynamic, allowing the cell to rapidly modify cytoskeletal structure and function when conditions change.

Cytoskeletal Filaments Are Dynamic, but Can Nevertheless Form Stable Structures

Cytoskeletal systems are dynamic and adaptable, organized more like ant trails than interstate highways. A single trail of ants may persist for many hours, extending from the ant nest to a delectable picnic site, but the individual ants within the trail are anything but static. If the ant scouts find a new and better source of food or if the picnickers clean up and leave, the dynamic structure adapts with astonishing rapidity. In a similar way, large-scale cytoskeletal structures can change or persist, according to need, lasting for lengths of time ranging from less than a minute up to the cell's lifetime. But the individual macromolecular components that make up these structures are in a constant state of flux. As a result, like the alteration of an ant trail, a structural rearrangement in a cell requires little extra energy when conditions change.

Regulation of the dynamic behavior and assembly of cytoskeletal filaments allows eukaryotic cells to build an enormous range of structures from the three basic filament systems. The micrographs in Panel 16–1 illustrate some of these structures. Actin filaments underlie the plasma membrane of animal cells in a layer called the *cell cortex*, providing strength and shape to the thin lipid bilayer. They also form many types of cell-surface projections. Some of these are dynamic structures, such as the *filopodia*, *lamellipodia*, and *pseudopodia* that cells use to explore territory and move around. More stable arrays allow cells to brace themselves against an underlying substratum and enable muscle to contract. The regular bundles of *stereocilia* on the surface of hair cells in the inner ear contain stable bundles of actin filaments that tilt as rigid rods in response to sound, and the *microvilli* on the surface of intestinal epithelial cells vastly increase the apical cell-surface area to enhance nutrient absorption. In plants, actin filaments drive rapid streaming of the cytoplasm inside cells.

Microtubules, which are frequently found in a cytoplasmic array that extends to the cell periphery, can quickly rearrange themselves to form a bipolar *mitotic spindle* during cell division. They can also form *cilia*, which function as motile whips or sensory devices on the surface of the cell, or tightly aligned bundles that serve as tracks for the transport of materials down long neuronal axons. In plant cells, organized arrays of microtubules help to direct the pattern of cell-wall synthesis, and in many protozoans they form the framework upon which the entire cell is built.

Intermediate filaments line the inner face of the nuclear envelope, forming a protective cage for the cell's DNA; in the cytosol, they are twisted into strong cables that can hold epithelial cell sheets together or help nerve cells to extend long and robust axons, and they allow us to form tough appendages such as hair and fingernails.

An important and dramatic example of rapid reorganization of the cytoskeleton occurs during cell division, as shown in **Figure 16-2** for a fibroblast growing in a tissue-culture dish. After the chromosomes have replicated, the interphase microtubule array that spreads throughout the cytoplasm is reconfigured into the bipolar *mitotic spindle*, which transfers the two copies of each chromosome into separate daughter nuclei. At the same time, the specialized actin structures that enable the fibroblast to crawl across the surface of the dish rearrange so that the cell stops moving and assumes a more spherical shape. Actin and its associated motor protein myosin then form a belt around the middle of the cell, the *contractile ring*, which constricts like a tiny muscle to pinch the cell in two. When division is complete, the cytoskeletons of the two daughter fibroblasts recreate their interphase structures, thereby converting the two rounded-up daughter cells into smaller versions of the flattened, crawling mother cell.

Many cells require rapid cytoskeletal rearrangements for their normal functioning during interphase as well. For example, the *neutrophil*, a type of white blood cell, chases and engulfs bacterial and fungal cells that accidentally gain

MBOC7_ptr_ch16_949-1026.indd 951 02/12/21 2:15 PM

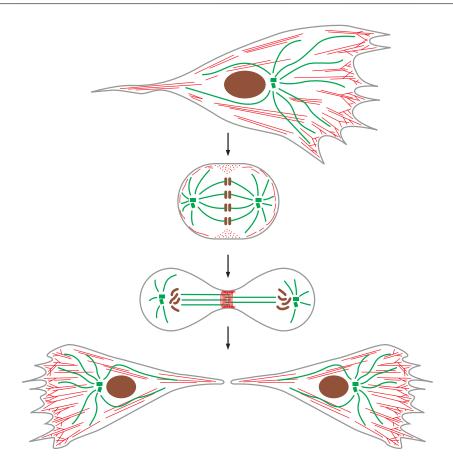

Figure 16-2 Diagram of changes in cytoskeletal organization associated with cell division. The crawling fibroblast drawn here has a polarized, dynamic actin cytoskeleton (shown in red) that assembles lamellipodia and filopodia to push its leading edge toward the right. The polarization of the actin cytoskeleton is assisted by the microtubule cytoskeleton (green), consisting of long microtubules that emanate from a microtubule-organizing center located in front of the nucleus. When the cell divides, actin filaments are reorganized and the cell assumes a spherical shape. The polarized microtubule array rearranges to form a bipolar mitotic spindle, which is responsible for aligning and then segregating the duplicated chromosomes (brown). After chromosome segregation, the actin filaments form a contractile ring at the center of the cell that pinches the cell in two. Then the two daughter cells reorganize their microtubule and actin cytoskeletons into smaller versions of those that were present in the mother cell, enabling them to crawl their separate ways.

access to the normally sterile parts of the body, as through a cut in the skin. Like most crawling cells, neutrophils advance by extending a protrusive structure filled with newly polymerized actin filaments. When the elusive bacterial prey moves in a different direction, the neutrophil can reorganize its polarized protrusive structures within seconds (Figure 16–3).

The Cytoskeleton Determines Cellular Organization and Polarity

In cells that have achieved a stable, differentiated morphology—such as mature neurons or epithelial cells—the dynamic elements of the cytoskeleton produce stable, large-scale structures for cellular organization. For example, on the specialized epithelial cells that line organs such as the intestine and the lung, cytoskeletal-based cell-surface protrusions including microvilli and cilia are able to maintain a constant location, length, and diameter over the entire lifetime of the cell. For the actin bundles at the cores of microvilli on intestinal epithelial cells, this is only a few days. But the actin bundles at the cores of

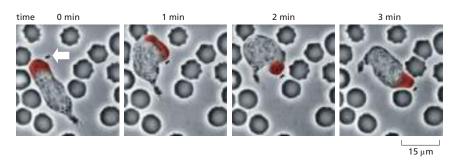

Figure 16–3 A neutrophil in pursuit of bacteria. In this preparation of human blood, a small clump of bacteria (white arrow) is about to be captured by a neutrophil. As the bacteria move, the neutrophil quickly reassembles the dense actin network within a pseudopod ("false foot") at its leading edge (highlighted in red) to push toward the location of the bacteria (Movie 16.1). Rapid disassembly and reassembly of the actin cytoskeleton in this cell enable it to change its orientation and direction of movement within a few minutes. (From a video recorded by David Rogers.)

MBOC7_ptr_ch16_949-1026.indd 952 02/12/21 2:15 PM

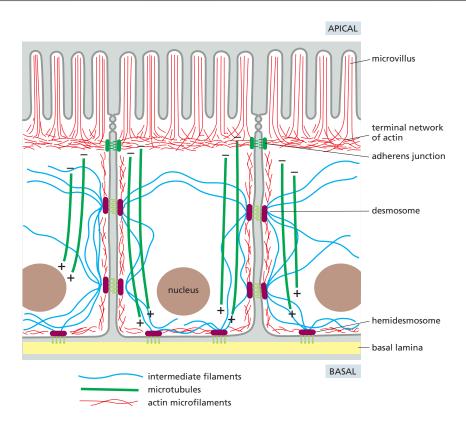

Figure 16-4 Organization of the cytoskeleton in polarized epithelial cells. All the components of the cytoskeleton cooperate to produce the characteristic shapes of specialized cells. including the epithelial cells that line the small intestine, diagrammed here. At the apical (upper) surface, facing the intestinal lumen, bundled actin filaments (red) form microvilli that increase the cell-surface area available for absorbing nutrients from food. Below the microvilli, a circumferential band of actin filaments is connected to cell-cell adherens junctions that anchor the cells to each other. Intermediate filaments (blue) are anchored to other kinds of adhesive structures, including desmosomes and hemidesmosomes, that connect the epithelial cells into a sturdy sheet and attach them to the underlying extracellular matrix: these structures are discussed in Chapter 19. Microtubules (green) run vertically from the top of the cell to the bottom and provide a global coordinate system that enables the cell to direct newly synthesized components to their proper locations.

stereocilia on the hair cells of the inner ear must maintain their stable organization for the entire lifetime of the animal, because these cells do not turn over. Remarkably, the actin filaments in stereocilia are very stable, and polymerization and depolymerization have been observed only at their tips. We do not understand how these actin structures are maintained at a constant length for decades.

Besides forming stable, specialized cell-surface protrusions, the cytoskeleton is also responsible for large-scale cellular polarity, enabling cells to tell the difference between top and bottom or front and back. The polarity information conveyed by cytoskeletal organization is often maintained over the lifetime of the cell. For example, polarized epithelial cells use organized arrays of microtubules, actin filaments, and intermediate filaments to maintain the critical differences between the *apical surface* and the *basolateral surface*. They also must maintain strong adhesive contacts with one another to enable this single layer of cells to serve as an effective physical barrier (Figure 16-4). How cell polarity is established is discussed in the last part of this chapter.

Filaments Assemble from Protein Subunits That Impart Specific Physical and Dynamic Properties

Cytoskeletal filaments can reach from one end of the cell to the other, spanning tens or even hundreds of micrometers. Yet the individual protein molecules that form the filaments are only a few nanometers in size. The cell builds the filaments by assembling large numbers of the small subunits, like building a skyscraper out of bricks. Because these subunits are small, they can diffuse rapidly in the cytosol, whereas the assembled filaments cannot. In this way, cells can undergo rapid structural reorganizations, disassembling filaments at one site and reassembling them at another site far away.

Actin filaments and microtubules are built from subunits that are compact and globular—actin subunits for actin filaments and tubulin subunits for

MBOC7_ptr_ch16_949-1026.indd 953 02/12/21 2:15 PM

microtubules—whereas intermediate filaments are made up of subunits that are themselves elongated and fibrous. All three major types of cytoskeletal filaments form as polymeric assemblies of subunits that self-associate, using a combination of end-to-end and side-to-side protein contacts. Whereas covalent linkages between their subunits hold together the backbones of many biological polymers—including DNA, RNA, and proteins—it is weak noncovalent interactions that hold together the three types of cytoskeletal polymers. Because covalent bonds are not being formed or broken, assembly and disassembly can occur rapidly. Differences in the structures of the subunits and how they associate with one another produce important differences in the stability and mechanical properties of each type of filament.

The subunits of actin filaments and microtubules are asymmetrical and bind to one another head-to-tail so that they all point in one direction. This subunit polarity gives the filaments structural polarity along their length and makes the two ends of each polymer behave differently. In addition, the actin and tubulin subunits are enzymes that catalyze the hydrolysis of a nucleoside triphosphate (NTP)—ATP and GTP, respectively. As we discuss later, the energy derived from NTP hydrolysis helps the filaments to remodel rapidly. It allows the cell to harness the polar and dynamic properties of these filaments to generate force in a specific direction to move the leading edge of a migrating cell forward, for example, or to pull chromosomes apart during cell division. In contrast, the subunits of intermediate filaments are symmetrical and thus do not form polarized filaments with two different ends. Intermediate filament subunits also do not catalyze the hydrolysis of ATP or GTP. Nevertheless, intermediate filaments can be disassembled rapidly when required. In mitosis, for example, kinases phosphorylate the subunits, leading to their dissociation.

Cytoskeletal filaments in living cells are not built by simply stringing subunits together in single file. A thousand tubulin subunits lined up end-to-end, for example, would span the diameter of a small eukaryotic cell, but a filament formed in this way would lack the strength to avoid breakage by ambient thermal energy, unless each subunit in the filament was bound extremely tightly to its two neighbors. Such tight binding would limit the rate at which the filaments could disassemble, making the cytoskeleton a static and less useful

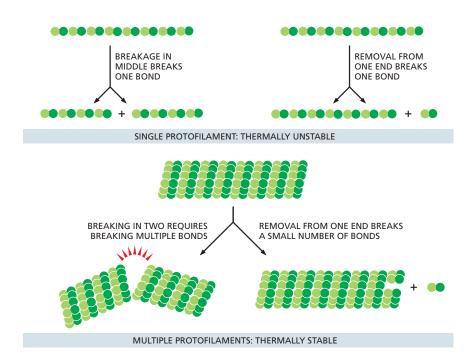

Figure 16-5 The thermal stability of cytoskeletal filaments with dynamic ends. A protofilament consisting of a single strand of subunits is thermally unstable, because breakage of a single bond between subunits is sufficient to break the filament. In contrast, formation of a cytoskeletal filament from more than one protofilament allows the ends to be dynamic, while enabling the filaments themselves to resist thermal breakage. In a microtubule, for example, removing a single subunit dimer from the end of the filament requires breaking noncovalent bonds with a maximum of three other subunits, whereas fracturing the filament in the middle requires breaking noncovalent bonds in all 13 protofilaments.

MBOC7_ptr_ch16_949-1026.indd 954 02/12/21 2:15 PM

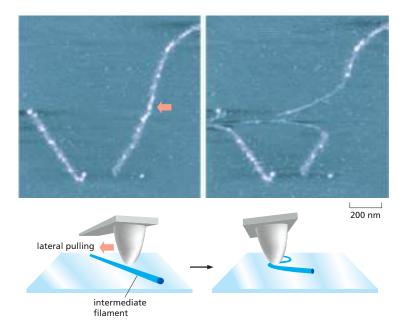

Figure 16-6 Flexibility and stretch in an intermediate filament. Intermediate filaments are formed from elongated fibrous subunits with strong lateral contacts, resulting in resistance to stretching forces. In this experiment, a tiny mechanical probe was used to rapidly scan across a surface to which intermediate filaments were adhered, providing a measurement of the height and contour of the filaments as shown in shades of grav to white. Along a single scan line (arrow) the applied force of the probe was increased from less than 1 nN to 30-40 nN. At this position one of the filaments stretched to more than three times its length before breaking, as illustrated in the micrographs. This technique is called atomic force microscopy. (Adapted from L. Kreplak et al., J. Mol. Biol. 354:569-577, 2005. With permission from Elsevier.)

structure. To provide both strength and adaptability, microtubules are built of 13 protofilaments—linear strings of subunits joined end to end—that associate with one another laterally to form a hollow cylinder. The addition or loss of a subunit at the end of one protofilament makes or breaks a small number of bonds. In contrast, loss of a subunit from the middle of a protofilament requires breaking many more bonds, while breaking it in two requires breaking bonds in multiple protofilaments all at the same time (Figure 16–5). The greater energy required to break multiple noncovalent bonds simultaneously allows microtubules to resist thermal breakage, while allowing rapid subunit addition and loss at the filament ends. Although made up of only two strands instead of 13, helical actin filament subunits also make both end-to-end and side-to-side contacts, allowing for rapid dynamics at filament ends while providing sufficient strength along the length of the filament. However, the tubular geometry of a microtubule makes it much stiffer than a two-stranded actin filament.

As with other specific protein–protein interactions, many hydrophobic interactions and noncovalent bonds hold the subunits in a cytoskeletal filament together (see Figure 3–4). The locations and types of subunit–subunit contacts differ for the different filaments. Intermediate filaments, for example, assemble by forming strong lateral contacts between α -helical coiled-coils, which extend over most of the length of each elongated fibrous subunit. Because the individual subunits are staggered in the filament, intermediate filaments form strong, ropelike structures that tolerate stretching and bending to a greater extent than do either actin filaments or microtubules (Figure 16–6).

Accessory Proteins and Motors Act on Cytoskeletal Filaments

The cell regulates the length and stability of its cytoskeletal filaments, their number and geometry, and their attachments to one another and to other components of the cell. Filaments can thereby form a wide variety of higher-order structures. Direct covalent modification of the filament subunits regulates some filament properties, but most of the regulation is performed by hundreds of accessory proteins that determine the spatial distribution and the dynamic behavior of the filaments, converting information received through signaling pathways into cytoskeletal action. These accessory proteins bind to the filaments or their subunits to determine the sites of assembly of new filaments, to regulate the partitioning of polymer proteins between filament and subunit forms, to change

MBOC7_ptr_ch16_949-1026.indd 955 02/12/21 2:15 PM

the kinetics of filament assembly and disassembly, to harness energy to generate force, and to link filaments to one another or to other cell structures such as organelles and the plasma membrane. In these processes, the accessory proteins bring cytoskeletal structure under the control of extracellular and intracellular signals, including those that trigger the dramatic transformations of the cytoskeleton that occur during each cell cycle. Acting in groups, the accessory proteins enable cells to maintain a highly organized but flexible internal structure and, in many cases, to move.

Among the most fascinating proteins that associate with the cytoskeleton are the motor proteins. These proteins bind to a polarized cytoskeletal filament and use the energy derived from repeated cycles of ATP hydrolysis to move along it. Dozens of different motor proteins coexist in every eukaryotic cell. They differ in the type of filament they bind to (either actin or microtubules), the direction in which they move along the filament, and the "cargo" they carry. Many motor proteins carry membrane-enclosed organelles—such as mitochondria, Golgi stacks, or secretory vesicles—to their appropriate locations in the cell. Other motor proteins cause cytoskeletal filaments to exert tension or to slide against each other, generating the force that drives such phenomena as muscle contraction, ciliary beating, and cell division.

Cytoskeletal motor proteins that move unidirectionally along an oriented polymer track are reminiscent of some other proteins and protein complexes discussed elsewhere in this book, such as DNA and RNA polymerases, helicases, and ribosomes. All of these proteins have the ability to use chemical energy to propel themselves along a linear track, with the direction of sliding dependent on the structural polarity of the track. All of them generate motion by coupling nucleoside triphosphate hydrolysis to a large-scale conformational change (see Figure 3–71).

Molecular Motors Operate in a Cellular Environment Dominated by Brownian Motion

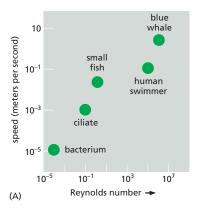

Because of the microscopic size of cells, motor-based movements occur in an environment that is highly dynamic due to random thermal fluctuations called *Brownian motion*. As introduced in Chapter 1 (see p. 9), Brownian motion drives the diffusion of all of the molecules inside cells, and it is thereby critical for the rate of biochemical reactions, which require molecular collisions. Another important effect is its generation of viscous drag forces at small scales. For example, a motor protein moving along a cytoskeletal filament is constantly buffeted by random collisions with water and other molecules. As soon as its motor activity ceases, the motor protein will stop dead in its tracks due to the viscous drag forces generated by these collisions.

The stopping distance for any object moving through a fluid is determined by the **Reynolds number**, which is the ratio of inertial to viscous forces acting on that object. This ratio depends on the size of the object and the velocity of its movement through the fluid. For example, whereas both a bacterium and a fish can propel themselves through water, the size and speed of the fish provide it with significant inertia, such that when it stops swimming it continues to glide through the water for some distance. In contrast, with its much smaller size and slow speed of movement, a bacterium that stops propelling itself will come to an immediate halt (**Figure 16-7**). For a fish to behave similarly, it would need to be placed in an extremely viscous medium, such as roofing tar. Inside the cell, the tiny size and slow speeds of moving molecules result in extremely low Reynolds numbers, because viscous forces are far greater than inertial forces. Thus, there is no "gliding" inside a cell.

Random Brownian motion can also be harnessed to control movement at small scales, even in the absence of motor proteins. As we describe later in this chapter, some intracellular pathogens such as the bacterium *Listeria monocytogenes* use the force of actin polymerization to move around inside a cell. This movement does not involve motor proteins. Instead, actin filaments are induced to polymerize adjacent to the bacterial surface at one end. When the bacterium randomly

MBOC7_ptr_ch16_949-1026.indd 956 02/12/21 2:15 PM

ACTIN 957

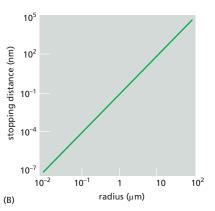

Figure 16–7 Cellular life occurs at a low Reynolds number. (A) The inertia of a swimming organism is counteracted by the viscous drag of water, and the ratio of these two forces is the *Reynolds number*, which is dimensionless. As illustrated in the graph, the Reynolds number is in the range of 10⁶ for a blue whale traveling at about 10 meters per second. For a tiny swimming bacterium moving at 10⁻⁵ meters per second, the viscosity of the water dominates and the Reynolds number decreases to about 10⁻⁴. (B) The Reynolds number indicates the extent to which an object will continue to coast or glide through a fluid after the motive force has stopped. The stopping distance in water for a sphere that has an initial velocity equal to its diameter per second is plotted. Thus, a one micron–diameter organelle would come to a halt within just a few angstroms once its forward motion ceases.

moves in the forward direction due to Brownian motion, actin quickly fills in the gap so that the bacterium cannot slip back to its original position. In this way, actin polymerization generates a force that pushes the bacterium through the cytoplasm (see Figure 16–17). A similar process drives forward movement of the plasma membrane at the leading edge of a migrating animal cell (see Figure 1–7). This phenomenon, in which random thermal motions are harnessed in a directed way, creates a *Brownian ratchet*.

Summary

The cytoplasm of eukaryotic cells is spatially organized by a network of protein filaments known as the cytoskeleton. This network contains three principal types of filaments: actin filaments, microtubules, and intermediate filaments. All three types of filaments form from assemblies of subunits that self-associate using a combination of end-to-end and side-to-side protein contacts. Differences in the structure of the subunits and the manner of their self-assembly give the filaments different mechanical properties. Subunit assembly and disassembly constantly remodel all three types of cytoskeletal filaments. Actin and tubulin (the subunits of actin filaments and microtubules, respectively) bind and hydrolyze nucleoside triphosphates (ATP and GTP, respectively) and assemble head-to-tail to generate polarized filaments capable of generating force. In living cells, accessory proteins including molecular motors modulate the dynamics and organization of cytoskeletal filaments, resulting in complex events such as cell division, migration, or muscle contraction, and generating elaborate cellular architecture to form polarized tissues such as epithelia.

ACTIN

The actin cytoskeleton performs a wide range of functions in diverse cell types. Each actin subunit, sometimes called globular or G-actin, is a 375-amino-acid polypeptide carrying a tightly associated molecule of ATP or ADP (Figure 16–8A). Actin is extraordinarily well conserved among eukaryotes. The amino acid sequences of actins from different eukaryotic species are usually about 90% identical. Small variations in actin amino acid sequence can cause significant functional differences: In vertebrates, for example, there are three isoforms of

MBOC7_ptr_ch16_949-1026.indd 957 02/12/21 2:15 PM

(B) Arrangement of monomers in a filament consisting of two protofilaments, held together by lateral contacts, which wind around each other as two parallel strands of a helix, with a twist repeating every 37 nm. All the subunits within the filament have the same orientation. (C) Electron micrograph of negatively stained actin filament. (C, courtesy of Roger Craig.)

actin, termed α , β , and γ , that differ slightly in their amino acid sequences and have distinct functions. α -Actin is expressed only in muscle cells, while β - and γ -actins are found together in almost all non-muscle cells.

Actin Subunits Assemble Head-to-Tail to Create Flexible, Polar Filaments

Actin subunits assemble head-to-tail to form a tight, right-handed helix, forming a structure about 8 nm wide called filamentous or F-actin (Figure 16-8B and C). Because the asymmetrical actin subunits of a filament all point in the same direction, filaments are polar and have structurally different ends: a slower-growing *minus end* and a faster-growing *plus end*. The minus end is also referred to as the *pointed end* and the plus end as the *barbed end* because of the arrowhead appearance of the complex formed between actin filaments and the motor protein myosin visible in electron micrographs (Figure 16-9). Within the filament, the subunits are positioned with their ATP-binding cleft directed toward the minus end.

Individual actin filaments are quite flexible. The stiffness of a filament can be characterized by its *persistence length*, the minimum filament length at which random thermal fluctuations are likely to cause it to bend. The persistence length of an actin filament is only a few tens of micrometers. In a living cell, however, accessory proteins frequently cross-link and bundle the filaments together, making large-scale actin structures that are much more rigid than an individual actin filament.

Nucleation Is the Rate-limiting Step in the Formation of Actin Filaments

The regulation of actin filament formation is an important mechanism by which cells control their shape and movement. Actin subunits can spontaneously bind one another, but the association is unstable until subunits assemble into an initial

oligomer, or nucleus, that is stabilized by multiple subunit-subunit contacts and can then elongate rapidly by addition of more subunits. This process is called filament *nucleation*.

Many features of actin nucleation and polymerization have been studied with purified actin in a test tube (Figure 16–10). The instability of smaller actin oligomers makes nucleation inefficient. When polymerization is initiated, this results in a lag phase during which no filaments are observed. During this lag phase, however, the small, unstable oligomers gradually succeed in making the transition to a more stable form that resembles an actin filament. This leads to a phase of rapid filament elongation during which subunits are added quickly to the ends of the nucleated filaments (Figure 16–10A). Finally, as the concentration of actin monomers declines, the system approaches a steady state at which the rate of addition of new subunits to the filament ends exactly balances the rate of subunit dissociation. The concentration of free subunits left in solution at this point is called the *critical concentration*, C_c . As explained in Panel 16–2, the

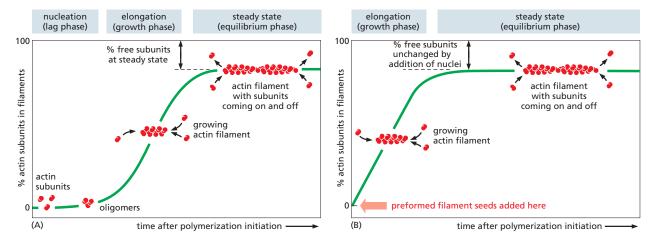

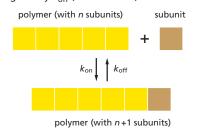

Figure 16–10 The time course of actin polymerization. Purified actin subunits were induced to polymerize in a test tube. (A) Polymerization of actin subunits into filaments occurs after a lag phase. (B) Polymerization occurs more rapidly in the presence of preformed fragments of actin filaments, which act as nuclei for filament growth. The percent (%) free subunits after polymerization reflects the critical concentration (C_c), at which there is no net change in polymer. The C_c has a constant value of ~0.1 μ M, but the percent of actin subunits in filaments varies depending on how much actin is present in the reaction. Actin polymerization is often studied by observing the change in the light emission from a fluorescent probe, called pyrene, that has been covalently attached to the actin. Pyrene-actin fluoresces more brightly when it is incorporated into actin filaments.

960

ON RATES AND OFF RATES

A linear polymer of protein molecules, such as an actin filament or a microtubule, assembles (polymerizes) and disassembles (depolymerizes) by the addition and removal of subunits at the ends of the polymer. The rate of addition of these subunits (called monomers) is given by the rate constant $k_{\rm on}$, which has units of ${\rm M}^{-1}$ sec $^{-1}$. The rate of loss is given by $k_{\rm off}$ (units of sec $^{-1}$).

NUCLEATION

A helical polymer is stabilized by multiple contacts between adjacent subunits. In the case of actin, two actin molecules bind relatively weakly to each other, but addition of a third actin monomer to form a trimer makes the entire group more stable.

Further monomer addition can take place onto this trimer, which therefore acts as a nucleus for polymerization. For tubulin, the nucleus is larger and has a more complicated structure (possibly a ring of 13 or more tubulin molecules)—but the principle is the same.

The assembly of a nucleus is relatively slow, which explains the lag phase seen during polymerization. The lag phase can be reduced or abolished entirely by adding premade nuclei, such as fragments of already polymerized microtubules or actin filaments.

THE CRITICAL CONCENTRATION

The number of monomers that add to the polymer (actin filament or microtubule) per second will be proportional to the concentration of the free subunit $(k_{on}C)$, but the subunits will leave the polymer end at a constant rate (k_{off}) that does not depend on C. As the polymer grows, subunits are used up, and C is observed to drop until it reaches a constant value, called the critical concentration (C_c) . At this concentration, the rate of subunit addition equals the rate of subunit loss. At this equilibrium,

$$k_{\text{on}}C = k_{\text{off}}$$

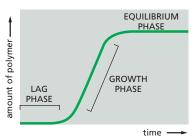

so that

$$C_{\rm c} = \frac{k_{\rm off}}{k_{\rm on}} = K_{\rm d}$$

where K_d is the dissociation constant.

TIME COURSE OF POLYMERIZATION

The *in vitro* assembly of a protein into a long polymer such as a cytoskeletal filament typically shows the following time course:

The lag phase corresponds to time taken for nucleation.

The growth phase occurs as monomers add to the exposed ends of the growing filament, causing filament elongation.

The equilibrium phase, or steady state, is reached when the growth of the polymer due to monomer addition precisely balances the shrinkage of the polymer due to disassembly back to monomers.

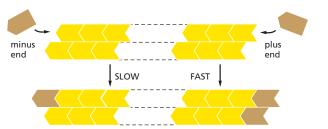

PLUS AND MINUS ENDS

The two ends of an actin filament or microtubule polymerize at different rates. The fast-growing end is called the plus end, whereas the slow-growing end is called the minus end. The difference in the rates of growth at the two ends is made possible by changes in the conformation of each subunit as it enters the polymer.

This conformational change affects the rates at which subunits add to the two ends.

Even though $k_{\rm on}$ and $k_{\rm off}$ will have different values for the plus and minus ends of the polymer, their ratio $k_{\rm off}/k_{\rm on}$ —and hence $C_{\rm c}$ —must be the same at both ends for a simple polymerization reaction (no ATP or GTP hydrolysis). This is because exactly the same subunit interactions are broken when a subunit is lost at either end, and the final state of the subunit after dissociation is identical. Therefore, the ΔG for subunit

loss, which determines the equilibrium constant for its association with the end, is identical at both ends: if the plus end grows four times faster than the minus end, it must also shrink four times faster. Thus, for $C > C_{cr}$ both ends grow; for $C < C_{cr}$ both ends shrink.

The nucleoside triphosphate hydrolysis that accompanies actin and tubulin polymerization removes this constraint.

NUCLEOTIDE HYDROLYSIS

Each actin molecule carries a tightly bound ATP molecule that is hydrolyzed to a tightly bound ADP molecule soon after its assembly into the polymer. Similarly, each tubulin molecule carries a tightly bound GTP molecule that is converted to a tightly bound GDP molecule soon after the molecule assembles into the polymer.

Hydrolysis of the bound nucleotide reduces the binding affinity of the subunit for neighboring subunits and makes it more likely to dissociate from each end of the filament. It is usually the T form that adds to the filament and the D form that leaves.

Considering events at the plus end only:

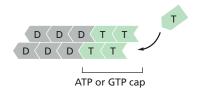

As before, the polymer will grow until $C = C_c$. For illustrative purposes, we can ignore $k^{\rm D}_{\rm on}$ and $k^{\rm T}_{\rm off}$ since they are usually very small, so that polymer growth ceases when

$$k^{\mathsf{T}}_{\mathsf{on}}\mathsf{C} = k^{\mathsf{D}}_{\mathsf{off}}$$
 or $\mathsf{C}_{\mathsf{c}} = \frac{k^{\mathsf{D}}_{\mathsf{off}}}{k^{\mathsf{T}}_{\mathsf{on}}}$

This is a steady state and not a true equilibrium, because the ATP or GTP that is hydrolyzed must be replenished by a nucleotide exchange reaction of the free subunit $(\Box \Box \to \Box)$.

ATP CAPS AND GTP CAPS

The rate of addition of subunits to a growing actin filament or microtubule can be faster than the rate at which their bound nucleotide is hydrolyzed. Under such conditions, the end has a "cap" of subunits containing the nucleoside triphosphate—an ATP cap on an actin filament or a GTP cap on a microtubule.

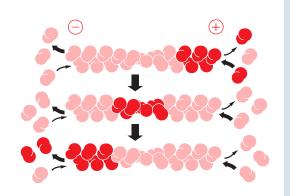

DYNAMIC INSTABILITY and TREADMILLING are two behaviors observed in cytoskeletal polymers. Both are associated with nucleoside triphosphate hydrolysis. Dynamic instability is believed to predominate in microtubules, whereas treadmilling may predominate in actin filaments.

TREADMILLING

One consequence of the nucleotide hydrolysis that accompanies polymer formation is to change the critical concentration at the two ends of the polymer. Because $k^{\rm D}_{\rm off}$ and $k^{\rm T}_{\rm on}$ refer to different reactions, their ratio $k^{\rm D}_{\rm off}/k^{\rm T}_{\rm on}$ need not be the same at both ends of the polymer, so that:

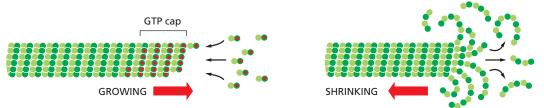

C_c (minus end) > C_c (plus end)

Thus, if both ends of a polymer are exposed, polymerization proceeds until the concentration of free monomer reaches a value that is above $C_{\rm c}$ for the plus end but below $C_{\rm c}$ for the minus end. At this steady state, subunits undergo a net assembly at the plus end and a net disassembly at the minus end at an identical rate. The polymer maintains a constant length, even though there is a net flux of subunits through the polymer, known as treadmilling.

DYNAMIC INSTABILITY

Microtubules depolymerize about 100 times faster from an end containing GDP-tubulin than from one containing GTP-tubulin. A GTP cap favors growth, but if it is lost, then depolymerization ensues.

Individual microtubules can therefore alternate between a period of growth and a period of rapid disassembly, a phenomenon called dynamic instability.

MBOC7_ptr_ch16_949-1026.indd 961 02/12/21 2:15 PM

value of the critical concentration is equal to the rate constant for subunit loss divided by the rate constant for subunit addition; that is, $C_{\rm c} = k_{\rm off}/k_{\rm on}$, which is equal to the dissociation constant, $K_{\rm d}$, and the inverse of the equilibrium constant, K (see Figure 3–42). In a test tube, the $C_{\rm c}$ for actin polymerization—that is, the free actin monomer concentration at which the fraction of actin in the polymer stops increasing—is about 0.1 μ M. Inside the cell, the concentration of unpolymerized actin is much higher than this, and the cell has evolved mechanisms to prevent most of its monomeric actin from assembling into filaments, as we discuss later.

The lag phase in filament growth is eliminated if preexisting seeds (such as fragments of actin filaments) are added to the solution at the beginning of the polymerization reaction (Figure 16–10B). The cell takes great advantage of the barrier to nucleation: it uses special proteins to catalyze filament nucleation at specific sites, thereby determining the location at which new actin filaments are assembled.

Actin Filaments Have Two Distinct Ends That Grow at Different Rates

Because of the uniform orientation of asymmetrical actin subunits in the filament, the structures at its two ends are different. This orientation makes the two ends of each polymer different in ways that have a profound effect on filament growth rates. The kinetic rate constants for actin subunit association and dissociation— $k_{\rm on}$ and $k_{\rm off}$, respectively—are much greater at the plus end than at the minus end. This can be seen when an excess of purified actin monomers is allowed to assemble onto polarity-marked filaments—the plus end of the filament elongates up to 10 times faster (see Figure 16–9). If filaments are rapidly diluted so that the free subunit concentration drops below the critical concentration, the plus end also depolymerizes faster.

It is important to note, however, that the two ends of an actin filament have the same net affinity for actin subunits, if all of the subunits are bound to either ATP or ADP. Addition of a subunit to either end of a filament of n subunits results in a filament of n+1 subunits. Thus, the free-energy difference, and therefore the equilibrium constant (and the critical concentration), must be the same for addition of subunits at either end of the polymer. In this case, the ratio of the rate constants, $k_{\rm off}/k_{\rm on}$, must be identical at the two ends, even though the absolute values of these rate constants are very different at each end (see Panel 16–2).

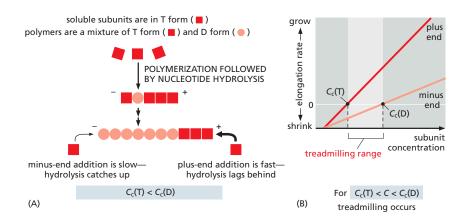

The cell takes advantage of actin filament dynamics and polarity to do mechanical work. Filament elongation proceeds spontaneously when the free-energy change (ΔG) for addition of the soluble subunit is less than zero. This is the case when the concentration of subunits in solution exceeds the critical concentration. A cell can couple an energetically unfavorable process to this spontaneous process; thus, the cell can use free energy released during spontaneous filament polymerization to move an attached load. For example, by orienting the fast-growing plus ends of actin filaments toward its leading edge, a motile cell can push its plasma membrane forward, as we discuss later.

ATP Hydrolysis Within Actin Filaments Leads to Treadmilling at Steady State

Thus far in our discussion of actin filament dynamics, we have ignored the critical fact that actin can catalyze the hydrolysis of the nucleoside triphosphate ATP. For free actin subunits, this hydrolysis proceeds very slowly; however, it is accelerated when the subunits are incorporated into filaments. Shortly after ATP hydrolysis occurs, the free phosphate group is released from each subunit, but the ADP remains trapped in the filament structure. Thus, two different types of filament structures can exist, one in the ATP-bound *T form* and one in the ADP-bound *D form*.

MBOC7_ptr_ch16_949-1026.indd 962 02/12/21 5 PM

ACTIN 963

When the ATP is hydrolyzed, much of the free energy released by cleavage of the phosphate-phosphate bond is stored in the polymer. This makes the free-energy change for dissociation of a subunit from the D-form polymer more negative than the free-energy change for dissociation of a subunit from the T-form polymer. Consequently, the ratio of $k_{\rm off}/k_{\rm on}$ for the D-form polymer, which is numerically equal to its critical concentration $[C_{\rm c}({\rm D})]$, is larger than the corresponding ratio for the T-form polymer. Thus, $C_{\rm c}({\rm D})$ is greater than $C_{\rm c}({\rm T})$. At certain concentrations of free subunits, D-form polymers will therefore shrink while T-form polymers grow.

In living cells, most soluble actin subunits are in the T form, as the free concentration of ATP is about tenfold higher than that of ADP. However, the longer the time that subunits have been in the actin filament, the more likely they are to have hydrolyzed their ATP. Whether the subunit at each end of a filament is in the T or the D form depends on the rate of this hydrolysis compared with the rate of subunit addition. If the concentration of actin monomers is greater than the critical concentration for both the T-form and D-form polymers, then subunits will add to the polymers at both ends before the ATP in the previously added subunits is hydrolyzed; as a result, the tips of the actin filament will remain in the T form. On the other hand, if the subunit concentration is less than the critical concentrations for both the T-form and D-form polymers, then hydrolysis may occur before the next subunit is added, and both ends of the filament will be in the D form and will shrink. At intermediate concentrations of actin subunits, it is possible for the rate of subunit addition to be faster than ATP hydrolysis at the plus end but slower than ATP hydrolysis at the minus end. In this case, the plus end of the filament remains in the T conformation, while the minus end adopts the D conformation. The filament then undergoes a net addition of subunits at the plus end while simultaneously losing subunits from the minus end. This leads to the remarkable property of filament treadmilling (Figure 16-11; see Panel 16-2).

At a particular intermediate subunit concentration, the filament growth at the plus end exactly balances the filament shrinkage at the minus end. Under these conditions, the subunits cycle rapidly between the free and filamentous states, while the total length of the filament remains unchanged. This *steady-state tread-milling* requires a constant consumption of energy in the form of ATP hydrolysis.

The Functions of Actin Filaments Are Inhibited by Both Polymer-stabilizing and Polymer-destabilizing Chemicals

Chemical compounds that stabilize or destabilize actin filaments are important tools in studies of the filaments' dynamic behavior and function in cells. The *cytochalasins* are fungal products that prevent actin polymerization by binding to the plus end of actin filaments. *Latrunculin* prevents actin polymerization by binding to actin subunits. The *phalloidins* are toxins isolated from the *Amanita* mushroom that bind tightly all along the side of actin filaments and stabilize them

Figure 16-11 Treadmilling of an actin filament, made possible by the ATP hydrolysis that follows subunit addition. (A) Explanation for the different critical concentrations (C_c) at the plus and minus ends. Subunits with bound ATP (T-form subunits) polymerize at both ends of a growing filament and then undergo ATP hydrolysis within the filament. As the filament grows, elongation is faster than hydrolysis at the plus end in this example. and the terminal subunits at this end are therefore always in the T form. However, hydrolysis is faster than elongation at the minus end, and so terminal subunits at this end are in the D form. (B) Treadmilling occurs at intermediate concentrations of free subunits. The critical concentration for polymerization on a filament end in the T form, $C_c(T)$, is lower than that for a filament end in the D form, $C_{c}(D)$. If the actual subunit concentration is somewhere between these two values, the plus end grows while the minus end shrinks, resulting in treadmilling.

against depolymerization. All of these compounds cause dramatic changes in the actin cytoskeleton and are toxic to cells, indicating that the function of actin filaments depends on a dynamic equilibrium between filaments and actin monomers (Table 16–1).

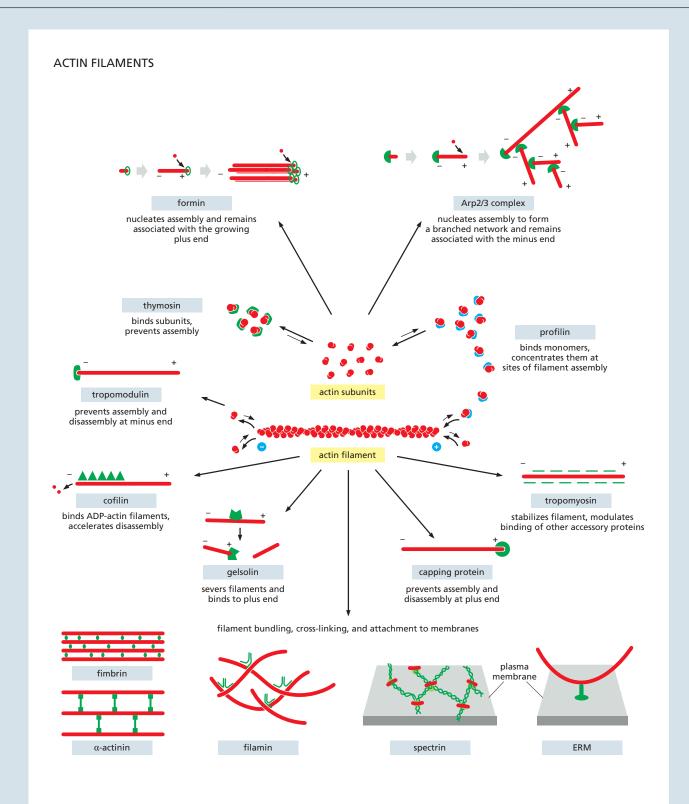

Actin-binding Proteins Influence Filament Dynamics and Organization

In a test tube, polymerization of actin is controlled simply by its concentration, as described earlier, and by pH and the concentrations of salts and ATP. Within a cell, however, actin behavior is also regulated by numerous accessory proteins that bind actin monomers or filaments (summarized in Panel 16–3). At steady state in vitro, when the monomer concentration is 0.1 μ M, filament half-life, a measure of how long an individual actin monomer spends in a filament as it treadmills, is approximately 30 minutes. In a non-muscle vertebrate cell, the actin half-life in filaments is only 30 seconds, demonstrating that cellular factors modify the dynamic behavior of actin filaments. Actin-binding proteins dramatically alter actin filament dynamics through spatial and temporal control of filament nucleation, elongation, and depolymerization. They also regulate the association of actin with membranes as well as how filaments are organized. In the following sections, we describe the ways in which these accessory proteins modify actin function in the cell, enabling actin polymerization to generate the forces required to support, shape, and move cellular membranes.

Actin Nucleation Is Tightly Regulated and Generates Branched or Straight Filaments

In most non-muscle vertebrate cells, approximately 50% of the actin is in filaments and 50% is soluble—and yet the soluble monomer concentration is 50–200 μ M, well above the critical concentration. Why does so little of the actin polymerize into filaments? A major reason is that actin filament polymerization is tightly regulated in cells by a large number of proteins that control actin filament nucleation, almost always adjacent to a membrane surface. Proteins that contain actin monomer binding motifs linked in tandem mediate the simplest mechanism of filament nucleation. These actin-nucleating proteins bring several actin subunits together to form a seed. In most cases, actin nucleation is catalyzed by one of two different factors: the Arp2/3 complex or the formins. The first of these is a complex of proteins that includes two *actin-related proteins*, or *ARPs*, each of which is about 45% identical to actin. The **Arp2/3 complex** nucleates actin filament growth and remains bound to the

MBOC7_ptr_ch16_949-1026.indd 964 02/12/21 2:15 PM

Some of the major accessory proteins of the actin cytoskeleton. Except for the myosin motor proteins, an example of each major type is shown. Each of these is discussed in the text. However, most cells contain more than a hundred different actin-binding proteins, and it is likely that there are important types of actin-associated proteins that are not yet recognized.

MBOC7_ptr_ch16_949-1026.indd 965 02/12/21 2:15 PM

minus end, allowing rapid elongation at the plus end (Figure 16–12A and B). Arp2/3 complex-mediated actin filament nucleation requires the activity of a nucleation-promoting factor (NPF). The Arp2/3 complex is further stimulated when it attaches to the side of a preexisting actin filament. Thus, Arp2/3 complex activation generates a branched array of actin filaments adjacent to a membrane, building individual filaments into a treelike network

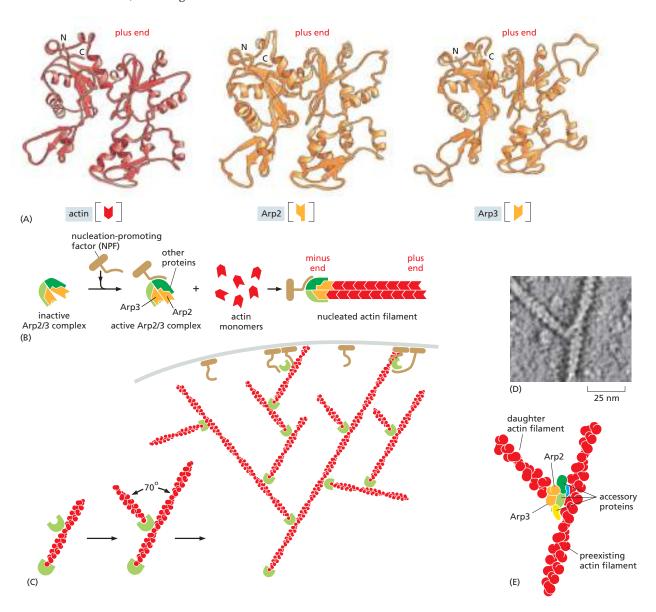

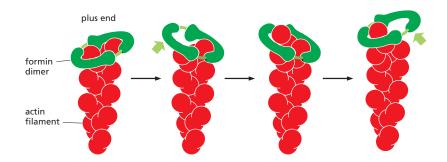

Figure 16–12 Nucleation and branching of actin filaments by the Arp2/3 complex. (A) The structures of Arp2 and Arp3 compared to the structure of actin. Although the face of the molecule equivalent to the plus end (top) in both Arp2 and Arp3 is very similar to the plus end of actin itself, differences on the sides and minus end prevent these actin-related proteins from forming filaments on their own or coassembling into filaments with actin. (B) A model for actin filament nucleation by the Arp2/3 complex. In the absence of an activating factor, Arp2 and Arp3 are held by their accessory proteins in an orientation that prevents them from nucleating a new actin filament. When a nucleation-promoting factor (NPF; brown) binds the complex, Arp2 and Arp3 are brought together into a new configuration that resembles the plus end of an actin filament. Actin subunits can then assemble onto this structure, bypassing the rate-limiting step of filament nucleation. In cells, NPF activation required to induce Arp2/3-dependent nucleation occurs at membrane surfaces. (C) The Arp2/3 complex nucleates filaments most efficiently when it is bound to the side of a preexisting actin filament. The result is a filament branch that grows at a 70° angle relative to the original filament. Repeated rounds of branching nucleation result in a treelike web of actin filaments. (D) Electron micrograph of a branched actin filament formed by mixing purified actin subunits with purified Arp2/3 complexes. (E) Diagram showing the position of the Arp2/3 complex at the branch between the preexisting mother filament and the daughter filament. (D, from I. Rouiller et al., J. Cell Biol. 180:887–895, 2008. © 2008A. Rouiller et al. Originally published in J. Cell Biol. 180:887–895. https://doi.org/10.1083/jcb.200709092. With permission from Rockefeller University Press.)

ACTIN 967

(**Figure 16–12C**, **D**, and **E**). Cells express multiple NPFs, each of which makes branched actin networks that are used to initiate various actin polymerization-dependent processes, such as transport of membrane-bound vesicles across short distances within the cell, the formation of *adherens junctions* (see Chapter 19), and *phagocytosis* (see Figure 13–70). As discussed below, NPF-driven actin polymerization frequently plays a direct role in protrusion of the leading edge of the cell during cell migration.

Formins are dimeric proteins that nucleate the growth of unbranched filaments that can be cross-linked by other proteins to form parallel bundles. Each formin subunit has a binding site for monomeric actin, and the formin dimer appears to nucleate actin filament polymerization by capturing two monomers. As the newly nucleated filament grows, the formin dimer remains associated with the rapidly growing plus end while still allowing the addition of new subunits at that end (Figure 16–13). This mechanism of filament assembly is clearly different from that used by the Arp2/3 complex, which remains stably bound to the filament minus end, preventing subunit addition or loss at that end. In addition to their role in actin nucleation, formin proteins also dramatically accelerate actin filament growth. Formins mediate assembly of a variety of cellular structures that contain polarized actin cables, including filopodia, stress fibers, and the contractile ring.

Actin filament nucleation by the Arp2/3 complex and formins occurs primarily at the plasma membrane, and therefore the highest density of actin filaments in most cells is at the cell periphery within the **cell cortex**. Actin filaments in this region determine the shape and movement of the cell surface, allowing the cell to change its shape and stiffness rapidly in response to changes in its external environment.

Actin Filament Elongation Is Regulated by Monomer-binding Proteins

Once nucleated, rapid polymerization of actin depends on the further addition of actin monomers at the plus end of each filament. A key factor is the monomerbinding protein *profilin*. Profilin binds to the face of the actin monomer opposite the ATP-binding cleft, blocking the side of the monomer that would normally associate with the filament minus end, while leaving exposed the site on the monomer that binds to the plus end (see Figure 16–8). When the profilin–actin complex binds a free plus end, a conformational change in actin reduces its affinity for profilin and the profilin falls off, leaving the actin filament one subunit longer. In some cell types, a small protein called *thymosin* is highly abundant and competes with profilin for actin monomer binding, thereby further regulating the pool of actin monomers available for polymerization.

Growth of actin filaments is greatly enhanced by profilin for two reasons. First, profilin maintains a large pool of actin monomers poised for polymerization at filament plus ends. Second, binding sites for profilin are present in many formin proteins, as well as in many NPFs that activate the Arp2/3 complex. By binding to the factors that stimulate filament nucleation, profilin-bound actin monomers are recruited directly to sites of filament elongation, rapidly accelerating actin filament assembly (Figure 16–14).

Figure 16-13 Actin filament elongation mediated by formins. Formin proteins (green) form a dimeric complex that can nucleate the formation of a new actin filament (red) and remain associated with the rapidly growing plus end as it elongates. The formin protein maintains its binding to one of the two actin subunits exposed at the plus end as it allows each new subunit to assemble. Only part of the large dimeric formin molecule is shown here. Other regions regulate its activity and link it to particular structures in the cell. Many formins are indirectly connected to the cell plasma membrane and aid the insertional polymerization of the actin filament directly beneath the membrane surface.

MBOC7_ptr_ch16_949-1026.indd 967 02/12/21 2:15 PM

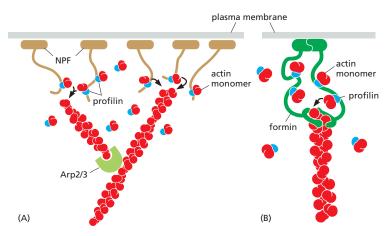

Figure 16–14 Profilin stimulates actin filament elongation. (A) Many nucleation-promoting factors (NPFs; brown) contain binding sites for profilin (blue), which is bound to actin monomers. As a result, NPF activation leads not only to nucleation of branched actin filaments by Arp2/3 (green; see Figure 16–12), but also to rapid elongation of the new filaments. (B) Some members of the formin protein family possess whisker-like unstructured domains that contain several binding sites for profilin–actin complexes. This serves to recruit actin monomers to the growing plus end of the actin filament when formin is bound. Under some conditions, profilin can enhance the rate of actin filament elongation so that filament growth is faster than that expected for a diffusion-controlled reaction (see also Figure 3–76). Like NPFs, formin proteins inside the cell are activated to promote actin filament polymerization at membrane surfaces.

Actin Filament-binding Proteins Alter Filament Dynamics and Organization

Actin filament behavior is regulated by two major classes of binding proteins: those that bind along the side of a filament and those that bind to the ends (see Panel 16–3). Side-binding proteins include *tropomyosin*, an elongated protein unrelated to the myosin motor that binds simultaneously to six or seven adjacent actin subunits along each of the two grooves of the helical actin filament. In addition to stabilizing and stiffening the filament, the binding of tropomyosin can prevent the actin filament from interacting with other proteins; this aspect of tropomyosin function is important in the control of muscle contraction, as we discuss later.

An actin filament that stops growing and is not specifically stabilized in the cell will depolymerize rapidly, particularly at its plus end, once the actin molecules have hydrolyzed their ATP. The binding of plus-end *capping protein* (also called *CapZ* for its location in the muscle Z band) stabilizes an actin filament at its plus end by rendering it inactive, greatly reducing the rates of filament growth and depolymerization (**Figure 16-15**). At the minus end, an actin filament may be capped by the Arp2/3 complex that was responsible for its nucleation,

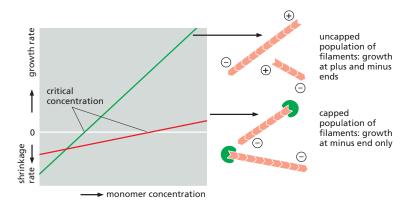

Figure 16-15 Filament capping and its effects on filament dynamics. A population of uncapped filaments adds and loses subunits at both the plus and minus ends, resulting in rapid growth or shrinkage, depending on the concentration of available free monomers (green line). In the presence of a protein that caps the plus end (red line), only the minus end is able to add or lose subunits: consequently. filament growth will be slower at all monomer concentrations above the critical concentration, and filament shrinkage will be slower at all monomer concentrations below the critical concentration. In addition. the critical concentration for the population shifts to that of the filament minus end.

MBOC7_ptr_ch16_949-1026.indd 968 02/12/21 2:15 PM

ACTIN 969

although many minus ends in a typical cell are released from the Arp2/3 complex and are uncapped.

Tropomodulin, best known for its function in the capping of actin filaments in muscle, binds tightly to the minus ends of actin filaments that have been coated and thereby stabilized by tropomyosin. A large family of tropomodulin proteins regulates actin filament length and stability in many cell types.

End-binding proteins can affect filament dynamics even when they are present at very low levels. Because subunit addition and loss occur exclusively at filament ends, one molecule of an end-binding protein per actin filament (roughly one molecule per 200–500 actin subunits) can be enough to transform the architecture of an actin filament network. For example, rapid capping of actin filament plus ends after their nucleation at membranes focuses actin polymerization at new sites of nucleation, so that plus ends grow only where a pushing force is needed (see Figure 16–17).

The three-dimensional organization of cellular actin networks also depends on the activity of actin cross-linking proteins. Some of these cross-linking proteins bundle actin filaments into a parallel array, while others hold two actin filaments together at a large angle to each other, thereby creating a looser meshwork. Actin cross-linking proteins generally have two similar actin filament-binding sites, which can either be part of a single polypeptide chain or contributed by each of two polypeptide chains held together in a dimer (see Panel 16-3). The spacing and arrangement of these two filament-binding domains influence the type of actin structure that a given cross-linking protein forms. For example, the small monomeric protein fimbrin contributes to the tight packing of parallel bundles of actin filaments found in long cellular protrusions such as microvilli and the stereocilia of the inner ear's sensory hair cells. Other actin cross-linking proteins have either a flexible or a stiff, bent connection between their two binding domains, allowing them to form actin filament webs or three-dimensional networks, rather than actin bundles. The protein filamin achieves this by clamping together pairs of actin filaments roughly at right angles, thereby promoting the formation of a loose and highly viscous gel.

Each type of bundling protein also influences which other molecules can interact with the cross-linked actin filaments. Myosin II is the motor protein that enables stress fibers and other contractile arrays to exert tension. The very close packing of actin filaments caused by fimbrin apparently excludes myosin, and thus the parallel actin filaments held together by fimbrin are not contractile. On the other hand, $\alpha\text{-actinin cross-links oppositely polarized actin filaments into loose bundles, allowing the binding of myosin and formation of contractile actin bundles. Because of the very different spacing and orientation of the actin filaments, bundling by fimbrin automatically discourages bundling by <math display="inline">\alpha\text{-actinin}$, and vice versa, so that the two types of bundling protein are mutually exclusive.

As discussed previously, much of the actin polymerization in animal cells initiates at the plasma membrane where nucleation proteins are activated. Dozens of other actin-binding proteins associate with the cortical actin network. For example, a netlike meshwork of the protein spectrin connects to actin in the cortex of red blood cells, where it maintains cell shape and structural integrity of the plasma membrane (see pp. 630-631). More widely expressed are members of the ERM family (named for its first three members, ezrin, radixin, and moesin), which help organize membrane domains through their ability to interact with transmembrane proteins and the underlying actin cytoskeleton in many cell types. In so doing, they not only provide structural links to strengthen the cell cortex but also regulate the activities of signal transduction pathways. Moesin also increases cortical stiffness to promote cell rounding during mitosis. ERM proteins are thought to bind to and organize the cortical actin cytoskeleton in a variety of contexts, thereby affecting the shape and stiffness of the membrane as well as the localization and activity of signaling molecules.

MBOC7_ptr_ch16_949-1026.indd 969 02/12/21 2:15 PM

Severing Proteins Regulate Actin Filament Depolymerization

Another important mechanism of actin filament regulation depends on proteins that break an actin filament into many smaller filaments, thereby generating a large number of new filament ends. The fate of these new ends depends on the presence of other accessory proteins. Under some conditions, newly formed ends nucleate filament elongation, thereby accelerating the assembly of new filament structures. Under other conditions, severing promotes the depolymerization of old filaments, speeding up the depolymerization rate by tenfold or more. In addition, severing changes the physical and mechanical properties of the cytoplasm: stiff, large bundles and gels become more fluid.

One class of actin-severing proteins is the *gelsolin superfamily*. These proteins are activated by high levels of cytosolic Ca²⁺. Gelsolin interacts with the side of the actin filament and contains subdomains that bind to two different sites: one that is exposed on the surface of the filament and one that is hidden between adjacent subunits. Activated gelsolin is thought to sever an actin filament when a thermal fluctuation creates a small gap between neighboring subunits, at which point gelsolin inserts itself into the gap to break the filament. After the severing event, gelsolin remains attached to the actin filament and caps the new plus end.

A second actin filament-destabilizing protein, found in all eukaryotic cells, is *cofilin*. Also called *actin-depolymerizing factor*, cofilin binds along the length of the actin filament, forcing the filament to twist a little more tightly (Figure 16–16). Mechanical stress induced by cofilin binding weakens the contacts between actin subunits in the filament, making the filament less stable and more easily severed by thermal motions, generating filament ends that undergo rapid disassembly. As a result, most of the actin filaments inside cells are shorter lived than are filaments formed from pure actin in a test tube.

Cofilin binds preferentially to ADP-containing actin filaments rather than to ATP-containing filaments. Because ATP hydrolysis is usually slower than filament assembly, the newest actin filaments in the cell still contain mostly ATP and are resistant to depolymerization by cofilin. Cofilin therefore tends to dismantle the older filaments in the cell. As discussed later, the cofilin-mediated disassembly of old but not new actin filaments is critical for the polarized, directed growth of the actin network that drives the intracellular motility of pathogens as well as cell migration. Actin filaments can be protected from cofilin by tropomyosin binding. Thus, the dynamics of actin in different subcellular locations depend on the balance of stabilizing and destabilizing accessory proteins.

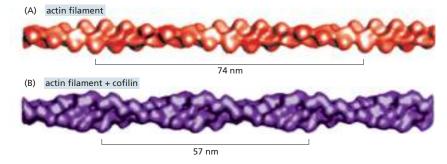

Figure 16–16 Twisting of an actin filament induced by cofilin. (A) Three-dimensional reconstruction from cryo-electron micrographs of filaments made of pure actin. The bracket shows the span of two twists of the actin helix. (B) Reconstruction of an actin filament coated with cofilin, which binds in a 1:1 stoichiometry to actin subunits all along the filament. Cofilin is a small protein (14 kilodaltons) compared to actin (43 kilodaltons), and so the filament appears only slightly thicker. The energy of cofilin binding serves to deform the actin filament, twisting it more tightly and reducing the distance spanned by each twist of the helix. (© 1997 A. McGough et al. ACTIN 971

Bacteria Can Hijack the Host Actin Cytoskeleton

The importance of accessory proteins in actin-based motility and force production is illustrated beautifully by studies of certain bacteria and viruses that use components of the host-cell actin cytoskeleton to move through the cytoplasm. The cytoplasm of mammalian cells is extremely viscous, containing organelles and cytoskeletal elements that inhibit diffusion of large particles such as bacteria or viruses. To move around in a cell and invade neighboring cells, several pathogens, including Listeria monocytogenes (which causes a rare but serious form of food poisoning), overcome this problem by recruiting and activating the Arp2/3 complex at their surface. The Arp2/3 complex nucleates the assembly of actin filaments that generate a substantial force and push the bacterium through the cytoplasm at rates of up to 15 μm/min, leaving behind a long actin "comet tail" (Figure 16-17; see also Figures 23-29 and 23-30). This motility can be reconstituted in a test tube by adding the bacteria to a mixture of pure actin, Arp2/3 complex, cofilin, and capping protein, illustrating how actin polymerization dynamics generates movement through spatial regulation of filament assembly and disassembly. As we shall see, actin-based movement of this sort also underlies membrane protrusion at the leading edge of motile cells.

Actin at the Cell Cortex Determines Cell Shape

Although actin is found throughout the cytoplasm of a eukaryotic cell, dynamic actin filament behavior occurs primarily at the cell cortex. Here, through interaction with many different proteins, actin filaments are organized into several types of arrays, including branched networks, parallel bundles, and combinations of straight and branched filaments (Figure 16–18). Different structures are initiated by the action of distinct nucleating proteins: the actin filaments of branched networks are nucleated by the Arp2/3 complex, while bundles are made of the long, straight filaments produced by formins. Dynamics here generate distinct

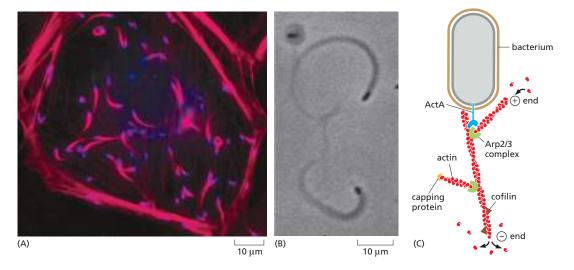

Figure 16–17 The actin-based movement of *Listeria monocytogenes*. (A) Fluorescence micrograph of an infected cell that has been stained to reveal bacteria in *blue* and actin filaments in *red*. Note the cometlike tail of actin filaments behind each moving bacterium. (B) *Listeria* motility can be reconstituted in a test tube with ATP and just four purified proteins: actin, Arp2/3 complex, capping protein, and cofilin. This micrograph shows the dense actin tails behind bacteria (*black*). (C) The ActA protein on the bacterial surface activates the Arp2/3 complex to nucleate new filament assembly along the sides of existing filaments. Filaments grow at their plus end until capped by capping protein. Actin is recycled through the action of cofilin, which enhances depolymerization at the minus ends of the filaments. By this mechanism, polymerization is focused at the rear surface of the bacterium, propelling it forward (see Movie 23.7). (A, courtesy of Julie Theriot and Tim Mitchison; B, from T.P. Loisel et al., *Nature* 401:613–616, published 1999 by Nature Publishing Group. Reproduced with permission of SNCSC.)

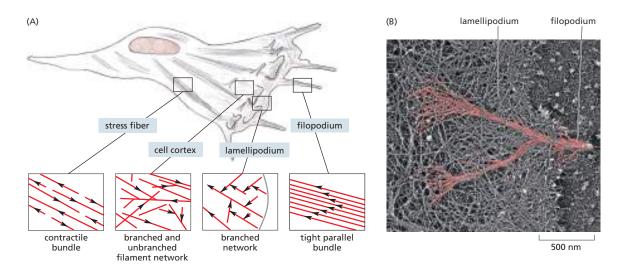

Figure 16–18 Actin arrays in a cell moving along a flat surface. (A) A schematic of a fibroblast migrating in a tissue-culture dish is shown with four areas enlarged to show the arrangement of actin filaments. The actin filaments are shown in red, with arrowheads pointing toward the minus end. Stress fibers are contractile and exert tension. The actin cortex underlies the plasma membrane and consists of actin networks that enable membrane protrusion at lamellipodia. Filopodia are spikelike projections of the plasma membrane that sense extracellular signals and allow a cell to explore its environment. (B) A migrating cell that was fixed, dried, and shadowed with platinum reveals a dense network of actin filaments at the leading edge (right side of image). The fast-growing plus ends are oriented toward the cell edge. Accessory proteins organize the filaments. Pseudo-colored in red are actin filaments in the process of becoming a filopodium. (B, courtesy of Tatyana Svitkina.)

cellular shapes and properties, as well as protrusive structures termed **filopodia** and **lamellipodia** observed in migrating fibroblasts. These are filled with dense cores of filamentous actin, which excludes membrane-enclosed organelles. The structures differ primarily in the way in which the actin is organized by actin cross-linking proteins (see Panel 16–3). Filopodia are essentially one-dimensional. They contain a core of long, bundled actin filaments, which are reminiscent of those in microvilli but longer and thinner, as well as more dynamic. Lamellipodia are two-dimensional, sheet-like structures. They contain a cross-linked mesh of actin filaments, most of which lie in a plane parallel to the solid substratum. Filopodia help cells sense environmental cues and function in cell migration. For example, filopodia extend from the leading edge of the growth cone in developing neurons and help guide them to their target. Protrusion of lamellipodia and related actinrich structures, discussed in more detail later, drives the forward movement of the leading edge of many migrating cells.

Distinct Modes of Cell Migration Rely on the Actin Cytoskeleton

Cell movement is one of the most striking of all cell behaviors. While some cells employ microtubule-based cilia or flagella to swim (discussed later in this chapter), many cells undergo crawling movements that rely on the actin cyto-skeleton. Predatory amoebae continually crawl in search of food, and they can easily be observed to attack and devour smaller ciliates and flagellates in a drop of pond water (see Movie 1.4). During embryogenesis, the structure of an animal is created by the migrations of individual cells to specific target locations and by the coordinated movements of whole epithelial sheets (discussed in Chapter 21). In vertebrates, *neural crest cells* migrate long distances from their site of origin in the neural tube to a variety of sites throughout the embryo (see Movie 21.7). Similarly, actin-rich growth cones at the advancing tips of developing axons travel to distant synaptic targets.

The adult animal seethes with crawling cells. Macrophages and neutrophils crawl to sites of infection and engulf foreign invaders as a critical part of

MBOC7_ptr_ch16_949-1026.indd 972 02/12/21 2:15 PM

ACTIN 973

the innate immune response. Osteoclasts tunnel into bone, forming channels that are filled in by the osteoblasts that follow them, in a continual process of bone remodeling and renewal. Similarly, fibroblasts migrate through connective tissues, remodeling them where necessary and helping to rebuild damaged structures at sites of injury. In an ordered procession, the cells in the epithelial lining of the intestine travel up the sides of the intestinal villi, replacing absorptive cells lost at the tip of the villus. Cell migration also has a role in many cancers, when cells in a primary tumor invade neighboring tissues and crawl into blood vessels or lymph vessels and then emerge at other sites in the body to form metastases.

Cell migration depends on the actin-rich cortex that lies beneath the plasma membrane. **Figure 16–19** illustrates distinct modes of cell migration on the basis of how the actin is organized. All migration is characterized by *protrusion,* in which the plasma membrane is pushed out at the front of the cell. In **mesenchymal cell migration**, characteristic of fibroblasts or epithelial cells grown on glass surfaces, the Arp2/3 complex mediates actin filament

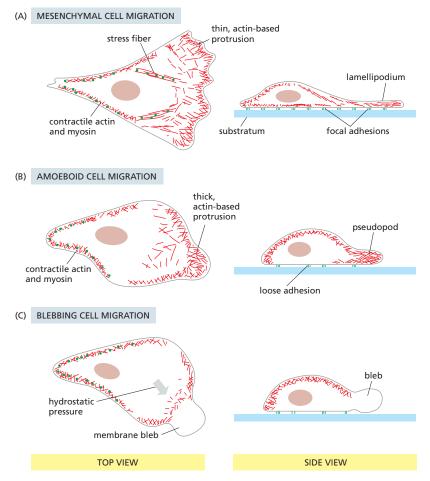

Figure 16–19 Modes of cell migration. (A) In the mesenchymal mode of cell migration, focal adhesions form behind protruding lamellipodia that connect to contractile stress fibers, bracing the cell against the surface (substratum) across which it is migrating. (B) In amoeboid cell migration, a three-dimensional pseudopod is formed by explosive actin polymerization at the leading edge. Cells maintain traction even though adhesion to the substratum is reduced, enabling much more rapid cell movement. (C) Leading edge protrusion can also occur through the formation of a bleb if the plasma membrane detaches from the underlying cortex and is pushed out by hydrostatic pressure. In all three modes of migration, contraction of cortical actin and myosin II at the rear of the cell drives locomotion of the cell body.

MBOC7_ptr_ch16_949-1026.indd 973 02/12/21 5 PM

nucleation at the leading edge of the cell, thereby generating a *lamellipodium* (see Figure 16–18). Behind the leading edge, *cofilin* (see Figure 16–16) disassembles the older (ADP-bound) actin filaments. The actin network is therefore assembling at the front and disassembling at the back, reminiscent of the treadmilling that occurs in individual actin filaments as discussed previously (see Figure 16–11). Mesenchymal cell migration requires firm attachment to the underlying substratum, which allows the cell body to generate traction and propel itself forward. The actin cytoskeleton braces itself using stress fibers connected to integrin-based focal adhesions on the bottom surface of the cell (see Figure 19–56). Contraction of bundles of actin filaments and myosin II motors at the rear of the cell, coordinated with disassembly of attachment sites, enables the cell body to translocate.

Mesenchymal cell migration is slow, with movement rates of less than 1 μ m per minute. In contrast, a second mode of cell migration, amoeboid cell migration, resembles the rapid movement and shape changes typical of amoebae and can be hundreds of times faster (Movie 16.2). This mode of movement is typical of white blood cells such as neutrophils and is characterized by the explosive extension of cell protrusions by local activation of the Arp2/3 complex. The protrusions are much thicker than lamellipodia and are called pseudopodia (or pseudopods). In contrast to mesenchymal cell migration, amoeboid-type movement does not rely as heavily on integrin-based attachments to the underlying surface. Traction nevertheless occurs through a weaker association to the substratum, and migrating cells appear more rounded. Locomotion is accompanied by a combination of protrusion at the front of the cell and contraction at the rear.

Protrusion of pseudopodia is driven by the same principles of actin filament polymerization and depolymerization that operate in lamellipodia, with cycles of actin nucleation, polymerization, and disassembly at the leading edge of the cell, but generating a three-dimensional rather than a two-dimensional structure. A distinct type of three-dimensional membrane protrusion can also result from a process called **blebbing**. In this case, the plasma membrane detaches locally from the underlying actin cortex, thereby allowing cytoplasmic flow to push the membrane outward. The formation of a membrane bleb depends on hydrostatic pressure, which is generated by the contraction of actin and myosin assemblies in the rear of the cell. Once blebs have extended, actin filaments reassemble on the inside surface of the blebbed membrane to form a new actin cortex.

Thus, leading-edge protrusion, adhesion to the surface, and contraction at the cell cortex underlie all modes of cell migration. These migration modes can interconvert depending on cell state, the extracellular environment, and the activation of different signaling pathways.

Cells Migrating in Three Dimensions Can Navigate Around Barriers

Studying the movement of cells on two-dimensional surfaces reveals important principles of cell migration. Most migrating cells in the body, however, must negotiate their way through a complex, three-dimensional environment. Surrounded by other cells and extracellular matrix, migrating cells are confined in space and must navigate around physical barriers separating them from their destination. During immune surveillance, for example, white blood cells called *dendritic cells* migrate between sites of infection and lymph nodes to initiate a systemic immune response (see Chapter 24). Dendritic cell migration can be mimicked by embedding them in a three-dimensional collagen gel matrix, in which they undergo rapid amoeboid migration toward a chemotactic signal, extending a large number of actin-rich protrusions (Figure 16–20A and B). When introduced into a microchamber containing different-sized channels, a cell will choose the widest path (Figure 16–20C). Later in this chapter, we discuss how chemotactic cues induce cell polarization and guide a migrating cell in the right direction.

MBOC7_ptr_ch16_949-1026.indd 974 02/12/21 2:15 PM

ACTIN 975

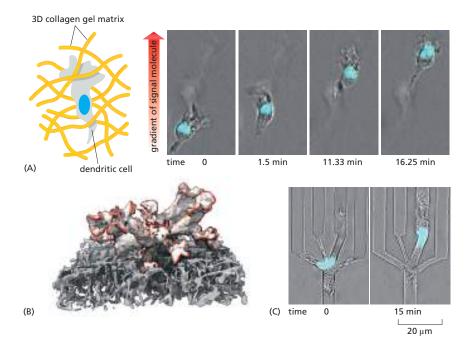

Figure 16-20 A dendritic cell migrating in three dimensions. (A) Schematic of a cell introduced into a collagen gel matrix. Images at right show that a chemotactic signal gradient induces polarized extension of pseudopodia that explore the environment, seeking out a path through gaps in the gel matrix that are typically smaller than the cell diameter. The nucleus is stained with a blue dve. (B) Three-dimensional image of a dendritic cell and its many pseudopodia (outlined in red) that is based on fluorescence microscopy. A portion of the collagen matrix surrounding the cell is shown in gray. (C) In this experiment, a dendritic cell was introduced into a microchannel that contains a decision point with four different pore sizes. Using the nucleus as a gauge, the cell ultimately chooses a path through the largest pore (Movie 16.3). (Courtesy of Michael Sixt.)

Some cells use specialized adhesion structures called **podosomes** that are important for cells to cross tissue barriers, for example during embryonic development. **Invadopodia** are related structures that contribute to the migration of metastatic cancer cells invading a tissue. Podosomes and invadopodia contain many of the same actin-regulatory components as other protrusions. They also secrete proteases that degrade the extracellular matrix, allowing them to carve through matrix barriers in their path.

Summary

Actin is a highly conserved cytoskeletal protein that is present in high concentrations in nearly all eukaryotic cells. Nucleation presents a kinetic barrier to actin polymerization, but once formed, actin filaments undergo dynamic behavior due to hydrolysis of the bound ATP. Actin filaments are polarized and can undergo treadmilling when a filament assembles at the plus end while simultaneously depolymerizing at the minus end. In cells, actin filament dynamics are regulated at every step, and the varied forms and functions of actin depend on a versatile repertoire of accessory proteins. Approximately half of the actin is kept in a monomeric form through association with proteins such as profilin. Nucleation factors such as the Arp2/3 complex and formins promote formation of branched and parallel filaments, respectively. Interplay between proteins that bind or cap actin filaments and those that promote filament severing or depolymerization can slow or accelerate the kinetics of filament assembly and disassembly. Another class of accessory proteins assembles the filaments into larger ordered structures by cross-linking them to one another in geometrically defined ways. Connections between these actin arrays and the plasma membrane of cells give an animal cell mechanical strength and permit the elaboration of cortical cellular structures such as lamellipodia, filopodia, pseudopodia, and microvilli. By inducing actin filament polymerization at their surface, intracellular pathogens can hijack the host-cell cytoskeleton and move around inside the cell. Cell migration depends on the formation of protrusions at the leading edge by assembly of new actin filaments or membrane blebbing, traction against the underlying substratum, and contractile forces generated by myosin motors to bring the cell body forward.

976

Figure 16–21 Myosin II. (A) The two globular heads and long tail of a myosin II molecule shadowed with platinum can be seen in this electron micrograph. (B) A myosin II molecule is composed of two heavy chains (each about 2000 amino acids long; green) and four light chains (blue). The light chains are of two distinct types, and one copy of each type is present on each myosin head. Dimerization occurs when the two α helices of the heavy chains wrap around each other to form a coiled-coil, driven by the association of regularly spaced hydrophobic amino acids (see Figure 3–8). The coiled-coil arrangement makes an extended rod in solution, and this part of the molecule forms the tail. (A, courtesy of David Shotton.)

MYOSIN AND ACTIN

A crucial feature of the actin cytoskeleton is that it can form contractile structures that cross-link and slide actin filaments relative to one another through the action of **myosin** motor proteins. Actin–myosin assemblies perform important functions in all eukaryotic cells, such as in cell migration as described earlier. In addition, actin and myosin drive muscle contraction.

Actin-based Motor Proteins Are Members of the Myosin Superfamily

The first motor protein to be identified was skeletal muscle myosin, which generates the force for muscle contraction. This protein, now called *myosin II*, is an elongated protein formed from two heavy chains and two copies of each of two light chains. Each heavy chain has a globular head domain at its N-terminus that contains the force-generating machinery, followed by a very long α -helical amino acid sequence that forms an extended coiled-coil to mediate heavy-chain dimerization (Figure 16–21). The two light chains bind close to the N-terminal head domain, while the long coiled-coil tail bundles itself with the tails of other myosin molecules. In skeletal muscle, these tail-tail interactions form large, bipolar *thick filaments* that have several hundred myosin heads, oriented in opposite directions at the two ends of the thick filament (Figure 16–22).

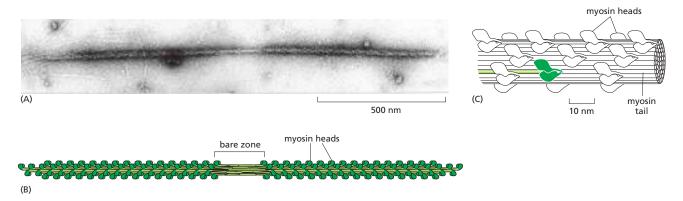

Figure 16–22 The myosin II bipolar thick filament in muscle. (A) Electron micrograph of a myosin II thick filament isolated from frog muscle. Note the central bare zone, which is free of head domains. (B) Schematic diagram, not drawn to scale. The myosin II molecules aggregate by means of their tail regions, with their heads projecting to the outside of the filament. The bare zone in the center of the filament consists entirely of myosin II tails. (C) A small section of a myosin II filament as reconstructed from electron micrographs. In the relaxed (noncontracting) state, the two heads of a myosin molecule are bent backward and sterically interfere with each other to switch off their activity. An individual myosin molecule in the inactive state is highlighted in *green*. The cytoplasmic myosin II filaments in non-muscle cells are much smaller, although similarly organized (see Figure 16–34). (A, from M. Stewart and R.W. Kensler, *J. Mol. Biol.* 192:831–851, 1986. With permission from Elsevier; C, based on R.A. Crowther et al., *J. Mol. Biol.* 184:429–439, 1985.)

MYOSIN AND ACTIN 977

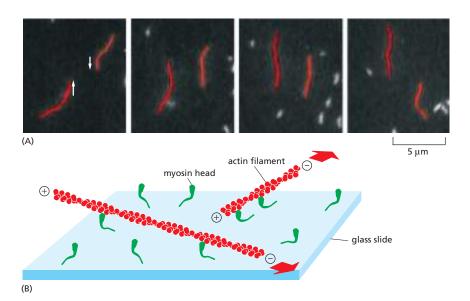

Figure 16-23 Direct evidence for the motor activity of the myosin head. In this experiment, purified myosin heads were attached to a glass slide, and then actin filaments labeled with fluorescent phalloidin were added and allowed to hind to the myosin heads. (A) When ATP was added, the actin filaments began to glide along the surface, owing to the many individual steps taken by each of the dozens of myosin heads bound to each filament. The video frames shown in this sequence were recorded about 0.6 second apart; the two actin filaments shown (red) were moving in opposite directions at a rate of about 4 μm/sec. (B) Diagram of the experiment. The large red arrows indicate the direction of actin filament movement (Movie 16.4). (A, courtesy of James Spudich.)

Each myosin head binds and hydrolyzes ATP, using the energy of ATP hydrolysis to walk toward the plus end of an actin filament (Figure 16–23). The opposing orientation of the heads in the thick filament makes the filament efficient at sliding pairs of oppositely oriented actin filaments toward each other, shortening the muscle. In skeletal muscle, in which carefully arranged actin filaments are aligned in *thin filament* arrays surrounding the myosin thick filaments, the ATP-driven sliding of actin filaments results in a powerful contraction. Cardiac and smooth muscle contain myosin II molecules that are similarly arranged, although different genes encode them.

Myosin Generates Force by Coupling ATP Hydrolysis to Conformational Changes

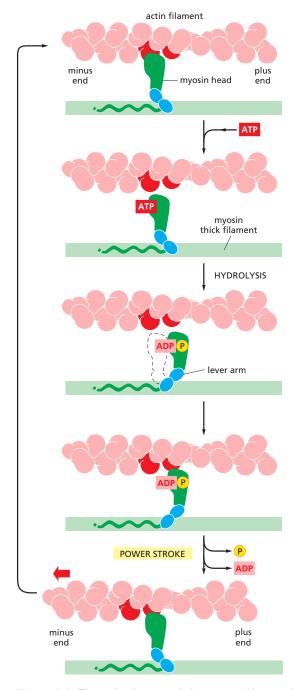

Motor proteins use structural changes in their ATP-binding sites to produce cyclic interactions with a cytoskeletal filament. Each cycle of ATP binding, hydrolysis, and release propels them forward in a single direction to a new binding site along the filament. For myosin II, each step of the movement along actin is generated by the swinging of an 8.5-nm-long α helix, or $\mathit{lever\ arm}$, which is structurally stabilized by the binding of light chains. At the base of this lever arm next to the head, there is a pistonlike helix that connects movements at the ATP-binding cleft in the head to small rotations of the so-called converter domain. A small change at this point can swing the helix like a long lever, causing the far end of the helix to move by about 5.0 nm.

These changes in the conformation of the myosin are coupled to changes in its binding affinity for actin, allowing the myosin head to release its grip on the actin filament at one point and snatch hold of it again at another. The full mechanochemical cycle of ATP binding, ATP hydrolysis, and phosphate release (which causes the *power stroke*) produces a single step of movement (Figure 16–24). At low ATP concentrations, the interval between the force-producing step and the binding of the next ATP is long enough that single steps can be observed (Figure 16–25).

Sliding of Myosin II Along Actin Filaments Causes Muscles to Contract

Muscle contraction is the most familiar and best-understood form of movement in animals. In vertebrates, running, walking, swimming, and flying all depend on the rapid contraction of skeletal muscle on its scaffolding of bone, while

MBOC7_ptr_ch16_949-1026.indd 977 02/12/21 5 PM

ATTACHED At the start of the cycle shown in this figure, a myosin head lacking a bound nucleotide is locked tightly onto an actin filament in a *rigor* configuration (so named because it is responsible for *rigor mortis*, the rigidity of death). In an actively contracting muscle, this state is very short-lived, being rapidly terminated by the binding of a molecule of ATP.

RELEASED A molecule of ATP binds to the large cleft on the "back" of the head (that is, on the side furthest from the actin filament) and immediately causes a slight change in the conformation of the actin-binding site, reducing the affinity of the head for actin. (The space drawn here between the head and actin emphasizes this change, although in reality the head probably remains very close to the actin.)

COCKED ATP binding triggers a conformational change in the cleft that leads to a rotation in the converter domain, causing the lever arm to swing out and the head to be displaced along the filament by a distance of about 5 nm. Hydrolysis of ATP occurs, but the ADP and inorganic phosphate (P) remain tightly bound to the protein.

RE-BINDING AND POWER STROKE The myosin head binds weakly to a new site on the actin filament, causing release of the inorganic phosphate produced by ATP hydrolysis, concomitantly with the tight binding of the head to actin. This release triggers the power stroke—the force-generating change in shape during which the head regains its original conformation. In the course of the power stroke, the head loses its bound ADP, thereby returning to the start of a new cycle.

FORCE GENERATING At the end of the cycle, the myosin head is again locked tightly to the actin filament in a rigor configuration. Note that the head has moved to a new position on the actin filament.

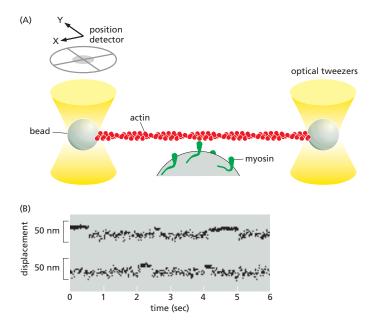

Figure 16–24 The cycle of structural changes used by myosin II to walk along an actin filament. In the myosin II cycle, the head remains bound to the actin filament for only about 5% of the entire cycle time, allowing many myosins to work together to move a single actin filament (Movie 16.5). (Based on I. Rayment et al., Science 261:58–65, 1993.)

involuntary movements such as heart pumping and gut peristalsis depend on the contraction of cardiac muscle and smooth muscle, respectively. All these forms of muscle contraction depend on the ATP-driven sliding of highly organized arrays of actin filaments against arrays of myosin II filaments.

Skeletal muscle was a relatively late evolutionary development, and muscle cells are highly specialized for rapid and efficient contraction. The long, thin muscle fibers of skeletal muscle are actually huge single cells that form during

MBOC7_ptr_ch16_949-1026.indd 978 02/12/21 2:15 PM

MYOSIN AND ACTIN 979

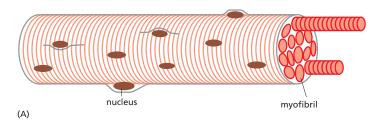

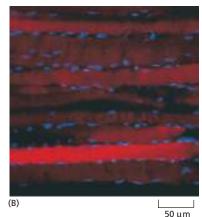

development by the fusion of many separate cells. The large muscle cell retains the many nuclei of the contributing cells. These nuclei lie just beneath the plasma membrane (Figure 16–26). The bulk of the cytoplasm inside is made up of myofibrils, which is the name given to the basic contractile elements of the muscle cell. A **myofibril** is a cylindrical structure 1–2 μ m in diameter that is often as long as the muscle cell itself. It consists of a long, repeated chain of tiny contractile units—called *sarcomeres*, each about 2.2 μ m long—which give the vertebrate myofibril its striated appearance (Figure 16–27).

Each sarcomere is formed from a miniature, precisely ordered array of parallel and partly overlapping thin and thick filaments. The *thin filaments* are composed of actin and associated proteins, and they are attached at their plus ends to a *Z disc* at each end of the sarcomere. The capped minus ends of the actin filaments extend in toward the middle of the sarcomere, where they overlap with *thick filaments*, the bipolar assemblies formed from specific muscle isoforms of myosin II (see Figure 16–22). When this region of overlap is examined in cross section by electron microscopy, the myosin filaments are arranged

Figure 16-25 The force of a single myosin molecule moving along an actin filament measured using an optical trap. (A) Schematic of the experiment, showing an actin filament with beads attached at both ends and held in place by focused beams of light called optical tweezers (Movie 16.6). The tweezers trap and move the bead and can also be used to measure the force exerted on the bead through the filament. In this experiment, the filament was positioned over another bead to which myosin II motors were attached, and the optical tweezers were used to determine the effects of myosin binding on movement of the actin filament. (B) These traces show filament movement in two separate experiments. Initially, when the actin filament is unattached to myosin, thermal motion of the filament produces noisy fluctuations in filament position. When a single myosin binds to the actin filament. thermal motion decreases abruptly, and a roughly 10-nm displacement results from movement of the filament by the motor. The motor then releases the filament. Because the ATP concentration is very low in this experiment, the myosin remains attached to the actin filament for much longer than it would in a muscle cell. (Adapted from C. Rüegg et al., News Physiol. Sci. 17:213-218, 2002. With permission from the American Physiological Society.)

Figure 16–26 Skeletal muscle cells (also called muscle fibers). (A) These huge multinucleated cells form by the fusion of many muscle cell precursors, called myoblasts. Here, a single muscle cell is depicted. In an adult human, a muscle cell is typically 50 μm in diameter and can be up to several centimeters long. (B) Fluorescence micrograph of rat muscle, showing the peripherally located nuclei (blue) in these giant cells. Myofibrils are stained red. (B, courtesy of Nancy L. Kedersha.)

(B) Detail of the skeletal muscle shown in A, showing portions of two adjacent myofibrils and the definition of a sarcomere (black arrow). (C) Schematic diagram of a single sarcomere, showing the origin of the dark and light bands seen in the electron micrographs. The Z discs, at each end of the sarcomere, are attachment sites for the plus ends of actin filaments (thin filaments); the M line, or midline, is the location of proteins that link adjacent myosin II filaments (thick filaments) to one another. (D) When the sarcomere contracts, the actin and myosin filaments slide past one another without shortening. (A and B, courtesy of Roger Craig.)

in a regular hexagonal lattice, with the actin filaments evenly spaced between them (Figure 16-28).

Sarcomere shortening is caused by the myosin filaments sliding past the actin thin filaments, with no change in the length of either type of filament (see Figure 16–27C and D). Bipolar thick filaments walk toward the plus ends of two sets of thin filaments of opposite orientations, driven by dozens of independent myosin heads that are positioned to interact with each thin filament. Because there is no coordination among the movements of the myosin heads, it is critical that they remain tightly bound to the actin filament for only a small fraction of each ATPase cycle so that they do not hold one another back. Each myosin thick filament has about 300 heads (294 in frog muscle), and each head cycles about five times per second in the course of a rapid contraction—sliding the myosin and actin filaments past one another at rates of up to 15 $\mu m/sec$ and enabling the sarcomere to shorten by 10% of its length in less than one-fiftieth of a second. The rapid synchronized shortening of the thousands of sarcomeres lying end-to-end in each myofibril enables skeletal muscle to contract rapidly enough for running and flying or for playing the piano.

Accessory proteins produce the remarkable uniformity in filament organization, length, and spacing in the sarcomere and enable it to withstand the constant wear-and-tear of contraction (Figure 16–29). The actin filament plus ends are anchored in the Z disc, which is built from CapZ and α -actinin; CapZ in the Z disc caps the filaments (preventing depolymerization), while α -actinin holds them together in a regularly spaced bundle. Actin filaments are stabilized along their length by tropomyosin and also by a protein of enormous size, called *nebulin*, which consists almost entirely of a repeating 35-amino-acid actin-binding motif. Nebulin stretches from the Z disc toward the minus end of each thin filament, which is capped and stabilized by tropomodulin. Although there is some slow exchange of actin subunits at both ends of the muscle thin filament, such that the components of the thin filament turn over with a half-life of several days, the actin filaments in sarcomeres are remarkably stable compared with those found

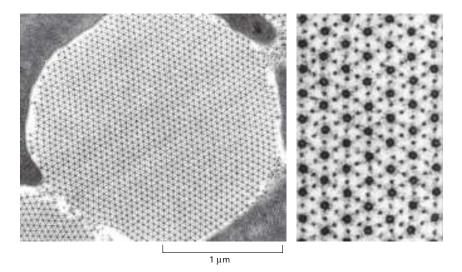

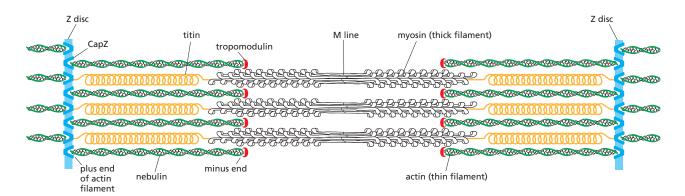

Figure 16–28 Electron micrographs of an insect flight muscle viewed in cross section. The myosin and actin filaments are packed together with almost crystalline regularity. Unlike their vertebrate counterparts, these myosin filaments have a hollow center, as seen in the enlargement on the right. The geometry of the hexagonal lattice is slightly different in vertebrate muscle. (From J. Auber and R. Couteaux, J. Microsc. 2:309–324, 1963. MYOSIN AND ACTIN 981

in most other cell types, whose dynamic actin filaments turn over with half-lives of a few minutes or less.

Opposing pairs of an even longer protein, called *titin*, position the thick filaments midway between the Z discs. Titin acts as a molecular spring, with a long series of immunoglobulin-like domains that can unfold one by one as stress is applied to the protein. A springlike unfolding and refolding of these domains keeps the thick filaments poised in the middle of the sarcomere and allows the muscle fiber to recover after being overstretched. In *Caenorhabditis elegans*, whose sarcomeres are longer than those in vertebrates, titin is longer as well, suggesting that it serves also as a molecular ruler, determining in this case the overall length of each sarcomere.

A Sudden Rise in Cytosolic Ca²⁺ Concentration Initiates Muscle Contraction

The force-generating molecular interaction between myosin thick filaments and actin thin filaments takes place only when a signal passes to the skeletal muscle from the nerve that stimulates it. Immediately upon arrival of the signal, the muscle cell needs to be able to contract very rapidly, with all the sarcomeres shortening simultaneously. Two major features of the muscle cell make extremely rapid contraction possible. First, as previously discussed, the individual myosin motor heads in each thick filament spend only a small fraction of the ATP cycle time bound to the filament and actively generating force, so many myosin heads can act in rapid succession on the same thin filament without interfering with one another. Second, a specialized membrane system relays the incoming signal rapidly throughout the entire cell. The signal from the nerve triggers an action potential in the muscle cell plasma membrane (discussed in Chapter 11), and this electrical excitation spreads swiftly into a series of membranous folds—the transverse tubules, or T tubules—that extend inward from the plasma membrane around each myofibril. The signal is then relayed across a small gap to the sarcoplasmic reticulum, an adjacent weblike sheath of modified endoplasmic reticulum that surrounds each myofibril like a net stocking (Figure 16-30A and B).

When the incoming action potential activates a Ca^{2+} channel in the T-tubule membrane, it triggers the opening of a Ca^{2+} -release channel in the closely associated sarcoplasmic reticulum membrane (**Figure 16–30C**). Ca^{2+} flooding into the cytosol then initiates the contraction of each myofibril. Because the signal from the muscle cell plasma membrane is passed within milliseconds (via the T tubules and sarcoplasmic reticulum) to every sarcomere in the cell, all of the myofibrils in the cell contract at once. The increase in Ca^{2+} concentration is transient because the Ca^{2+} is rapidly pumped back into the sarcoplasmic reticulum by an abundant, ATP-dependent Ca^{2+} -pump (also called a Ca^{2+} -ATPase) in its membrane (see Figure 11–14). Typically, the cytoplasmic Ca^{2+} concentration is restored to resting levels within 30 milliseconds, allowing the myofibrils to relax. Thus, muscle contraction depends

Figure 16-29 Organization of accessory proteins in a sarcomere. Each giant titin molecule extends from the Z disc to the M line—a distance of more than 1 μ m. Part of each titin molecule is closely associated with a myosin thick filament (which switches polarity at the M line); the rest of the titin molecule is elastic and changes length as the sarcomere contracts and relaxes. Each nebulin molecule is exactly the length of a thin filament. The actin filaments are also coated with tropomyosin and bound intermittently by troponin (not shown; see Figure 16-31) and are capped at both ends. Tropomodulin caps the minus end of the actin filaments, and CapZ anchors the plus end at the Z disc, which also contains α -actinin (not shown).

on two processes that consume enormous amounts of ATP: filament sliding, driven by the ATPase of the myosin motor domain, and $\rm Ca^{2+}$ pumping, driven by the $\rm Ca^{2+}$ -pump.

The Ca²⁺ dependence of vertebrate skeletal muscle contraction, and hence its dependence on commands transmitted via nerves, is due entirely to a set of specialized accessory proteins that are closely associated with the actin thin filaments. One of these accessory proteins is a muscle form of tropomyosin, the elongated protein that binds along the groove of the actin filament helix. The other is troponin, a complex of three polypeptides, troponins T, I, and C (named for their tropomyosin-binding, inhibitory, and Ca²⁺-binding activities, respectively). Troponin I binds to actin as well as to troponin T. In a resting muscle, the troponin I-T complex pulls the tropomyosin out of its normal binding groove into a position along the actin filament that interferes with the binding of myosin heads, thereby preventing any force-generating interaction. When the level of Ca²⁺ is raised, troponin C—which binds up to four molecules of Ca²⁺—causes troponin I to release its hold on actin. This allows the tropomyosin molecules to slip back into their normal position so that the myosin heads can walk along the actin filaments (Figure 16-31). Troponin C is closely related to the ubiquitous Ca²⁺-binding protein calmodulin (see Figure 15-34); it can be thought of as a specialized form of calmodulin that has acquired binding sites for troponin I and troponin T, thereby ensuring that the myofibril responds extremely rapidly to an increase in Ca²⁺ concentration.

MYOSIN AND ACTIN 983

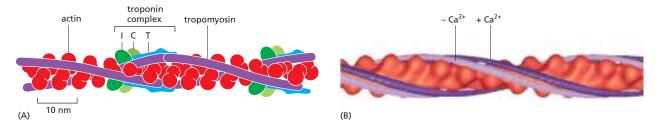

Figure 16–31 The control of skeletal muscle contraction by troponin. (A) A thin filament of a skeletal muscle cell, showing the positions of tropomyosin and troponin along the actin filament. Each tropomyosin molecule has seven evenly spaced regions with similar amino acid sequences, each of which is thought to bind to an actin subunit in the filament. (B) Reconstructed cryo-electron microscopy image of an actin filament showing the relative position of a superimposed tropomyosin strand in the presence (dark purple) or absence (light purple) of calcium. (A, adapted from G.N. Phillips et al., J. Mol. Biol. 192:111–131, 1986; B, adapted from C. Xu et al., Biophys. J. 77:985–992, 1999. With permission from the Biophysical Society.)

In smooth muscle cells, so called because they lack the regular striations of skeletal muscle, contraction is also triggered by an influx of calcium ions, but the regulatory mechanism is different. Smooth muscle forms the contractile portion of the stomach, intestine, and uterus, as well as the walls of arteries and many other structures requiring slow and sustained contractions. Smooth muscle is composed of sheets of highly elongated spindle-shaped cells, each with a single nucleus. Smooth muscle cells do not express the troponins. Instead, elevated intracellular Ca^{2+} levels regulate contraction by a mechanism that depends on calmodulin (Figure 16–32). Ca^{2+} -bound calmodulin activates myosin

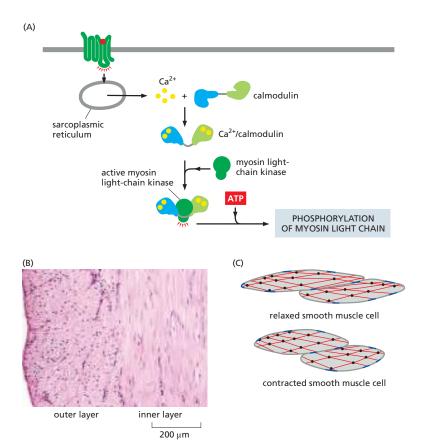

Figure 16-32 Smooth muscle contraction. (A) Upon muscle stimulation by activation of cell-surface receptors, Ca²⁺ released into the cytoplasm from the sarcoplasmic reticulum (SR) binds to calmodulin (see Figure 15-34). Ca²⁺-bound calmodulin then binds myosin light-chain kinase (MLCK), which phosphorylates myosin light chain, stimulating myosin activity. Nonmuscle myosin is regulated by the same mechanism (see Figure 16-34). (B) Smooth muscle cells in a cross section of cat intestinal wall. The outer layer of smooth muscle is oriented with the long axis of its cells extending parallel along the length of the intestine, and upon contraction will shorten the intestine. The inner layer is oriented circularly around the intestine and when contracted will cause the intestine to become narrower. Contraction of both layers squeezes material through the intestine, much like squeezing toothpaste out of a tube. (C) A model for the contractile apparatus in a smooth muscle cell, with bundles of contractile filaments containing actin and myosin (red) oriented obliquely to the long axis of the cell. Their contraction greatly shortens the cell. In this diagram, the bundle angles are exaggerated to schematically illustrate the effect of contraction. In addition, only a few of the many bundles are shown. (B, courtesy of Gwen V. Childs.)

MBOC7_ptr_ch16_949-1026.indd 983 02/12/21 2:15 PM

light-chain kinase (MLCK), thereby inducing the phosphorylation of smooth muscle myosin on one of its two light chains. When the light chain is phosphorylated, the myosin head can interact with actin filaments and cause contraction; when it is dephosphorylated, the myosin head tends to dissociate from actin and becomes inactive.

The phosphorylation events that regulate contraction in smooth muscle cells occur relatively slowly, so that maximum contraction often requires nearly a second (compared with the few milliseconds required for contraction of a skeletal muscle cell). But rapid activation of contraction is not important in smooth muscle: its myosin II hydrolyzes ATP about 10 times more slowly than does skeletal muscle myosin, producing a slow cycle of myosin conformational changes that results in slow contraction.

Heart Muscle Is a Precisely Engineered Machine

The heart is the most heavily worked muscle in the body, contracting about 3 billion (3×10^9) times during the course of a human lifetime (Movie 16.8). Heart cells express several specific isoforms of cardiac muscle myosin and cardiac muscle actin. Even subtle changes in these cardiac-specific contractile proteins—changes that would not cause any noticeable consequences in other tissues—can cause serious heart disease (Figure 16–33).

The normal cardiac contractile apparatus is such a highly tuned machine that a tiny abnormality anywhere in the works can be enough to gradually wear it down over years of repetitive motion. Familial hypertrophic cardiomyopathy is a common cause of sudden death in young athletes. It is a genetically dominant inherited condition that affects about two out of every thousand people, and it is associated with heart enlargement, abnormally small coronary vessels, and disturbances in heart rhythm (cardiac arrhythmias). The cause of this condition is either any one of more than 40 subtle point mutations in the genes encoding cardiac β -myosin heavy chain (almost all causing changes in or near the motor domain) or one of about a dozen mutations in other genes encoding contractile proteins—including myosin light chains, cardiac troponin, and tropomyosin. Minor missense mutations in the cardiac actin gene cause another type of heart condition, called dilated cardiomyopathy, which can also result in early heart failure.

Actin and Myosin Perform a Variety of Functions in Non-Muscle Cells

Most non-muscle cells contain contractile actin-myosin II assemblies that form transiently, enabling dynamic changes in cell morphology. Non-muscle contractile bundles are regulated by myosin phosphorylation rather than by troponin (Figure 16-34A). Contractile actin and myosin just beneath the plasma membrane in the cell cortex creates tension, and gradients in this tension lead to cell-shape changes. Actin-myosin II bundles also provide mechanical support by assembling into stress fibers that connect the cell to the extracellular matrix through focal adhesions or by forming a circumferential belt in an epithelial cell, connecting it to adjacent cells through adherens junctions (discussed in Chapter 19). As described in Chapter 17, actin and myosin II in the contractile ring generate the force for cytokinesis, the final stage in cell division. Finally, as discussed previously, contractile bundles also contribute to the adhesion and forward motion of migrating cells. Organization of contractile bundles is somewhat similar to the periodic organization of sarcomeres and involves many of the same proteins. However, non-muscle myosin II filaments are about sevenfold shorter than the thick filaments of skeletal muscle, and their formation is highly dynamic (Figure 16-34B and C).

Non-muscle cells also express a large family of other myosin proteins, which have diverse structures and functions in the cell. After the discovery of conventional muscle myosin, a second member of the family was found in the freshwater

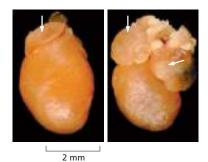

Figure 16–33 Effect on the heart of a subtle mutation in cardiac myosin. Left, normal heart from a 6-day-old mouse pup. Right, heart from a pup with a point mutation in both copies of its cardiac myosin gene, changing Arg403 to Gln. The arrows indicate the atria. In the heart from the pup with the cardiac myosin mutation, both atria are greatly enlarged (hypertrophic), and the mice die within a few weeks of birth. (From D. Fatkin et al., J. Clin. Invest. 103:147–153, 1999. With permission from the American Society for Clinical Investigation.)

MYOSIN AND ACTIN 985

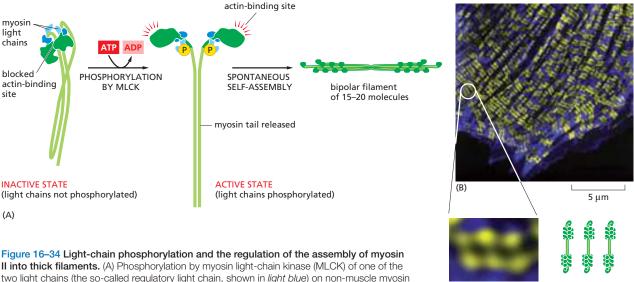

Figure 16–34 Light-chain phosphorylation and the regulation of the assembly of myosin II into thick filaments. (A) Phosphorylation by myosin light-chain kinase (MLCK) of one of the two light chains (the so-called regulatory light chain, shown in *light blue*) on non-muscle myosin II in a test tube has at least two effects: it causes a change in the conformation of the myosin heads, relieving steric inhibition to permit actin binding, and it releases the myosin tail from a "sticky patch" on the myosin head, thereby allowing the myosin molecules to assemble into short, bipolar, thick filaments. Smooth muscle is regulated by the same mechanism (see Figure 16–32). (B) Fluorescence micrograph showing the distribution of myosin light chain (*yellow*) and the actin filament cross-linker α -actinin (*blue*) in the contractile fibers of a rat embryo fibroblast. (C) A parallel stack of myosin filaments at higher magnification. These myosin II filaments are much smaller than those found in skeletal muscle cells (see Figure 16–22), but nevertheless form sarcomere-like units. (B and C, courtesy of Shiqiong Hu and Alexander Bershadsky.)

amoeba *Acanthamoeba castellanii*. This protein had a different tail structure and seemed to function as a monomer, and so it was named *myosin I* (for one-headed). Conventional muscle myosin was renamed *myosin II* (for two-headed). Subsequently, many other myosin types were discovered. The heavy chains generally start with a recognizable myosin motor domain at the N-terminus and then diverge widely with a variety of C-terminal tail domains (Figure 16–35). The myosin family includes a number of one-headed and two-headed varieties that are about equally related to myosin I and myosin II, and the nomenclature now reflects their approximate order of discovery (myosin III through at least myosin XVIII). Sequence comparisons among diverse eukaryotes indicate that there are at least 37 distinct myosin families in the superfamily. All of the myosins except one move toward the plus end of an actin filament, although they do so at different speeds. The exception is myosin VI, which moves toward the minus end. The

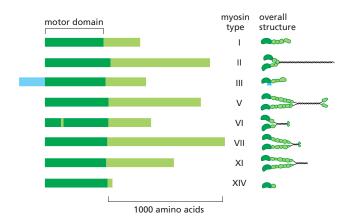

Figure 16-35 Myosin superfamily members. Comparison of the domain structure of the heavy chains of some myosin types. All myosins share similar motor domains (shown in dark green), but their C-terminal tails (light green) and N-terminal extensions (light blue) are very diverse. On the right are depictions of the molecular structures for these family members. Many myosins form dimers, with two motor domains per molecule, but a few (such as I, III, and XIV) seem to function as monomers, with just one motor domain. Myosin VI. despite its overall structural similarity to other family members, is unique in moving toward the minus end (instead of the plus end) of an actin filament. The small insertion within its motor head domain. not found in other myosins, is probably responsible for this change in direction.

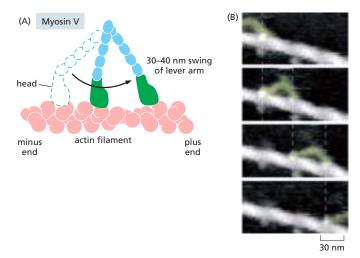

Figure 16–36 Myosin V walks along actin filaments. (A) The lever arm of myosin V is long, allowing it to take a bigger step along an actin filament than can myosin II (see Figure 16–24). (B) Atomic force microscopy images showing myosin V (green) walking along an actin filament. Myosin V functions to carry cargo in cells. (B, adapted from N. Kodera and T. Ando, *Biophys. Rev.* 6:237–260, 2014. Reproduced with permission of SNCSC.)

myosin tails (and the tails of motor proteins generally) have apparently diversified during evolution to permit the proteins to bind other subunits and to interact with different cargoes.

Some myosins are found only in plants, and some are found only in vertebrates. Most, however, are found in all eukaryotes, suggesting that myosins arose early in eukaryotic evolution. The human genome includes about 40 myosin genes. Nine of the human myosins are expressed primarily or exclusively in the hair cells of the inner ear, and mutations in five of them are known to cause hereditary deafness. These extremely specialized myosins are important for the construction and function of the complex and beautiful bundles of actin found in stereocilia that project from the apical surface of these cells; these cellular protrusions tilt in response to sound and convert sound waves into electrical signals.

The functions of most of the myosins remain to be determined, but several are well characterized. The myosin I proteins often contain either a second actin-binding site or a membrane-binding site in their tails, and they are generally involved in intracellular organization—including the protrusion of actin-rich structures at the cell surface, such as microvilli (see Panel 16-1 and Figure 16-4), and endocytosis. Myosin V is a two-headed myosin with a large step size (Figure 16-36) and is involved in organelle transport along actin filaments. In contrast to myosin II motors, which work in ensembles and are attached only transiently to actin filaments so as not to interfere with one another, myosin V moves continuously, or *processively*, along actin filaments without letting go. Myosin V functions are well studied in the yeast Saccharomyces cerevisiae, which undergoes a stereotypical pattern of growth and division called budding. Actin cables in the mother cell point toward the bud, where actin is found in patches that concentrate where cell-wall growth is taking place. Myosin V motors carry a wide range of cargoes—including mRNA, endoplasmic reticulum, and secretory vesicles—along the actin cables and into the bud (see Figure 16-76).

Summary

Using their neck domain as a lever arm, myosins convert ATP hydrolysis into mechanical work to move along actin filaments in a stepwise fashion. Skeletal muscle is made up of myofibrils containing thousands of sarcomeres assembled from highly ordered arrays of actin and myosin II filaments, together with many accessory proteins. Muscle contraction is stimulated by calcium, which causes the actin filament–associated protein tropomyosin to move, uncovering myosin binding sites and allowing the filaments to slide past one another. Smooth muscle and non-muscle cells have less well-ordered contractile bundles of actin and myosin, which are regulated by myosin light-chain phosphorylation. Myosin V transports cargo by walking along actin filaments.

MBOC7_ptr_ch16_949-1026.indd 986 02/12/21 2:15 PM

MICROTUBULES

Microtubules are structurally more complex than actin filaments, but they are also highly dynamic and play similarly diverse and important roles in the cell. Microtubules are polymers of the protein **tubulin**. The tubulin subunit is a heterodimer formed from two closely related globular proteins called α -tubulin and β -tubulin, each comprising 445–450 amino acids, which are tightly held together by noncovalent bonds (**Figure 16–37A**). These two tubulin proteins are found only in this heterodimer, and each α or β monomer has a binding site for one molecule of GTP. The GTP that is bound to α -tubulin is physically trapped at the dimer interface and is never hydrolyzed or exchanged; it can therefore be considered to be an integral part of the tubulin heterodimer structure. In contrast, β -tubulin may be bound to either GTP or GDP and—as we shall see—this difference is important for microtubule dynamics.

Tubulin is found in all eukaryotic cells, and it exists in multiple isoforms. Its amino acid sequence has been highly conserved during evolution: thus, yeast and human tubulins are 75% identical. In mammals, there are at least six forms of $\alpha\text{-tubulin}$ and a similar number of $\beta\text{-tubulins}$, each encoded by a different gene. Although the different forms of tubulin are very similar and can copolymerize into mixed microtubules in a test tube, they can have distinct locations in cells and tissues and perform subtly different functions.

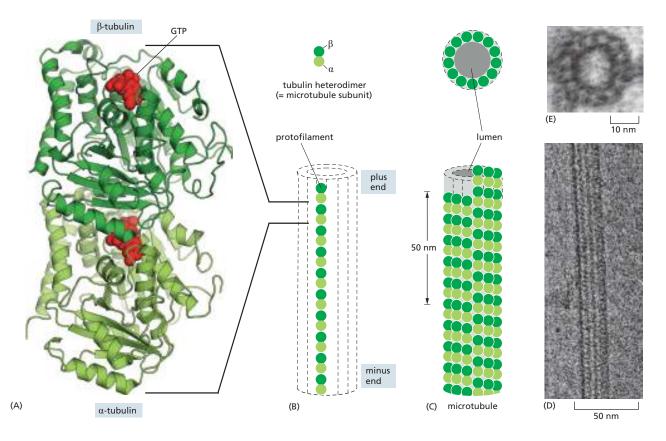

Figure 16–37 The structure of a microtubule and its subunit. (A) The subunit of each protofilament is a tubulin heterodimer, formed from a tightly linked pair of α - and β -tubulin monomers. The GTP molecule in the α -tubulin monomer is so tightly bound that it can be considered an integral part of the protein. The GTP molecule in the β -tubulin monomer, however, is less tightly bound and has an important role in filament dynamics. GTP is shown in red. (B) One tubulin subunit ($\alpha\beta$ -heterodimer) and one protofilament are shown schematically. Each protofilament consists of many adjacent subunits with the same orientation. (C) The microtubule is a stiff hollow tube formed from 13 protofilaments aligned in parallel. (D) A short segment of a microtubule viewed in an electron microscope. (E) Electron micrograph of a cross section of a microtubule showing a ring of 13 protofilaments. (A, PDB code: 1JFF; D, courtesy of Richard Wade; E, courtesy of Richard Linck.)

MBOC7_ptr_ch16_949-1026.indd 987 02/12/21 2:15 PM

As a striking example, mutations in a particular human β -tubulin gene give rise to a paralytic eye-movement disorder because of loss of ocular nerve function. Some human neurological diseases have also been linked to mutations in a specific tubulin gene.

Microtubules Are Hollow Tubes Made of Protofilaments

A microtubule is a hollow cylindrical structure built from 13 parallel protofilaments, each composed of $\alpha\beta$ -tubulin heterodimers stacked head to tail and then folded into a tube (Figure 16–37B, C, and D). The assembly of a microtubule generates two new types of protein–protein contacts. Along the longitudinal axis of a protofilament, the "top" of one β -tubulin molecule forms an interface with the "bottom" of the α -tubulin molecule in the adjacent heterodimer. This interface, which is very similar to the interface holding the α and β monomers together in the dimer subunit, has a high binding energy. Perpendicular to these interactions, neighboring protofilaments form lateral contacts, with the main lateral contacts occurring between monomers of the same type (α – α and β – β). A slight stagger in lateral contacts gives rise to the helical microtubule lattice, which holds most of the subunits tightly in place. As a result, the addition and loss of subunits occur almost exclusively at the microtubule ends (see Figure 16–5).

The multiple contacts among subunits make microtubules stiff and difficult to bend. The average length over which microtubules stay straight (persistence length) is more than 10 times that of actin filaments, making microtubules the stiffest and straightest structural elements found in most animal cells.

The subunits in each protofilament in a microtubule all point in the same direction, and the protofilaments themselves are aligned in parallel, with α -tubulins exposed at the minus end and β -tubulins exposed at the plus end. As for actin filaments, the regular, parallel orientation of their subunits gives microtubules both a structural and a dynamic polarity (Figure 16–38): the microtubule's plus end grows and shrinks much more rapidly than its minus end.

Microtubules Undergo a Process Called Dynamic Instability

Microtubule dynamics, like those of actin filaments, are profoundly influenced by the binding and hydrolysis of a nucleoside triphosphate—GTP for microtubules, as opposed to ATP for actin. GTP hydrolysis, which occurs only within the β -tubulin subunit of the tubulin dimer, proceeds very slowly in free tubulin subunits and is greatly accelerated when they are incorporated into microtubules. After GTP hydrolysis, a free phosphate group is released, leaving the GDP bound to β -tubulin within the microtubule lattice. Thus, as in the case of actin filaments, two different types of microtubule structures can exist, one in the *T form* bound to GTP and one in the *D form* bound to GDP. Because some of the energy of phosphate bond hydrolysis is stored as elastic strain in the polymer lattice, the

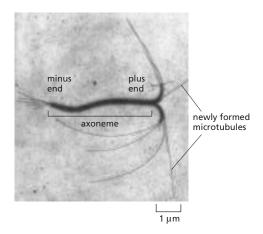

Figure 16–38 The preferential growth of microtubules at the plus end. Microtubules grow faster at one end than at the other. A stable bundle of microtubules obtained from the core of a cilium (called an axoneme) was incubated for a short time with tubulin subunits under polymerizing conditions. Microtubules grew fastest from the plus end of the microtubule bundle, the end on the right in this micrograph. (Courtesy of Gary Borisy.)

MBOC7_ptr_ch16_949-1026.indd 988 02/12/21 2:15 PM

free-energy change for dissociation of a subunit from the D-form polymer is more favorable (negative) than the free-energy change for dissociation of a subunit from the T-form polymer. This makes the ratio of $k_{\rm off}/k_{\rm on}$ for GDP-tubulin [which is equal to its critical concentration, $C_{\rm c}({\rm D})$] much higher than that of GTP-tubulin. As a result, under physiological conditions, the T form tends to polymerize and the D form tends to depolymerize.

Whether the tubulin subunits at the very end of a microtubule are in the T or the D form depends on the relative rates of tubulin addition and GTP hydrolysis. If the rate of subunit addition is low, hydrolysis is likely to occur before the next subunit is added, and the tip of the filament will then be in the D form. If the rate of subunit addition is high—and thus the filament is growing rapidly—then it is likely that a new subunit will be added to the end of the polymer before the GTP in the previously added subunit has been hydrolyzed. In this case, the tip of the polymer remains in the T form, forming a *GTP cap*. But this T form may not persist. Often GTP-tubulin subunits will assemble at the end of the microtubule at a rate similar to the rate of GTP hydrolysis, and in this case hydrolysis will sometimes "catch up" with the rate of subunit addition and transform the end to a D form. This transformation will be sudden and random, with a certain probability per unit time that depends on the concentration of free GTP-tubulin subunits, and it produces the microtubule's *dynamic instability*.

Suppose that the concentration of free tubulin is intermediate between the critical concentration for a T-form end and the critical concentration for a D-form end (that is, above the concentration necessary for T-form assembly, but below that for the D form). Now, any end that happens to be in the T form will grow, whereas any end that happens to be in the D form will shrink. On a single microtubule, an end might grow for a certain length of time in a T form, but then suddenly change to the D form and begin to shrink rapidly. At some later time, it might regain a T-form end and begin to grow again. This rapid interconversion between a growing and shrinking state, at a uniform free tubulin concentration, is called **dynamic instability** (Figure 16–39 and Figure 16–40A; see Panel 16–2). The change from growth to shrinkage is called a *catastrophe*, while the change from shrinkage to growth is called a *rescue*.

The structural basis for dynamic instability is uncertain. On the basis of observations of the ends of growing and shrinking microtubules $in\ vitro$, one model proposed that tubulin subunits in the T form, with GTP bound to the β monomer, produce straight protofilaments that make strong and regular lateral contacts with one another, and that the hydrolysis of GTP to GDP makes these protofilaments curve (Figure 16–40B). More recent studies indicate that free tubulin subunits possess a similar bent conformation in both the T form and the D form. Growing microtubules with curved protofilaments at their tips have now been observed both $in\ vitro$ and $in\ vivo$, and a straightening of the T form–containing protofilaments may occur subsequent to subunit incorporation as favorable lateral interactions zip them into the microtubule lattice. Regardless of the mechanism of microtubule assembly, the loss of a GTP cap and subsequent catastrophe causes protofilaments containing D-form subunits to spring apart and depolymerize (Figure 16–40C).

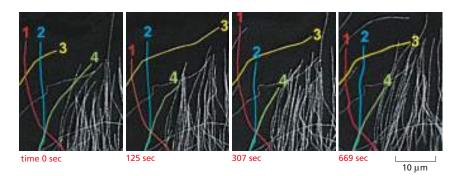

Figure 16–39 Direct observation of the dynamic instability of microtubules in a living cell. Microtubules in a newt lung epithelial cell were observed after the cell was injected with a small amount of fluorescently labeled tubulin. Notice the dynamic instability of microtubules at the edge of the cell. Four individual microtubules are highlighted for clarity; each of these shows alternating shrinkage and growth (Movie 16.9). (Courtesy of Wendy C. Salmon and Clare Waterman.)

MBOC7_ptr_ch16_949-1026.indd 989 02/12/21 2:15 PM

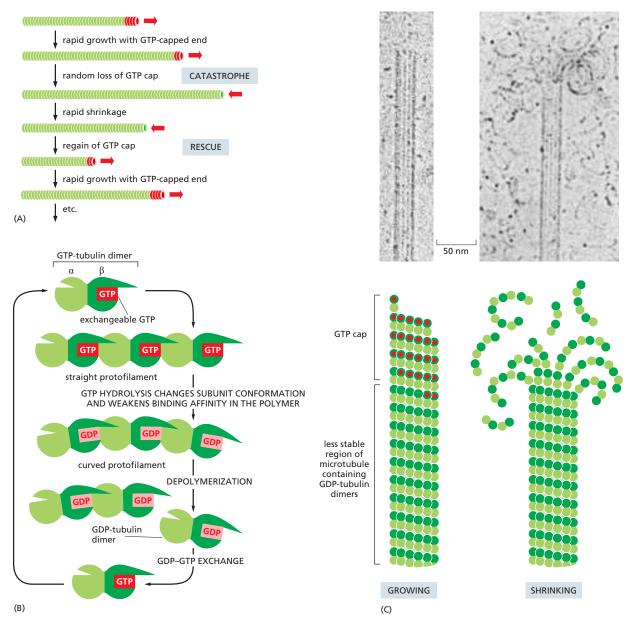

Figure 16-40 Dynamic instability due to the structural differences between a growing and a shrinking microtubule end. (A) If the free tubulin concentration in solution is near the critical concentration, a single microtubule end may undergo transitions between a growing state and a shrinking state. A growing microtubule has GTP-containing subunits at its end, forming a GTP cap. If GTP hydrolysis proceeds more rapidly than subunit addition, the cap is lost and the microtubule begins to shrink, an event called a catastrophe. But GTP-containing subunits may still add to the shrinking end, and if enough add to form a new cap, then microtubule growth resumes, an event called a rescue. (B) Model for the structural consequences of GTP hydrolysis in the microtubule lattice. The addition of GTP-containing tubulin subunits to the end of a protofilament causes the end to grow in a linear conformation that can readily pack into the cylindrical wall of the microtubule. Hydrolysis of GTP after assembly changes the conformation of the subunits and tends to force the protofilament into a curved shape that is less able to pack into the microtubule wall. (C) In an intact microtubule with a stable cap of GTP-tubulin, protofilaments made from GDP-containing subunits are forced into a linear conformation by the many lateral bonds within the microtubule wall. Loss of the GTP cap, however, allows the GDP-containing protofilaments to relax into their more curved conformation. This leads to a progressive disruption of the microtubule. Above the drawings of a growing and a shrinking microtubule, electron micrographs show actual microtubules in each of these two states. Note particularly the curling, disintegrating GDP-containing protofilaments at the end of the shrinking microtubule. (C, © 1991 E.M. Mandelkow, E. Mandelkow, and R.A. Milligan. MBOC7_ptr_ch16_949-1026.indd 990 02/12/21 2:15 PM

Why does nucleoside triphosphate hydrolysis lead to treadmilling of actin filaments, while microtubules undergo dynamic instability? One explanation is that the tubulin subunits with GDP bound have a very low affinity for one another, with a very high $k_{\rm off}/k_{\rm on}$. Therefore, as soon as GTP hydrolysis occurs at the tip of a microtubule growing *in vitro*, it undergoes a catastrophe and depolymerizes completely. In contrast, ADP-actin has a lower $k_{\rm off}/k_{\rm on}$ ratio and it depolymerizes more slowly. A second reason is thought to be differences in critical concentrations ($C_{\rm c}$) for the two ends of the filaments. The minus end of an actin filament has a much higher $C_{\rm c}$ than the plus end, whereas measurements of microtubules indicate that the plus and minus ends possess a similar $C_{\rm c}$. Therefore, although the basic principles of actin and microtubule dynamics are very similar, with nucleoside triphosphate binding and hydrolysis leading to dynamic behaviors, quantitative differences in affinities lead to dramatic differences in their intrinsic behavior.

Microtubule Functions Are Inhibited by Both Polymer-stabilizing and Polymer-destabilizing Drugs

Chemical compounds that impair polymerization or depolymerization of microtubules are powerful tools for investigating the roles of these polymers in cells. Whereas *colchicine* and *nocodazole* interact with tubulin subunits and lead to microtubule depolymerization, *Taxol* binds to and stabilizes microtubules, causing a net increase in tubulin polymerization (see Table 16–1). Drugs like these have a rapid and profound effect on the organization of the microtubules in living cells. Both microtubule-depolymerizing drugs (such as nocodazole) and microtubule-polymerizing drugs (such as Taxol) preferentially kill dividing cells, because microtubule dynamics are crucial for correct function of the mitotic spindle (discussed in Chapter 17). Some of these drugs kill certain types of tumor cells in a human patient, although not without toxicity to rapidly dividing normal cells, including those in the bone marrow, intestine, and hair follicles. Taxol in particular has been widely used to treat cancers of the breast and lung, and it is frequently successful in treatment of tumors that are resistant to other chemotherapeutic agents.

A Protein Complex Containing y-Tubulin Nucleates Microtubules

Because formation of a microtubule requires the interaction of many tubulin heterodimers, the concentration of tubulin subunits required for spontaneous nucleation of microtubules is very high. Microtubule nucleation therefore requires help from other factors. While α - and β -tubulins are the regular building blocks of microtubules, another type of tubulin, called γ -tubulin, is present in much smaller amounts than α - and β -tubulin and is involved in the nucleation of microtubule growth in organisms ranging from yeasts to humans. Microtubules are generally nucleated from a specific intracellular location known as a **microtubule-organizing center (MTOC)** where γ -tubulin is most enriched. Nucleation in many cases depends on the γ -tubulin ring complex (γ -TuRC). Within this complex, two accessory proteins bind directly to the γ -tubulin, along with several other proteins that help create a spiral ring of γ -tubulin molecules, which serves as a template that creates a microtubule with 13 protofilaments (Figure 16-41).

The Centrosome Is a Prominent Microtubule Nucleation Site

Many animal cells possess a single, well-defined MTOC called the centrosome, which is located adjacent to the nucleus and from which microtubules are nucleated at their minus ends, so the plus ends point outward and continually grow and shrink, probing the entire three-dimensional volume of the cell. A centrosome typically recruits more than 50 copies of γ -TuRC. However, most animal cells contain many hundreds of microtubules, most of which could not be stably anchored at the centrosome simply because they would not fit. Thus,

MBOC7_ptr_ch16_949-1026.indd 991 02/12/21 2:15 PM

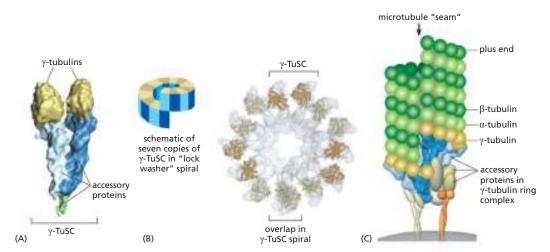

Figure 16–41 Microtubule nucleation by the γ -tubulin ring complex. (A) Two copies of γ -tubulin associate with a pair of accessory proteins to form the γ -tubulin small complex (γ -TuSC). This image was generated by high-resolution electron microscopy of individual purified complexes. (B) Seven copies of the γ -TuSC associate to form a spiral structure in which the last γ -tubulin lies beneath the first, resulting in 13 exposed γ -tubulin subunits in a circular orientation that matches the orientation of the 13 protofilaments in a microtubule. (C) In many cell types, the γ -TuSC spiral associates with additional accessory proteins to form the γ -tubulin ring complex (γ -TuRC), which is likely to nucleate the minus end of a microtubule as shown here. Note the longitudinal discontinuity between two protofilaments, which results from the spiral orientation of the γ -tubulin subunits. Microtubules often have one such "seam" breaking the otherwise uniform helical packing of the protofilaments. (λ and B, from J.M. Kollman et al., *Nature* 466:879–883, published 2010 by Macmillan Publishers Ltd. Reproduced with permission of SNCSC.)

the majority of $\gamma\textsc{-TuRC}$ is found in the cytoplasm, and centrosomes are not absolutely required for microtubule nucleation, as destroying them with a laser pulse does not prevent microtubule nucleation elsewhere in the cell. A variety of proteins have been identified that anchor $\gamma\textsc{-TuRC}$ to the centrosome, but mechanisms that activate microtubule nucleation at MTOCs and at other sites in the cell are poorly understood.

Embedded in the centrosome are the **centrioles**, a pair of cylindrical structures arranged at right angles to each other in an L-shaped configuration (**Figure 16–42**).

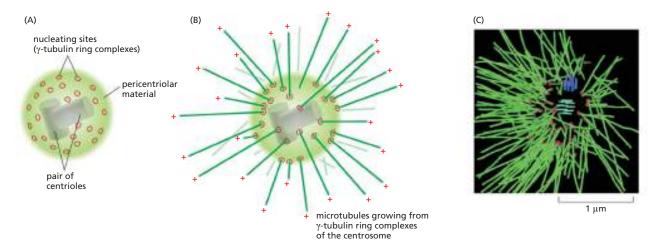

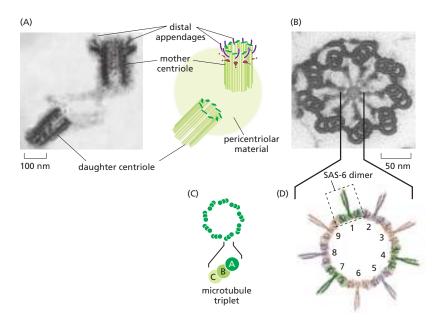

Figure 16–42 The centrosome. (A) The centrosome is a major MTOC in animal cells. Located in the cytoplasm next to the nucleus, it consists of a pair of centrioles surrounded by an amorphous matrix of fibrous proteins, the pericentriolar material, in which the γ -tubulin ring complexes that nucleate microtubule growth are embedded. (B) A centrosome with attached microtubules. The minus end of each microtubule is embedded in the centrosome, having grown from a γ -tubulin ring complex, whereas the plus end of each microtubule is free in the cytoplasm. (C) In a reconstructed image of the MTOC from a *C. elegans* cell, a dense thicket of microtubules can be seen emanating from the centrosome. (C, from E.T. O'Toole et al., *J. Cell Biol.* 163:451–456, 2003. With permission from the authors.)

A centriole consists of a cylindrical array of short, modified microtubules arranged into a barrel shape with striking ninefold symmetry (Figure 16–43). Together with a large number of accessory proteins, the centrioles recruit the *pericentriolar material*, where microtubule nucleation takes place. The pericentriolar material consists of a dense spherical matrix that is thought to form through a process of biomolecular condensation (see Figure 12–6). As described in Chapter 17 (see Figure 17–29), the centrosome duplicates before mitosis, forming a pair of centrosomes that each contain a centriole pair. When mitosis begins, the two centrosomes move apart to form the poles of the mitotic spindle (see Panel 17–1).

Microtubule Organization Varies Widely Among Cell Types

The arrangement of microtubules in the cytoplasm varies in different cell types (Figure 16-44). In budding yeast, microtubules are nucleated at an MTOC that is embedded in the nuclear envelope as a small, multilayered structure called the *spindle pole body*, also found in other fungi and diatoms. Higher-plant cells lack centrosomes and nucleate microtubules at sites distributed all around the nuclear envelope and at the cell cortex. Neither fungi nor most plant cells contain centrioles. Despite these differences, all these cells seem to use γ -TuRC to nucleate their microtubules.

Cultured fibroblasts contain an aster-like configuration of microtubules, with dynamic plus ends pointing outward toward the cell periphery and stable

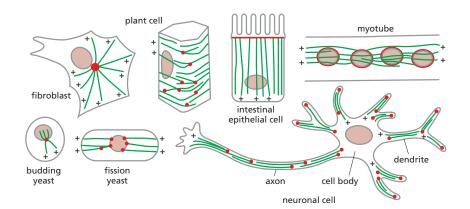

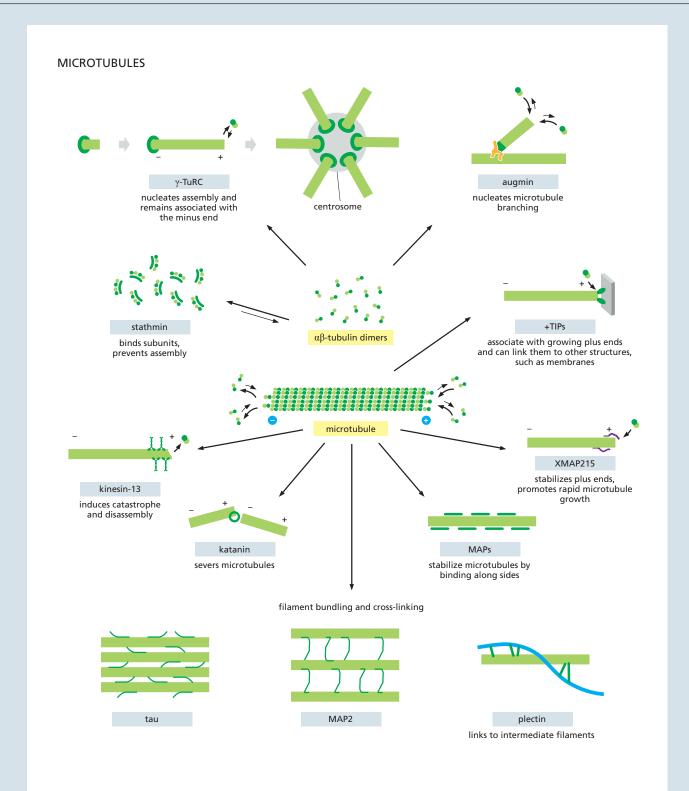

Figure 16-43 A pair of centrioles in the centrosome. (A) An electron micrograph of a thin section of an isolated centrosome from an interphase cell showing the mother centriole with its distal appendages and the adjacent daughter centriole, which formed through a duplication event during S phase (see Figure 17-29). In the centrosome, the centriole pair is surrounded by a dense matrix of pericentriolar material from which microtubules nucleate. Centrioles also function as basal bodies to nucleate the formation of ciliary axonemes (see Figure 16-58). (B) Electron micrograph of a cross section through a centriole in the cortex of a protozoan. Each centriole is composed of nine sets of microtubule triplets arranged to form a cylinder. (C) Each triplet contains one complete microtubule (the A microtubule) fused to two incomplete microtubules (the B and C microtubules). (D) The centriolar protein SAS-6 forms a coiled-coil dimer. Nine SAS-6 dimers can self-associate to form a ring. Located at the hub of the centriole cartwheel-like structure, the SAS-6 ring is thought to generate the ninefold symmetry of the centriole. (A, from M. Paintrand et al., J. Struct. Biol. 108:107, 1992. With permission from Elsevier; B, courtesy of Richard Linck; D, courtesy of Michel Steinmetz.)

Figure 16–44 Microtubule organization in different cell types. Microtubules (green) are organized by MTOCs (red), which nucleate, anchor, or stabilize the microtubule minus ends. A single focal MTOC in a fibroblast or yeast cell is the primary nucleation site and leads to microtubules organized with their plus ends extending out toward the cell periphery. A more complex distribution of microtubule plus and minus ends is observed in other cell types.

MBOC7_ptr_ch16_949-1026.indd 993 02/12/21 2:15 PM

Some of the major accessory proteins of the microtubule cytoskeleton. Except for two classes of motor proteins, an example of each major type is shown. Each of these is discussed in the text. However, most cells contain more than a hundred different microtubule-binding proteins, and—as for the actin-associated proteins—it is likely that there are important types of microtubule-associated proteins that are not yet recognized.

MBOC7_ptr_ch16_949-1026.indd 994 02/12/21 2:15 PM

minus ends gathered near the nucleus. Most microtubule minus ends detach from the centrosome and can be organized by other cellular structures, such as the Golgi apparatus, which functions as an MTOC in mesenchymal cells. The organization of microtubules in the cell establishes a general coordinate system, which is then used to position many organelles within the cell. Highly differentiated cells with complex morphologies, such as neurons, muscles, and epithelial cells, use additional mechanisms to establish their more elaborate internal organization. Thus, for example, when an epithelial cell forms cell-cell junctions and becomes highly polarized, the microtubule minus ends relocalize to a region near the apical plasma membrane. From this asymmetrical location, a microtubule array extends along the long axis of the cell, with plus ends directed toward the basal surface (see Figure 16-4). In many cells, the minus ends of microtubules are stabilized by association with γ-TuRC or other capping proteins, or else they serve as microtubule-depolymerization sites. One class of capping proteins, called CAMSAPs in vertebrates, acts to protect minus ends from depolymerization and anchor them to cellular structures, such as the Golgi apparatus or the cell cortex.

Neurons contain complex cytoskeletal structures. As they differentiate, neurons send out specialized processes that will either receive electrical signals (dendrites) or transmit electrical signals (axons) (see Figure 16-45). Axons and dendrites (collectively called neurites) are filled with bundles of microtubules that are critical to their structure and their function. In axons, all the microtubules are oriented with their minus ends pointing back toward the cell body and their plus ends pointing toward the axon terminals (see Figure 16-44). Microtubules do not reach from the cell body all the way to the axon terminals; each is typically only a few micrometers in length, but large numbers are staggered in an overlapping array. These aligned microtubule tracks act as a highway to transport specific proteins, protein-containing vesicles, and mRNAs to the axon terminals, where synapses are constructed and maintained. The longest axon in the human body reaches from the base of the spinal cord to the foot and is up to a meter in length. Dendrites are generally much shorter. The microtubules in dendrites lie parallel to one another but their polarities are mixed, with some pointing their plus ends toward the dendrite tip, and others pointing in the opposite direction.

Microtubule-binding Proteins Modulate Filament Dynamics and Organization

Microtubule polymerization dynamics are very different in cells than in solutions of pure tubulin. Microtubules in cells exhibit a much higher polymerization rate (typically 10–15 $\mu m/min$, relative to about 1.5 $\mu m/min$ with purified tubulin at similar concentrations), a greater catastrophe frequency, and extended pauses in microtubule growth, a dynamic behavior rarely observed in pure tubulin solutions. These and other differences arise because microtubule dynamics inside the cell are governed by a variety of proteins that bind tubulin dimers or microtubules, as summarized in Panel 16–4.

Proteins that bind to microtubules are collectively called **microtubule** associated proteins, or MAPs. Because the short (~20 amino acid) C-terminal tails of both α - and β -tubulin that protrude from the microtubule are enriched in glutamic and aspartic acids, the surface of the microtubule possesses a net negative charge. Many MAPs are positively charged and bind to microtubules through electrostatic interactions. Some MAPs can stabilize microtubules against disassembly. A subset of MAPs can also mediate the interaction of microtubules with other cell components. This subset is prominent in neurons, where stabilized microtubule bundles form the core of the axons and dendrites that extend from the cell body (Figure 16–45). These MAPs have at least one domain that binds to the microtubule surface and another that projects outward. The length of the projecting domain can determine how closely MAP-coated microtubules pack together, as demonstrated in cells engineered to overproduce different MAPs.

Figure 16–45 Localization of MAPs in the axon and dendrites of a neuron. This immunofluorescence micrograph shows the distribution of the proteins tau (green) and MAP2 (orange) in a hippocampal neuron in culture. Whereas tau staining is confined to the axon (long and branched in this neuron), MAP2 staining is confined to the cell body and its dendrites. The antibody used here to detect tau binds only to unphosphorylated tau; phosphorylated tau is also present in dendrites. (Courtesy of James W. Mandell and Gary A. Banker.)

MBOC7_ptr_ch16_949-1026.indd 995 02/12/21 2:15 PM

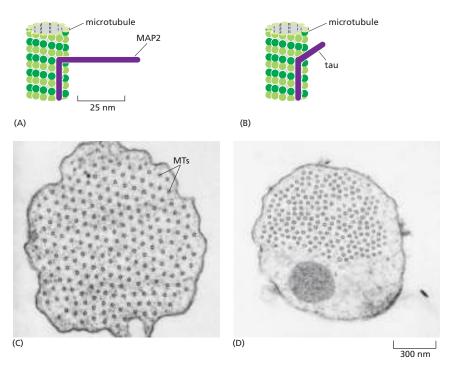

Figure 16–46 Organization of microtubule bundles by MAPs. (A) One end of MAP2 binds along the microtubule lattice and extends a long projecting arm. (B) Tau possesses a shorter projection arm. (C) Electron micrograph showing a cross section through a microtubule bundle in a cell overexpressing MAP2. The regular spacing of the microtubules (MTs) in this bundle results from the constant length of the projecting arms of MAP2. (D) Similar cross section through a microtubule bundle in a cell overexpressing tau. Here the microtubules are spaced more closely together than they are in C because of tau's relatively short projecting arm. (C and D, from J. Chen et al., Nature 360:674–677, published 1992 by Nature Publishing Group. Reproduced with permission of SNCSC.)

Cells overexpressing MAP2, which has a long projecting domain, form bundles of stable microtubules that are kept widely spaced, while cells overexpressing tau, a MAP with a much shorter projecting domain, form bundles of more closely packed microtubules (Figure 16-46). MAPs are the targets of several protein kinases, and phosphorylation of a MAP can control both its activity and localization inside cells by disrupting its electrostatic interaction with microtubules.

MAPs can also recruit other proteins that organize the microtubule cytoskeleton. An important example is augmin, an 8-subunit protein complex that binds to sites along the microtubule and recruits $\gamma\textsc{-}\textsc{TuRC}$, which nucleates a new microtubule to form a microtubule branch (Figure 16–47A). Thus, similar to the activity of the Arp2/3 complex on actin filaments, augmin causes branching nucleation on preexisting microtubules (Movie 16.10). Augmin-induced branches help build the spindle during mitosis. Because they lack centrosomes, plant cells rely extensively on augmin-dependent microtubule branching nucleation to organize the microtubule cytoskeleton (Figure 16–47B and C).

Microtubule Plus End-binding Proteins Modulate Microtubule Dynamics and Attachments

While the minus ends of microtubules in many cells are usually stabilized and inert, plus ends, in contrast, efficiently explore and probe the entire volume of the cell. This process is facilitated by numerous proteins that bind to microtubule plus ends and thereby influence microtubule dynamics. These proteins can influence the rate at which a microtubule switches from a growing to a shrinking state (the frequency of catastrophes) or from a shrinking to a growing state

MBOC7_ptr_ch16_949-1026.indd 996 02/12/21 2:15 PM

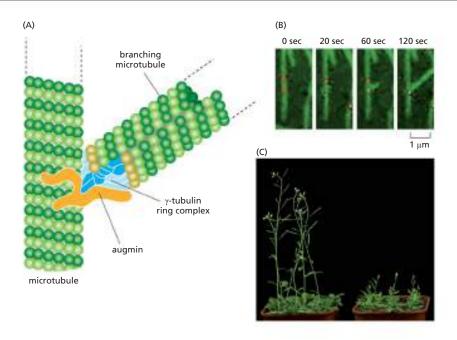

Figure 16–47 Microtubule branching by augmin. (A) Augmin binds along the side of an existing microtubule and recruits a γ-tubulin ring complex that nucleates a new microtubule with a low branching angle. (B) Fluorescence micrographs showing augmin (orange) nucleating a microtubule branch in the cortex of an epidermal cell in the plant Arabidopsis thaliana. (C) Depletion of augmin severely stunts plant growth. (B, from W. Liu et al., J. Integr. Plant Biol. 61:388–393, 2019; C, from T. Liu et al., Curr. Biol. 24:2708–2713, 2014. With permission from Elsevier.)

(the frequency of rescues). For example, members of a family of kinesin proteins known as *catastrophe factors* (or kinesin-13s) bind to microtubule ends and appear to pry protofilaments apart, lowering the normal activation-energy barrier that prevents a microtubule from springing apart into the curved protofilaments that are characteristic of the shrinking state (**Figure 16–48**). Other plus end-associated proteins act to promote rapid microtubule growth. A particularly ubiquitous example is *XMAP215*, which has close homologs in organisms that range from yeast to humans. Like formin proteins that concentrate actin subunits at the plus end of a growing actin filament, XMAP215 binds free tubulin subunits and delivers them to the plus end of a microtubule, dramatically accelerating polymerization (see Figure 16–48).

A large subset of MAPs is enriched at microtubule plus ends. Called *plus-end tracking proteins* (+ TIPs), these MAPs bind an actively growing plus end and dissociate when the microtubule begins to shrink (Figure 16-49). The kinesin-13 catastrophe factors and XMAP215 mentioned above behave as +TIPs and act to modulate the growth and shrinkage of the microtubule end to which they are

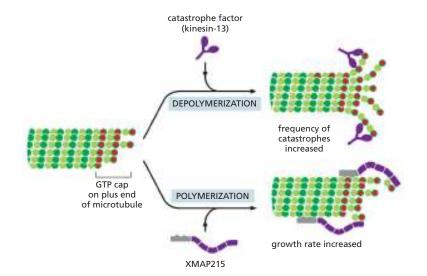

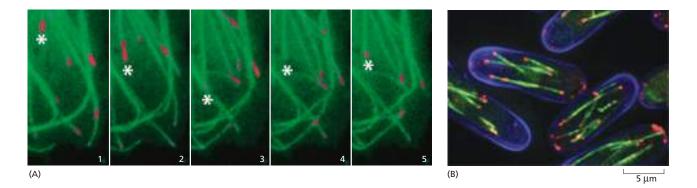

Figure 16-48 The effects of proteins that bind to microtubule ends. The transition between microtubule growth and shrinkage is controlled in cells by a variety of proteins. Catastrophe factors such as kinesin-13, a member of the kinesin motor protein superfamily, bind to microtubule ends and pry them apart, thereby promoting depolymerization. On the other hand, a MAP such as XMAP215 promotes rapid microtubule polymerization (XMAP stands for Xenopus microtubuleassociated protein, and the number refers to its molecular mass in kilodaltons). XMAP215 binds tubulin dimers and delivers them to the microtubule plus end, thereby increasing the microtubule growth rate.

attached. Other +TIPs control microtubule positioning by helping to capture and stabilize the growing microtubule end at specific cellular targets, such as the cell cortex or the kinetochore of a mitotic chromosome. EB1 and its relatives, small dimeric proteins that are highly conserved in animals, plants, and fungi, are key players in this process. EB1 proteins do not actively move toward plus ends, but rather recognize a structural feature of the growing plus end (see Figure 16–49). Several +TIPs depend on EB1 proteins for their plus-end accumulation and also interact with each other and with the microtubule lattice. By attaching to the plus end, these factors control microtubule dynamics and also allow the cell to harness the energy of microtubule polymerization to generate pushing forces that can be used for positioning the spindle, chromosomes, or organelles.

Tubulin-sequestering and Microtubule-severing Proteins Modulate Microtubule Dynamics

As it does with actin monomers, the cell sequesters unpolymerized tubulin subunits to maintain a pool of active subunits at a level near the critical concentration. One molecule of the small protein *stathmin* (also called Op18) binds two tubulin heterodimers and prevents their addition to the ends of microtubules (Figure 16–50). Stathmin thus decreases the effective concentration of tubulin subunits that are available for polymerization (an action analogous to that of the drug colchicine) and enhances the likelihood that a growing microtubule will switch to the shrinking state. Phosphorylation of stathmin inhibits its binding to tubulin, and signals that cause stathmin phosphorylation can increase the rate of microtubule elongation and suppress dynamic instability. Stathmin has been implicated in the regulation of both cell proliferation and cell death. Notably, mice lacking stathmin develop normally but are less fearful than wild-type mice, reflecting a role for stathmin in neurons of the amygdala, where it is normally expressed at high levels.

Severing is another mechanism employed by the cell to destabilize microtubules. To sever a microtubule, 13 longitudinal bonds must be broken, one for each protofilament. The protein *katanin*, named after the Japanese word for "sword," accomplishes this demanding task (Figure 16–51A and B). Katanin belongs to a large family of proteins that use the energy of ATP hydrolysis to disassemble or remodel protein complexes. By extracting tubulin subunits from the wall of the microtubule, katanin weakens the structure and thereby promotes breakage. Katanin also releases microtubules from microtubule-organizing centers and is thought to contribute to the rapid microtubule depolymerization observed at the poles of spindles during mitosis.

Paradoxically, the loss of microtubule-severing protein activity in many cell types leads to a decrease rather than an increase in microtubules. Thus, microtubule-severing proteins play an unexpected role in stabilizing microtubules. How is this possible? During the intermediate steps of a microtubule-severing event, GDP-bound tubulin subunits are lost from the wall of the microtubule and are replaced with GTP-tubulin subunits from

Figure 16-49 +TIP proteins found at the growing plus ends of microtubules. (A) Frames from a fluorescence time-lapse movie of the edge of a cell expressing fluorescently labeled tubulin that incorporates into microtubules (green) as well as the +TIP protein EB1 tagged with a different color (red). The same microtubule is marked (asterisk) in successive movie frames. When the microtubule is growing (frames 1, 2), EB1 is associated with the tip. When the microtubule undergoes a catastrophe and begins shrinking, EB1 is lost (frames 3, 4). The labeled EB1 is regained when growth of the microtubule is rescued (frame 5). See Movie 16.11. (B) In the fission yeast Schizosaccharomyces pombe, microtubules (green) are bound at their plus ends by the homolog of EB1 (red) as they grow toward the two poles of the rod-shaped cells. (A, courtesy of Anna Akhmanova and Ilya Grigoriev; B, courtesy of Takeshi Toda.)

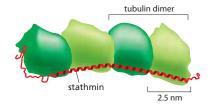

Figure 16–50 Sequestration of tubulin by stathmin. Structural studies with electron microscopy and crystallography suggest that the elongated stathmin protein binds along the side of two tubulin heterodimers. (Adapted from M.O. Steinmetz et al., *EMBO J.* 19:572–580, 2000.)

MBOC7_ptr_ch16_949-1026.indd 998 02/12/21 2:15 PM

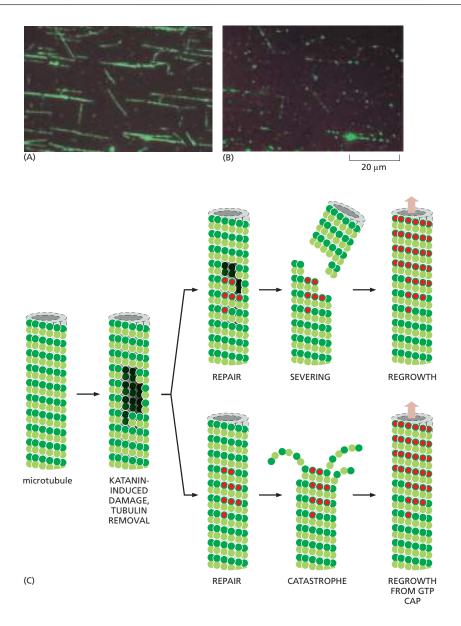

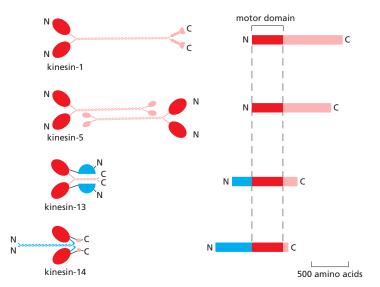

Figure 16-51 Microtubule severing by katanin can destabilize or amplify microtubules. (A) Taxol-stabilized, fluorescently labeled microtubules were adsorbed on the surface of a glass slide, to which purified katanin was added along with ATP. There are a few breaks in the microtubules 30 seconds after the addition of katanin. (B) Three minutes after the addition of katanin, the filaments have been severed in many places, leaving a series of small fragments at the previous locations of the long microtubules. (C) Incorporation of GTP-tubulin subunits from the soluble pool into sites of katanin-induced damage in the microtubule lattice stabilizes the severed end or generates an island of GTPtubulin that promotes rescue. (A and B, from J.J. Hartman et al., Cell 93:277-287 1998. With permission from Elsevier. C, adapted from A. Vemu et al., Science 361: eaau1504, 2018. With permission from AAAS.)

the soluble pool. If a sufficient number of GTP-tubulin subunits are incorporated before the severing is complete, the new plus end of the cut microtubule will possess a stabilizing GTP-tubulin cap and will therefore polymerize. Thus microtubule severing can generate plus ends that promote growth of more polymer. Alternatively, incomplete severing could lead to an island of GTP-tubulin in the microtubule lattice that could promote a future rescue event when this site is exposed after catastrophe (Figure 16–51C). Although insertion of GTP-tubulin into the lattice has been observed *in vitro* with pure microtubules, the importance of this activity in cells has not yet been fully established.

Two Types of Motor Proteins Move Along Microtubules

Like actin filaments, microtubules also work together with motor proteins in a variety of cellular processes. There are two major classes of microtubule-based motors, **kinesins** and **dyneins**, which perform three major functions. First, they move cargo such as organelles and macromolecules within the cell. Unlike actin-based transport, however, microtubule-based motors are used to transport

MBOC7_ptr_ch16_949-1026.indd 999 02/12/21 2:15 PM

cargo over long distances. Second, motors can slide microtubules relative to one another, thereby generating specific arrangements of microtubules, as in neurons and epithelial cells (see Figure 16–44), and in the mitotic spindle (see Chapter 17). Third, a subset of microtubule-based motors regulates microtubule dynamics, as illustrated by kinesin-13 (see Figure 16–48).

Like myosins, kinesins are a large protein superfamily in which the motor domain of the heavy chain is the common element (Figure 16-52). The yeast Saccharomyces cerevisiae has six distinct kinesins. The nematode C. elegans has 20 kinesins, and humans have 45. **Kinesin-1** is similar to myosin II in having two heavy chains per active motor; these form two globular head motor domains that are held together by an elongated coiled-coil tail that mediates heavy-chain dimerization. Most kinesins have their motor domain at the N-terminus and walk toward the plus end of the microtubule. Kinesins with the motor domain at the C-terminus walk in the opposite direction, toward the minus end of the microtubule, while kinesin-13 has a central motor domain and does not walk at all, but uses the energy of ATP hydrolysis to depolymerize microtubule ends (see Figure 16-48). Some kinesins are monomers, and others are homodimers, heterodimers, or tetramers. The motor may be linked to a membrane-enclosed organelle via a light chain or an adaptor protein. Some kinesins possess a second microtubule-binding domain that increases its affinity for the microtubule or mediates cross-linking and sliding of two microtubules.

In kinesin-1, small movements at the ATP-binding site regulate the docking and undocking of the motor head domain to a long linker region. This acts to throw the second head forward along the protofilament to a binding site 8 nm closer to the microtubule plus end, which is the distance between tubulin dimers of a protofilament. The ATP-hydrolysis cycles in the two heads are closely coordinated, so that this cycle of linker docking and undocking allows the two-headed motor to move in a hand-over-hand (or head-over-head) stepwise manner (Figure 16–53).

The dyneins are a family of minus end-directed microtubule motors unrelated to the kinesins. They are composed of one, two, or three heavy chains (that include the motor domain) and a large and variable number of associated intermediate, light-intermediate, and light chains. The dynein family has two major branches. The first contains the *cytoplasmic dyneins*, which are homodimers of two heavy chains (**Figure 16–54**). Cytoplasmic dynein 1 is encoded by a single gene in almost all eukaryotic cells but is missing from flowering plants and some algae. It is used for organelle and mRNA trafficking, for positioning the centrosome and nucleus during cell migration, and for construction of the microtubule spindle in mitosis and meiosis. Cytoplasmic dynein 2 is found only in eukaryotic

Figure 16-52 Kinesins. Structures of four kinesin superfamily members. As in the myosin superfamily, only the motor domains are conserved. Kinesin-1 has the motor domain at the N-terminus of the heavy chain and moves toward the microtubule plus end. The middle domain forms a long coiled-coil, mediating dimerization. The C-terminal domain forms a tail that attaches to cargo, such as a membrane-enclosed organelle. Kinesin-5 forms tetramers in which two dimers associate by their tails. The bipolar kinesin-5 tetramer is able to slide two microtubules past each other, analogous to the activity of the bipolar thick filaments formed by myosin II. Kinesin-13 has its motor domain located in the middle of the heavy chain. It is a member of a family of kinesins that have lost typical motor activity and instead bind to microtubule ends to promote depolymerization (see Figure 16-48). Kinesin-14 is a C-terminal kinesin. Unlike most kinesins, members of the kinesin-14 family travel toward the microtubule minus end.

MBOC7_ptr_ch16_949-1026.indd 1000 02/12/21 2:15 PM

Figure 16–53 The mechanochemical cycle of kinesin. Kinesin-1 is a dimer of two ATP-binding motor domains (heads) that are connected through a long coiled-coil tail (see Figure 16–52). The two kinesin motor domains work in a coordinated manner; during a kinesin "step," the rear head detaches from its tubulin binding site on the microtubule, passes the partner motor domain, and then rebinds to the next available binding site. Using this "hand-over-hand" motion, the kinesin dimer can move for long distances on the microtubule without completely letting go of its track.

At the start of each step, one of the two kinesin motor domain heads, the rear or lagging head (dark red), is tightly bound to the microtubule and to ATP, while the front or leading head is loosely bound to the microtubule with ADP in its binding site. The forward displacement of the rear motor domain is driven by the dissociation of ADP and binding of ATP in the leading head (between panels 2 and 3 in this drawing). The binding of ATP to this motor domain causes a small peptide called the neck linker to shift from a rearward-pointing to a forward-pointing conformation (the neck linker is drawn here as a purple connecting line between the leading motor domain and the intertwined coiled-coil). This shift pulls the rear head forward, once it has detached from the microtubule with ADP bound [detachment requires ATP hydrolysis and phosphate (P) release]. The kinesin molecule is now poised for the next step, which proceeds by an exact repeat of the process shown (Movie 16.12).

organisms that have cilia and is used to transport material from the tip to the base of the cilia—a process called *intraflagellar transport* (IFT). *Axonemal dyneins* comprise the second branch and include monomers, heterodimers, and heterotrimers, with one, two, or three motor-containing heavy chains, respectively. They are highly specialized for the rapid and efficient microtubule sliding movements that drive the beating of cilia and flagella (discussed later).

Dyneins are the largest of the known molecular motors. Although structurally unrelated to myosins and kinesins, dyneins follow the general rule of coupling ATP hydrolysis to microtubule binding and unbinding as well as to a force-generating conformational change (Figure 16–55).

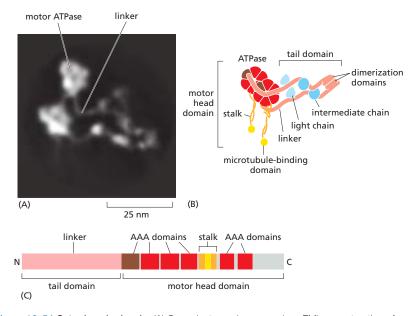

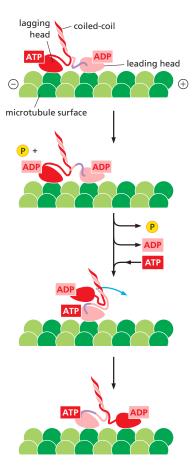

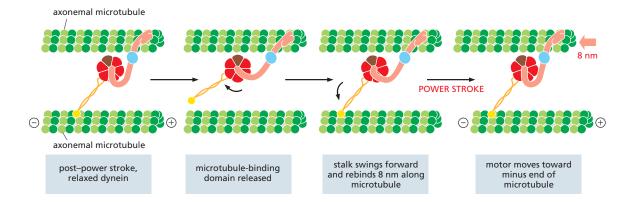

Figure 16–54 Cytoplasmic dynein. (A) Cryo-electron microscopy (cryoEM) reconstruction of a molecule of cytoplasmic dynein. Like myosin II and kinesin-1, cytoplasmic dynein is a two-headed molecule. The dynein head is very large compared with the head of either myosin or kinesin. (B) Schematic depiction of cytoplasmic dynein showing the two heavy chains that contain a motor head with domains for microtubule binding and ATP hydrolysis, connected by a long stalk. The tail domain consists of a linker that connects the motor heads to a dimerization domain. Bound to the linker domain are multiple intermediate chains and light chains (blue) that help to mediate many of dynein's functions. (C) The organization of domains in a dynein heavy chain. This is a huge polypeptide, containing more than 4000 amino acids. The conserved dynein motor head domain contains six AAA domains, four of which retain ATP-binding sequences, but only one of which has the major ATPase activity (brown). The tail domain is not as highly conserved as the head domain and varies among different dynein subtypes. (A, courtesy of Andrew Carter.)

Microtubules and Motors Move Organelles and Vesicles

A major function of cytoskeletal motors in interphase cells is the transport and positioning of membrane-enclosed organelles (Movie 16.13). Kinesin was originally identified as the protein responsible for fast anterograde axonal transport, the rapid movement of mitochondria, secretory vesicle precursors, and various synapse components down the microtubule highways of the axon to the distant nerve terminals. Cytoplasmic dynein 1 was identified as the motor responsible for transport in the opposite direction, retrograde axonal transport. Although organelles in most cells need not cover such long distances, their polarized transport is equally necessary. A typical microtubule array in an interphase cell is oriented with the minus ends near the center of the cell at the centrosome and the plus ends extending to the cell periphery. Thus, centripetal movements of organelles or vesicles toward the cell center require the action of minus end-directed cytoplasmic dynein motors, whereas centrifugal movements toward the periphery require plus end-directed kinesin motors. Notably, in animal cells, nearly all minus end-directed transport is driven by the single cytoplasmic dynein 1 motor, whereas at least 15 different kinesins are used for plus end-directed transport.

A clear example of the effect of microtubules and microtubule motors on the behavior of intracellular membranes is their role in organizing the endoplasmic reticulum (ER) and the Golgi apparatus. The network of ER membrane tubules aligns with microtubules and extends almost to the edge of the cell (Movie 16.14), whereas the Golgi apparatus is located near the centrosome. When cells are treated with a drug that depolymerizes microtubules, such as colchicine or nocodazole, the ER collapses to the center of the cell, while the Golgi apparatus fragments and disperses throughout the cytoplasm. *In vitro*, kinesins can tether ER-derived membranes to preformed microtubule tracks and walk toward the microtubule plus ends, dragging the ER membranes out into tubular protrusions and forming a membranous web that looks very much like the ER in cells. Conversely, dyneins are required for positioning the Golgi apparatus near the cell center of animal cells; they do this by moving Golgi vesicles along microtubule tracks toward the microtubules' minus ends at the centrosome.

The different tails and their associated light chains on specific motor proteins allow the motors to attach to their appropriate organelle cargo. Membrane-associated motor receptors that are sorted to specific membrane-enclosed compartments interact directly or indirectly with the tails of the appropriate kinesin family members. Many viruses take advantage of microtubule motor-based transport during infection and use kinesin to move from their site of replication and assembly to the plasma membrane, from which they are poised to infect neighboring cells.

For dynein, a large macromolecular assembly mediates attachment to cargoes. To translocate organelles effectively, cytoplasmic dynein, itself a huge protein complex, requires association with a second large protein complex called *dynactin* as well as with an adaptor protein that mediates their interaction and

Figure 16-55 The power stroke of dynein. Illustration of the movement of a monomeric axonemal dynein found in the flagellum of the unicellular green alga Chlamydomonas reinhardtii. As in cytoplasmic dynein, the motor-containing head domain of axonemal dynein connects to a long, coiled-coil stalk with the microtubule-binding site at the tip. The tail attaches to an adjacent microtubule in the axoneme. Movement is thought to occur through a "linker-swing, dyneinwinch" mechanism. ATP binding and hydrolysis cause the linker to throw the head domain toward the microtubule minus end like a fishing hook. The microtubule-binding domain reattaches 8 nm along the microtubule. Release of ATP and phosphate then leads to a large conformational power stroke in the linker domain, pulling the tail and its attached microtubule toward the minus end. Each cycle generates a step of about 8 nm, thereby contributing to flagellar beating (see Figure 16-60). In the case of cytoplasmic dynein, the tail is attached to a cargo such as a vesicle, and a single power stroke transports the cargo about 8 nm along the microtubule toward its minus end (see Figure 16-56).

MBOC7_ptr_ch16_949-1026.indd 1002 02/12/21 2:15 PM

links to a cargo such as a vesicle. The dynactin complex includes a short, actinlike filament that forms from the actin-related protein Arp1 (distinct from Arp2 and Arp3, the components of the Arp2/3 complex involved in the nucleation of conventional actin filaments) (Figure 16-56). A number of other proteins also contribute to dynein cargo binding and motor regulation, and their function is especially important in neurons, where defects in microtubule-based transport have been linked to neurological diseases. A striking example is smooth brain, or lissencephaly, a human disorder in which cells fail to migrate to the cerebral cortex of the developing brain. One type of lissencephaly is caused by defects in Lis1, a dynein-binding protein required for nuclear migration in several species. In the normal brain, migration of the nucleus directs the developing neural cell body toward its correct position in the cortex. In the absence of Lis1, however, this process fails, and affected children suffer from developmental delays as well as a variety of neurological defects. Dynein is required continually for neuronal function, as mutations in a dynactin subunit or in the tail region of cytoplasmic dynein lead to neuronal degeneration in humans and mice. These effects are associated with decreased retrograde axonal transport and provide strong evidence for the importance of robust axonal transport in neuronal viability.

The cell can regulate the activity of motor proteins and thereby cause either a change in the positioning of its membrane-enclosed organelles or whole-cell movements. Fish melanophores provide one of the most dramatic examples. These giant cells, which are responsible for rapid changes in skin coloration in several species of fish, contain large pigment granules that can alter their location in response to neuronal or hormonal stimulation (Figure 16–57). The pigment granules aggregate or disperse by moving along an extensive network of microtubules that are anchored at the centrosome by their minus ends. The tracking of individual pigment granules reveals that the inward movement is rapid and smooth, while the outward movement is jerky, with frequent backward steps. Both dynein and kinesin microtubule motors are associated with the pigment granules. The jerky outward movements may result from a tug-of-war between the two opposing

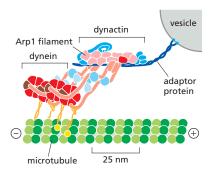

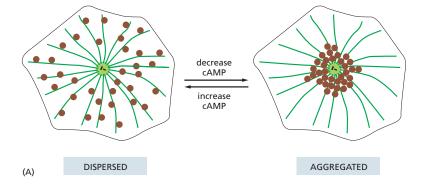

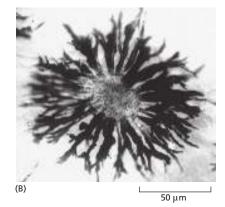

Figure 16–56 Dynactin and an adaptor protein mediate the attachment of dynein to a membrane-enclosed organelle. Dynein requires the presence of a large number of accessory proteins to associate with membrane-enclosed organelles. Dynactin is a large complex that includes components that bind weakly to microtubules, components that bind to dynein itself, and components that form a small, actin-like filament made of the actinrelated protein Arp1. Dynactin associates with two molecules of cytoplasmic dynein as well as with an adaptor protein that mediates the connection to a cargo.

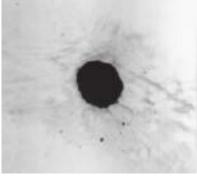

Figure 16–57 Regulated melanosome movements in fish pigment cells.

These giant cells, which are responsible for changes in skin coloration in several species of fish, contain large pigment granules called melanosomes. The melanosomes can change their location in the cell in response to a hormonal or neuronal stimulus. (A) Schematic view of a pigment cell, showing the dispersal and aggregation of melanosomes (brown) in response to an increase or decrease in intracellular cyclic AMP (cAMP), respectively. Both redistributions of melanosomes occur along microtubules. (B) Bright-field images of a single cell in a scale of an African cichlid fish, showing its melanosomes either dispersed throughout the cytoplasm (left) or aggregated in the center of the cell (right). (B, courtesy of Leah Haimo.)

microtubule motor proteins, with the stronger kinesin winning out overall. When intracellular cyclic AMP levels decrease, kinesin is inactivated, leaving dynein free to drag the pigment granules rapidly toward the cell center, changing the fish's color. In a similar way, the movement of other membrane organelles coated with particular motor proteins is controlled by a complex balance of competing signals that regulate both motor protein attachment and activity.

Motile Cilia and Flagella Are Built from Microtubules and Dyneins

Just as myofibrils are highly specialized and efficient motility machines built from actin and myosin filaments, cilia and flagella are highly specialized and efficient motility structures built from microtubules and dynein. Both cilia and flagella are hairlike cell appendages that have a bundle of microtubules at their core. Flagella are found on sperm and many protozoa. By their undulating motion, they enable the cells from which they emerge to swim through liquid media. Cilia are organized in a similar fashion, but they beat with a whiplike motion that resembles the breast-stroke in swimming. Ciliary beating can either propel single cells through a fluid (as in the swimming of the protozoan *Paramecium*) or can move fluid over the surface of a group of cells in a tissue. In the human body, huge numbers of cilia (10⁹/cm² or more) line our respiratory tract, sweeping layers of mucus, trapped particles of dust, and bacteria up to the mouth where they are swallowed and ultimately eliminated. Likewise, cilia along the oviduct help to sweep eggs toward the uterus.

The movement of a cilium or a flagellum is produced by the bending of its core, which is called the **axoneme**. The axoneme is composed of microtubules and their associated proteins, arranged in a distinctive and regular pattern. Nine special microtubule doublets (comprising one complete and one partial microtubule fused together so that they share a common tubule wall) are arranged in a ring around a pair of single microtubules (**Figure 16–58**). Almost all forms of motile eukaryotic flagella and cilia (from protozoans to humans) have this characteristic arrangement. The microtubules extend continuously for the length of the axoneme, which can be 10– $200~\mu m$. At regular positions along the length of the microtubules, accessory proteins cross-link the microtubules together.

Molecules of *axonemal dynein* form bridges between adjacent microtubule doublets around the circumference of the axoneme (Figure 16–59). When the motor domain of this dynein is activated, the dynein molecules attached to one microtubule doublet (see Figure 16–60) attempt to walk along the adjacent

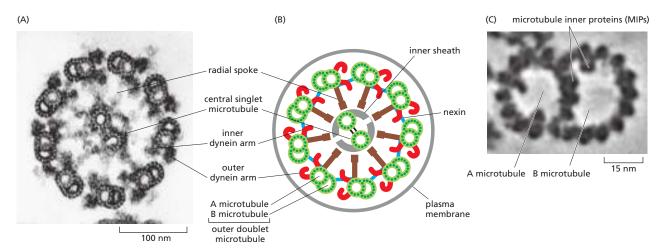

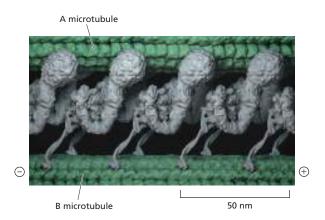

Figure 16–58 The arrangement of microtubules in a flagellum or cilium. (A) Electron micrograph of the flagellum of a green-alga cell (Chlamydomonas) shown in cross section, illustrating the distinctive "9 + 2" arrangement of microtubules. (B) Diagram of the parts of a flagellum or cilium. The various projections from the microtubules link the microtubules together and occur at regular intervals along the length of the axoneme. (C) High-resolution electron tomography image of an outer microtubule doublet showing structural details and features inside the microtubules called microtubule inner proteins (MIPs). flagellum showing dynein arms connecting the A microtubule of one doublet with the B microtubule of an adjacent doublet at regular intervals. Sperm axonemal dynein is dimeric. The tail of the molecule binds tightly to an A microtubule, while the two globular heads each have a stalk that connects to an ATP-dependent binding site on a B microtubule (see Figure 16-58). When the heads hydrolyze their bound ATP, they move toward the minus end of the B microtubule, thereby producing a sliding force between the adjacent microtubule doublets in a cilium or flagellum (see Figure 16-60). (Courtesy of Daniela Nicastro.)

Figure 16–59 Axonemal dynein. CryoEM reconstruction of a sea urchin sperm

microtubule doublet, tending to force the adjacent doublets to slide relative to one another, much as actin thin filaments slide during muscle contraction. However, the presence of other links between the microtubule doublets prevents this sliding, and the dynein force is instead converted into a bending motion (Figure 16–60). Not all dyneins in the axoneme are active at the same time, which results in the characteristic wave-like motion of the cilium or flagellum (Movie 16.15).

In humans, hereditary defects in axonemal dynein cause a condition called primary ciliary dyskinesia, or Kartagener's syndrome. This syndrome is characterized by inversion of the normal asymmetry of internal organs (situs inversus) due to disruption of fluid flow in the developing embryo, male sterility due to immotile sperm, and a high susceptibility to lung infections due to paralyzed cilia being unable to clear the respiratory tract of debris and bacteria.

Bacteria also swim using cell-surface structures called flagella, but these do not contain microtubules or dynein and do not wave or beat. Instead, *bacterial flagella* are long, rigid helical filaments, made up of repeating subunits of the protein flagellin. The flagella rotate like propellers, driven by a special rotary motor embedded in the bacterial cell wall. The use of the same name to denote these two very different types of swimming apparatus is an unfortunate historical accident.

Primary Cilia Perform Important Signaling Functions in Animal Cells

Many cells possess a shorter, nonmotile counterpart of cilia and flagella called the *primary cilium*. Primary cilia can be viewed as specialized compartments or organelles that perform a wide range of cellular functions but share many

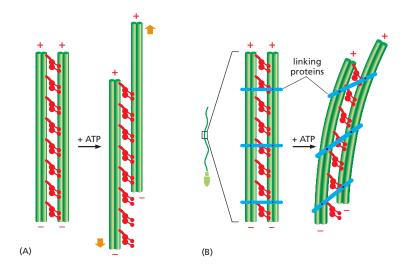

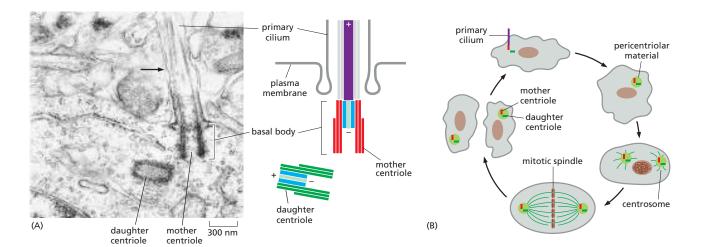

Figure 16–60 The bending of an axoneme. (A) When axonemes are exposed to the proteolytic enzyme trypsin, the flexible protein links holding adjacent microtubule doublets together are broken. In this case, the addition of ATP allows the motor action of the dynein heads to slide one microtubule doublet against the adjacent doublet. (B) In an intact axoneme (such as in a spermatozoon), the flexible protein links prevent the sliding of the doublet. The motor action therefore causes a bending motion, creating waves or beating motions.

structural features with motile cilia. Both motile and nonmotile cilia are generated during interphase at plasma membrane-associated structures called *basal bodies*, which anchor them at the cell surface. At the core of each basal body is a single centriole, the same structure found in pairs embedded at the center of animal centrosomes, with nine groups of fused microtubule triplets arranged in a cartwheel (see Figure 16-43). Centrioles are multifunctional, contributing to assembly of the mitotic spindle in dividing cells but migrating to the plasma membrane of interphase cells to template the nucleation of the axoneme (Figure 16-61). Because no protein translation occurs in cilia, construction of the axoneme requires intraflagellar transport (IFT), a transport system discovered in the green algae *Chlamydomonas*. Analogous to the axon, motors move cargoes in both anterograde and retrograde directions, in this case driven by kinesin-2 and cytoplasmic dynein 2, respectively.

Primary cilia are found on the surface of almost all cell types, where they sense and respond to the exterior environment, functions best understood in the context of smell and sight. In the nasal epithelium, cilia protruding from dendrites of olfactory neurons are the site of both odorant reception and signal amplification. Similarly, the rod and cone cells of the vertebrate retina possess a specialized primary cilium called the outer segment, which is specialized for converting light into a neural signal (see Figure 15–40). Maintenance of the outer segment requires continual IFT-mediated transport of large quantities of lipids and proteins into the cilium, at rates of up to 1000 molecules per second. The links between cilia function and the senses of sight and smell are underscored by the ciliopathies, a set of disorders associated with defects in IFT, the cilium, or the basal body. In the ciliopathy Bardet–Biedl syndrome, patients cannot smell and suffer from retinal degeneration. Other characteristics of this multifaceted disorder include hearing loss, polycystic kidney disease, diabetes, obesity, and polydactyly, suggesting that primary cilia have functions in many aspects of human physiology.

Summary

Microtubules are stiff polymers of tubulin molecules. They assemble by addition of GTP-containing tubulin subunits to the free end of a microtubule, with one end (the plus end) growing faster than the other. Hydrolysis of the bound GTP takes place after assembly and weakens the bonds that hold the microtubule together. Microtubules are dynamically unstable and liable to catastrophic disassembly, but they can be stabilized in cells by association with other structures. Microtubule-organizing centers such as centrosomes protect the minus ends of microtubules and continually nucleate the formation of new microtubules. Microtubule-associated proteins (MAPs) stabilize microtubules, and those that localize to the plus end (+TIPs) can alter the dynamic properties of the microtubule or mediate their interaction with

Figure 16-61 Primary cilia. (A) Electron micrograph and diagram of the basal body of a mouse neuron primary cilium. The axoneme of the primary cilium (black arrow) is nucleated by the mother centriole at the basal body, which localizes at the plasma membrane near the cell surface. (B) Centrioles function alternately as basal bodies and as the core of centrosomes. Before a cell enters the cell-division cycle, the primary cilium is shed or resorbed. The centrioles recruit pericentriolar material and duplicate during S phase, generating two centrosomes, each of which contains a pair of centrioles. The centrosomes nucleate microtubules and localize to the poles of the mitotic spindle. Upon exit from mitosis, a primary cilium again grows from the mother centriole. (A, courtesy of Josef Spacek.)

MBOC7_ptr_ch16_949-1026.indd 1006 02/12/21 2:16 PM

other structures. Counteracting the stabilizing activity of MAPs are catastrophe factors, such as kinesin-13 proteins, that act to peel apart microtubule ends. Other kinesin family members as well as dynein use the energy of ATP hydrolysis to move unidirectionally along a microtubule. The motor dynein moves toward the minus end of microtubules, and its sliding of axonemal microtubules underlies the beating of cilia and flagella. Primary cilia are nonmotile sensory organelles found on many cell types.

INTERMEDIATE FILAMENTS AND OTHER CYTOSKELETAL POLYMERS

All eukaryotic cells contain actin and tubulin. But the third major type of cyto-skeletal protein, the *intermediate filament*, forms a cytoplasmic filament only in some metazoans—including vertebrates, nematodes, and mollusks. Intermediate filaments are particularly prominent in the cytoplasm of cells that are subject to mechanical stress and are generally not found in animals that have rigid exoskeletons, such as arthropods and echinoderms. It seems that intermediate filaments impart mechanical strength to tissues for the squishier animals.

Cytoplasmic intermediate filaments are closely related to their ancestors, the much more prevalent *nuclear lamins*, which are found in many eukaryotes but missing from unicellular organisms. The nuclear lamins form a meshwork lining the inner membrane of the nuclear envelope, where they provide anchorage sites for chromosomes and nuclear pores. Several times during metazoan evolution, lamin genes have apparently duplicated, and the duplicates have evolved to produce rope-like, cytoplasmic intermediate filaments. In contrast to the highly conserved actins and tubulin isoforms that are encoded by a handful of genes, different families of intermediate filaments are much more diverse and are encoded by 70 different human genes with distinct, cell type–specific functions (Table 16–2).

Intermediate Filament Structure Depends on the Lateral Bundling and Twisting of Coiled-Coils

Although their amino- and carboxyl-terminal domains differ, all intermediate filament family members are elongated proteins with a conserved central α -helical domain containing 40 or so heptad repeat motifs that form an extended

TABLE 16-2 Major Types of Intermediate Filament Proteins in Vertebrate Cells				
Types of intermediate filament	Component polypeptides	Location		
Nuclear	Lamins A, B, and C	Nuclear lamina (inner lining of nuclear envelope)

Epithelial	Type I keratins (acidic)	Epithelial cells and their derivatives (e.g., hair and nails)		
Epithelial	Type II keratins (neutral/basic)			
Axonal	Neurofilament proteins (NF-L, NF-M, and NF-H)	Neurons		

MBOC7_ptr_ch16_949-1026.indd 1007 02/12/21 2:16 PM

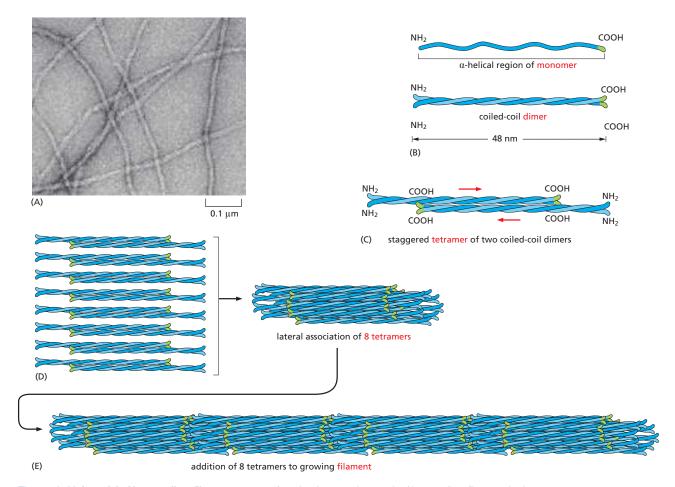

Figure 16–62 A model of intermediate filament construction. An electron micrograph of intermediate filaments is shown in (A). The monomer shown in (B) pairs with another monomer to form a dimer, in which the conserved central rod domains are aligned in parallel and wound together into a coiled-coil. (C) Two dimers then line up side by side to form an antiparallel tetramer of four polypeptide chains. Dimers and tetramers are the soluble subunits of intermediate filaments. (D) Within each tetramer, the two dimers are offset with respect to one another, thereby allowing it to associate with another tetramer. (E) In the final 10-nm-diameter filament, tetramers are packed together in a rope-like array, which has 16 dimers (32 coiled-coils) in cross section. Half of these dimers are pointing in each direction. An electron micrograph of intermediate filaments is shown on the upper left (Movie 16.16). (A, from L. Norlén et al., Exp. Cell Res. 313:2217–2227, 2007. With permission from Elsevier.)

coiled-coil structure with another monomer (see Figure 3-8). A pair of parallel dimers then associates in an antiparallel fashion to form a staggered tetramer (Figure 16-62). Unlike actin or tubulin subunits, intermediate filament subunits do not contain a binding site for ATP or GTP. Furthermore, because the tetrameric subunit is made up of two dimers pointing in opposite directions, its two ends are the same. The assembled intermediate filament therefore lacks the overall structural polarity that is critical for actin filaments and microtubules. The tetramers pack together laterally to form the filament, which includes eight parallel protofilaments made up of tetramers. Each individual intermediate filament therefore has a cross section of 32 individual α -helical coils. This large number of polypeptides all lined up together, with the strong lateral hydrophobic interactions typical of coiled-coil proteins, gives intermediate filaments a ropelike character. They can be easily bent, with a persistence length of less than 1 μm (compared to several millimeters for microtubules and about 10 µm for actin), but they are extremely difficult to break and can be stretched to more than three times their length (see Figure 16-6).

Less is understood about the mechanisms of assembly and disassembly of intermediate filaments than of actin filaments and microtubules. In pure protein

MBOC7_ptr_ch16_949-1026.indd 1008 02/12/21 2:16 PM

solutions, intermediate filaments are extremely stable due to tight association of subunits, but some types of intermediate filaments, including *vimentin*, form highly dynamic structures in cells such as fibroblasts. Protein phosphorylation probably regulates their disassembly, in much the same way that phosphorylation regulates the disassembly of nuclear lamins in mitosis (see Figure 12–65). As evidence for rapid turnover, labeled subunits microinjected into tissue-culture cells incorporate into intermediate filaments within a few minutes. Remodeling of the intermediate filament network accompanies events requiring dynamic cellular reorganization, such as division, migration, and differentiation.

Intermediate Filaments Impart Mechanical Stability to Animal Cells

Keratins are the most diverse intermediate filament family: there are about 20 found in different types of human epithelial cells and about 10 more that are specific to hair and nails; analysis of the human genome sequence has revealed that there are 54 distinct keratins. Every keratin filament is made up of an equal mixture of type I (acidic) and type II (neutral/basic) keratin proteins; these form a heterodimer filament subunit (see Figure 16–62). Cross-linked keratin networks held together by disulfide bonds can survive even the death of their cells, forming tough coverings for animals, as in the outer layer of skin and in hair, nails, claws, and scales. The diversity in keratins is clinically useful in the diagnosis of epithelial cancers (carcinomas), as the particular set of keratins expressed gives an indication of the epithelial tissue in which the cancer originated and thus can help to guide the choice of treatment.

A single epithelial cell may produce multiple types of keratins, and these copolymerize into a single network (Figure 16-63). Keratin filaments impart mechanical strength to epithelial tissues in part by anchoring the intermediate filaments at sites of cell-cell contact, called *desmosomes*, or cell-matrix contact, called *hemidesmosomes* (see Figure 16-4). We discuss these important adhesive structures in Chapter 19. Accessory proteins, such as *filaggrin*, bundle keratin filaments in differentiating cells of the epidermis to give the outermost layers of the skin their special toughness. Individuals with mutations in the gene encoding filaggrin are strongly predisposed to dry skin diseases such as eczema.

Mutations in keratin genes cause several human genetic diseases. For example, when defective keratins are expressed in the basal cell layer of the epidermis, they produce a disorder called *epidermolysis bullosa simplex*, in which the skin blisters in response to even very slight mechanical stress, which ruptures the basal

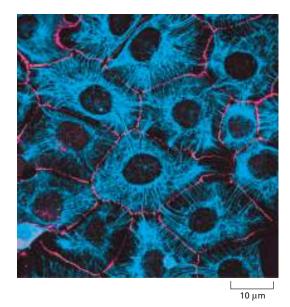

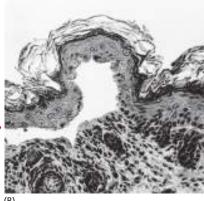

Figure 16–63 Keratin filaments in epithelial cells. Immunofluorescence micrograph of the network of keratin filaments (blue) in a sheet of epithelial cells in culture. The filaments in each cell are indirectly connected to those of its neighbors by desmosomes (discussed in Chapter 19). A second protein (red) has been stained to reveal the location of the cell boundaries. (From K.J. Green and C.A. Gaudry, Nat. Rev. Mol. Cell Biol. 1:208–216, published 2000 by Nature Publishing Group. Reproduced with permission of SNCSC.)

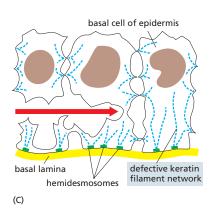

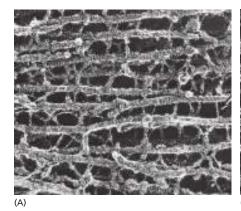

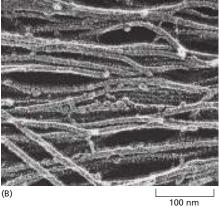

Figure 16–64 Blistering of the skin caused by a mutant keratin gene. A mutant gene encoding a truncated keratin protein (lacking both the N- and C-terminal domains) was expressed in a transgenic mouse. The defective protein assembles with the normal keratins and thereby disrupts the keratin filament network in the basal cells of the skin. Light micrographs of cross sections of (A) normal and (B) mutant skin show that the blistering results from the rupturing of cells in the basal layer of the mutant epidermis (short red arrows). (C) A sketch of three cells in the basal layer of the mutant epidermis, as observed by electron microscopy. As indicated by the red arrow, the cells rupture between the nucleus and the hemidesmosomes (discussed in Chapter 19), which connect the keratin filaments to the underlying basal lamina. (A and B, © 1991 P.A. Coulombe et al. Originally published in J. Cell Biol. https://doi.org/10.1083/jcb.115.6.1661. With permission from Rockefeller University Press.)

cells (Figure 16-64). Other types of blistering diseases, including disorders of the mouth, esophageal lining, and the cornea of the eye, are caused by mutations in the different keratins whose expression is specific to those tissues. All of these maladies are typified by cell rupture as a consequence of mechanical trauma and a disorganization or clumping of the keratin filament cytoskeleton. Many of the specific mutations that cause these diseases alter the ends of the central rod domain, demonstrating the importance of this particular part of the protein for correct filament assembly.

Members of another family of intermediate filaments, called **neurofilaments**, are found in high concentrations along the axons of vertebrate neurons (**Figure 16–65**). Three types of neurofilament proteins (NF-L, NF-M, and NF-H)

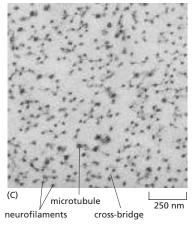

Figure 16–65 Two types of intermediate filaments in cells of the nervous system. (A) Freeze-etch electron microscopy image of neurofilaments in a nerve cell axon, showing the extensive cross-linking through protein cross-bridges—an arrangement believed to give this long cell process great tensile strength. The cross-bridges are formed by the long, nonhelical extensions at the C-terminus of the largest neurofilament protein (NF-H). (B) Freeze-etch image of glial filaments in glial cells, showing that these intermediate filaments are smooth and have few cross-bridges. (C) Conventional transmission electron micrograph of a cross section of an axon showing the regular side-to-side spacing of the neurofilaments, which greatly outnumber the microtubules. (A and B, courtesy of Nobutaka Hirokawa; C, courtesy of Anthony Brown.)

MBOC7_ptr_ch16_949-1026.indd 1010 02/12/21 2:16 PM

coassemble *in vivo*, forming heteropolymers. The NF-H and NF-M proteins have lengthy C-terminal tail domains that bind to neighboring filaments, generating aligned arrays with a uniform interfilament spacing. During axonal growth, new neurofilament subunits are incorporated all along the axon in a dynamic process that involves the addition of subunits along the filament length and at the ends. After an axon has grown and connected with its target cell, the diameter of the axon may increase as much as fivefold. The level of neurofilament gene expression seems to directly control axonal diameter, which in turn influences how fast electrical signals travel down the axon. In addition, neurofilaments provide strength and stability to the long cell processes of neurons.

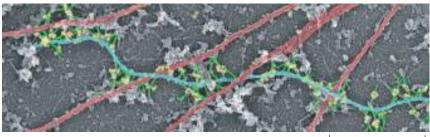

The neurodegenerative disease amyotrophic lateral sclerosis (ALS, or Lou Gehrig's disease) is associated with an accumulation and abnormal assembly of neurofilaments in motor neuron cell bodies and in the axon, aberrations that may interfere with normal axonal transport. The degeneration of the axons leads to muscle weakness and atrophy, which is usually fatal. The overexpression of human NF-L or NF-H in mice results in mice that have an ALS-like disease. However, a causative link between neurofilament pathology and ALS has not been firmly established.

The vimentin-like filaments are a third family of intermediate filaments. *Desmin*, a member of this family, is expressed in skeletal, cardiac, and smooth muscle, where it forms a scaffold around the Z disc of the sarcomere (see Figure 16–29). Mice lacking desmin show normal initial muscle development, but adults have various muscle cell abnormalities, including misaligned muscle fibers. In humans, mutations in desmin are associated with various forms of muscular dystrophy and cardiac myopathy, illustrating the important role of desmin in stabilizing muscle fibers.

Inside the nucleus, nuclear lamins maintain the mechanical stability of the nucleus. In addition, it is becoming increasingly evident that one class of lamins, the A-type, together with many proteins of the nuclear envelope, are scaffolds for proteins that control myriad cellular processes including transcription, chromatin organization, and signal transduction. The majority of *laminopathies* is associated with mutant versions of lamin A and include tissue-specific diseases. Skeletal and cardiac abnormalities might be explained by a weakened nuclear envelope leading to cell damage and death, but laminopathies are also thought to arise from pathogenic and tissue-specific alterations in gene expression.

Linker Proteins Connect Cytoskeletal Filaments and Bridge the Nuclear Envelope

The intermediate filament network is linked to the rest of the cytoskeleton by members of a family of proteins called *plakins*. Plakins are large and modular, containing multiple domains that connect cytoskeletal filaments to each other and to junctional complexes. *Plectin* is a particularly interesting example. In addition to bundling intermediate filaments, it links the intermediate filaments to microtubules, actin filament bundles, and filaments of the motor protein myosin II; it also helps attach intermediate filament bundles to adhesive structures at the plasma membrane (Figure 16–66).

0.5 μm

Figure 16–66 Plectin cross-linking of diverse cytoskeletal elements. Plectin (green) is seen here making cross-links from intermediate filaments (blue) to microtubules (red). MBOC7_ptr_ch16_949-1026.indd 1011 02/12/21 2:16 PM

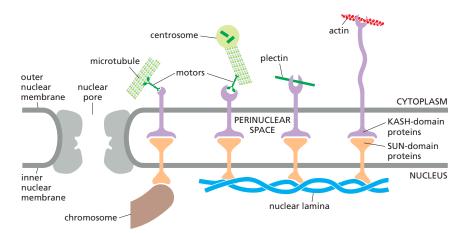

Figure 16-67 SUN-KASH protein complexes connect the nucleus and cytoplasm through the nuclear envelope. The cytoplasmic cytoskeleton is linked across the nuclear envelope to the nuclear lamina or chromosomes through SUN and KASH proteins (orange and purple, respectively). The SUN and KASH domains of these proteins bind within the lumen of the nuclear envelope. From the inner nuclear envelope, SUN proteins connect to the nuclear lamina or chromosomes. KASH proteins in the outer nuclear envelope connect to the cytoplasmic cytoskeleton by binding microtubule motor proteins, actin filaments, or plectin.

Mutations in the gene for plectin cause a devastating human disease that combines epidermolysis bullosa (caused by disruption of skin keratin filaments), muscular dystrophy (caused by disruption of desmin filaments), and neurodegeneration (caused by disruption of neurofilaments). Mice lacking a functional plectin gene die within a few days of birth, with blistered skin and abnormal skeletal and heart muscles. Thus, although plectin may not be necessary for the initial formation and assembly of intermediate filaments, its cross-linking action is required to provide cells with the strength they need to withstand the mechanical stresses inherent to vertebrate life.

Plectin and other plakins can interact with protein complexes that connect the cytoskeleton to the nuclear interior. These complexes consist of SUN proteins of the inner nuclear membrane and KASH proteins of the outer nuclear membrane (Figure 16-67). SUN and KASH proteins bind to each other within the lumen of the nuclear envelope, forming a bridge that connects the nuclear and cytoplasmic cytoskeletons. Inside the nucleus, the SUN proteins bind to the nuclear lamina or chromosomes, whereas in the cytoplasm, KASH proteins can bind directly to actin filaments and indirectly to microtubules and intermediate filaments through association with motor proteins and plakins, respectively. This linkage serves to mechanically couple the nucleus to the cytoskeleton and is involved in many cellular functions, including chromosome movements inside the nucleus during meiosis, nuclear and centrosome positioning, nuclear migration, and global cytoskeletal organization.

Septins Form Filaments That Contribute to Subcellular Organization

GTP-binding proteins called *septins* serve as an additional filament system in all eukaryotes except terrestrial plants. Septins assemble into nonpolar filaments that form rings and cage-like structures, which act as scaffolds to compartmentalize membranes into distinct domains or to recruit and organize the actin and microtubule cytoskeletons. First identified in budding yeast, septin filaments localize to the neck between a dividing yeast mother cell and its growing bud (Figure 16-68A). At this location, septins form a barrier that restricts lateral diffusion of proteins embedded in the plasma membrane, enabling cell growth to be concentrated preferentially within the bud. Septins also recruit the actin-myosin machinery that forms the contractile ring required for cytokinesis. In animal cells, septins function in cell division, migration, vesicle trafficking, and cell signaling. In primary cilia, for example, a ring of septin filaments assembles at the base of the cilium and serves as a diffusion barrier at the plasma membrane, restricting the movement of membrane proteins and establishing a specific composition in the ciliary membrane (Figure 16-68B and C). Reduction of septin levels impairs primary cilium formation and signaling.

MBOC7_ptr_ch16_949-1026.indd 1012 02/12/21 2:16 PM

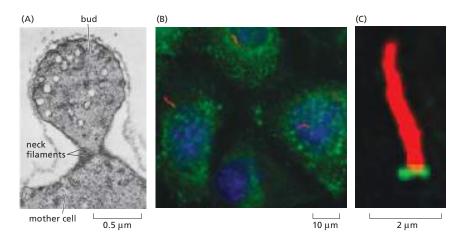

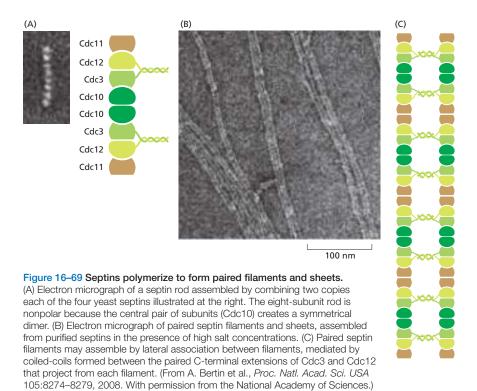

Figure 16–68 Cell compartmentalization by septins. (A) Septins form filaments in the neck region between a mother yeast cell and bud. (B) In this photomicrograph of human cultured cells, the DNA is stained blue and septins are labeled in green. The microtubules of primary cilia are labeled with an antibody that recognizes a modified (acetylated) form of tubulin (red) that is enriched in the axoneme. (C) A magnified image reveals a collar of septin at the base of the cilium. (A, © 1976 B. Byers and L. Goetsch. Originally published in J. Cell Biol. https://doi.org/10.1083 /jcb.69.3.717. With permission from Rockefeller University Press; B and C, from Q. Hu et al., Science 329:436-439, 2010. With permission from AAAS.)

There are 7 septin genes in yeast and 13 in humans, and septin proteins fall into four groups on the basis of sequence relationships. In a test tube, purified septins assemble into symmetrical hetero-hexamers or hetero-octamers that form nonpolar paired filaments (Figure 16–69). GTP binding is required for the folding of septin polypeptides, but the role of GTP hydrolysis in septin function is not understood. Septin structures assemble and disassemble inside cells, but they are not as dynamic as actin filaments and microtubules.

Bacterial Cell Shape and Division Depend on Homologs of Eukaryotic Cytoskeletal Proteins

Although they are much smaller than a typical eukaryotic cell, bacterial cells of different species assume a variety of shapes, from spheres or rods to more elaborate morphologies including stars, spirals, and branched filaments (see Figure 23–3).

MBOC7_ptr_ch16_949-1026.indd 1013 02/12/21 2:16 PM

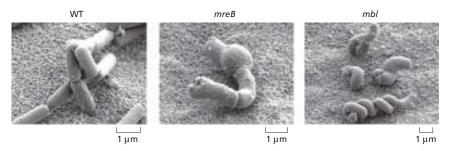

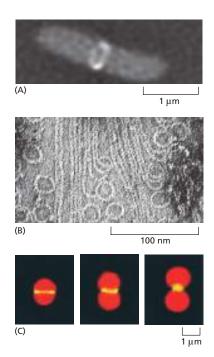

Figure 16–70 Actin homologs in bacteria determine cell shape. The common soil bacterium *Bacillus subtilis* normally forms cells with a regular rodlike shape when viewed by scanning electron microscopy (*left*). In contrast, *B. subtilis* cells lacking the actin homolog MreB or Mbl grow in distorted or twisted shapes and eventually die (*center* and *right*). WT = wild type. [From A. Chastanet and R. Carballido-Lopez, *Front. Biosci.* (*Schol. Ed.*) 4:1582–1606, 2012. With permission from Frontiers in Bioscience.]

Historically, biologists assumed that a cytoskeleton was not necessary in such simple cells that also lack extensive networks of intracellular membrane-enclosed organelles. We now know, however, that the outwardly simple morphology of bacterial cells is deceptive. Bacterial cells are highly organized and contain homologs of actin, tubulin, and intermediate filaments. These filament systems are essential to regulate the synthesis and remodeling of the peptidoglycan cell wall to define cell shape and mediate cell division. Furthermore, the bacterial cytoskeleton can also play important roles in DNA segregation and intracellular organization.

Many bacteria contain homologs of actin. Two of these, MreB and Mbl, are found primarily in rod-shaped or spiral-shaped cells where they assemble to form dynamic patches that move circumferentially along the length of the cell. These proteins contribute to cell shape by serving as a scaffold to direct the synthesis of the peptidoglycan cell wall, in much the same way that microtubules help organize the synthesis of the cellulose cell wall in higher plant cells (see Figure 19-66). MreB and Mbl filaments are highly dynamic, with half-lives of a few minutes, and ATP hydrolysis accompanies the polymerization process. Mutations disrupting MreB or Mbl expression cause extreme abnormalities in cell shape (Figure 16-70).

Nearly all bacteria and many archaea also contain a homolog of tubulin called FtsZ, which can polymerize into filaments and assemble into a ring (called the Z-ring) at the site where the **septum** forms during cell division (**Figure 16–71**). Although the Z-ring persists for many minutes, the individual filaments within it are highly dynamic and have an average half-life of about 30 seconds, as they treadmill along the cell circumference and organize the cell-wall synthesis machinery. As the bacterium divides, the Z-ring becomes smaller until it has completely disassembled. However, because of high turgor pressure within bacterial cells, the energy derived from GTP hydrolysis within FtsZ filaments is unlikely to generate enough bending force to drive the membrane invagination necessary to complete cell division. Instead, FtsZ dynamics in the Z-ring are thought to spatially organize the cell-wall synthesis machinery to promote even, processive constriction. This hypothesis may explain why FtsZ GTPase mutants are viable, but yield deformed septa in *Escherichia coli* cells.

Figure 16–71 The bacterial FtsZ protein, a tubulin homolog in prokaryotes. (A) A band of FtsZ protein forms a ring in a dividing bacterial cell. This ring has been labeled by fusing the FtsZ protein to green fluorescent protein (GFP), which allows it to be observed in living *E. coli* cells with a fluorescence microscope. (B) FtsZ filaments and circles, formed *in vitro*, as visualized using electron microscopy. (C) Dividing chloroplasts (red) from a red alga also cleave using a protein ring made from FtsZ (yellow). MBOC7_ptr_ch16_949-1026.indd 1014 02/12/21 2:16 PM

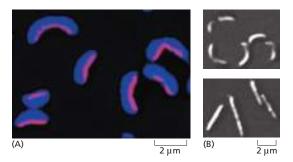

Figure 16–72 Caulobacter and crescentin. The sickle-shaped bacterium Caulobacter crescentus expresses a protein, crescentin, with a series of coiled-coil domains similar in size and organization to the domains of eukaryotic intermediate filaments. (A) The crescentin protein forms a fiber (labeled in red) that runs down the inner side of the curving bacterial cell wall. (B) When the gene is disrupted, the bacteria grow as straight rods (bottom). (From N. Ausmees et al., Cell 115:705–713, 2003. With permission from Elsevier.)

In addition to actin and tubulin homologs, at least one bacterial species, *Caulobacter crescentus*, also harbors a protein with significant structural similarity to intermediate filaments. A protein called crescentin forms a filamentous structure that influences the unusual crescent shape of this species; when the gene encoding crescentin is deleted, the *Caulobacter* cells grow as straight rods (Figure 16-72). Attached to the membrane along the side of inner curvature, crescentin is thought to exert a compressive force that locally decreases peptidoglycan insertion and therefore biases cell-wall synthesis to the opposite side.

Other bacterial cytoskeletal proteins function in DNA segregation during cell division. A particularly intriguing bacterial actin homolog is ParM, which is encoded by a gene on certain bacterial plasmids that also carry genes responsible for antibiotic resistance and cause the spread of multidrug resistance in epidemics. Bacterial plasmids typically encode all the gene products that are necessary for their own segregation, presumably as a strategy to ensure their inheritance and propagation in bacterial hosts after plasmid replication. ParM assembles into filaments that associate at each end with a copy of the plasmid, and growth of the ParM filament pushes the replicated plasmid copies apart (Figure 16–73). This spindle-like structure apparently arises from the selective stabilization of filaments that bind to specialized proteins recruited to the origins of replication on

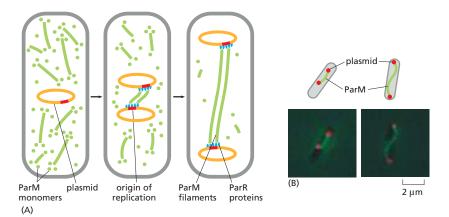

Figure 16–73 Role of the actin homolog ParM in plasmid segregation in bacteria.

(A) Some bacterial drug-resistance plasmids (orange) encode an actin homolog, ParM, that will spontaneously nucleate to form small, dynamic filaments (green) throughout the bacterial cytoplasm. A second plasmid-encoded protein called ParR (blue) binds to specific DNA sequences in the plasmid and also stabilizes the dynamic ends of the ParM filaments. When the plasmid duplicates, both ends of the ParM filaments become stabilized, and the growing ParM filaments push the duplicated plasmids to opposite ends of the cell. (B) In these bacterial cells harboring a drug-resistance plasmid, the plasmids are labeled in red and the ParM protein in green. Left, a short ParM filament bundle connects the two daughter plasmids shortly after their duplication. Right, the fully assembled ParM filament has pushed the duplicated plasmids to the cell poles. (A, adapted from E.C. Garner et al., Science 306:1021–1025, 2004; B, from J. Møller-Jensen et al., Mol. Cell 12:1477–1487, 2003. With permission from Elsevier.)

MBOC7_ptr_ch16_949-1026.indd 1015 02/12/21 2:16 PM

the plasmids. A distant relative of both tubulin and FtsZ, called TubZ, has a similar function in other bacterial species.

Finally, the cytoskeleton plays a role in the internal organization of some bacterial cells. The best-known example applies to magnetotactic bacteria, which are capable of swimming along Earth's magnetic field to seek the optimum aquatic environment. These bacteria contain *magnetosomes*, which are small vesicles invaginated from the plasma membrane that surround magnetite crystals. Arranged in a straight line along the length of the cell, magnetosomes produce a dipole, reminiscent of a compass needle. The organization of magnetosome chains requires their association with filaments of the actin-like protein MamK (Figure 16–74).

Thus, all cells contain cytoskeletal proteins that perform a wide variety of functions, and the actin and tubulin families are very ancient, predating the split between the eukaryotic and bacterial kingdoms.

Summary

Whereas tubulin and actin have been highly conserved in evolution, intermediate filament proteins are very diverse. There are many tissue-specific forms of intermediate filaments in the cytoplasm of animal cells, including keratin filaments in epithelial cells, neurofilaments in nerve cells, and desmin filaments in muscle cells. The primary function of these filaments is to provide mechanical strength. Septins comprise an additional system of filaments that organize compartments inside cells. Bacterial cells also contain homologs of actin, tubulin, and intermediate filaments that form dynamic structures essential for cell shape and division.

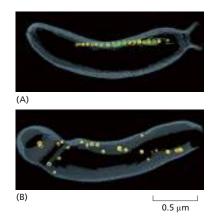

CELL POLARITY AND COORDINATION OF THE CYTOSKELETON

A central challenge in cell biology is to understand how multiple individual molecular components collaborate to produce complex cell behaviors. Cell polarity, which we describe in this final part of the chapter, controls many aspects of cell function, such as the direction of protein secretion and signaling, the orientation of cell division, and the path a migrating cell will take. Cells polarize in response to extracellular cues or intracellular landmarks to establish specific domains on their surface. Coordination with the cytoskeleton is then required for a cell to build different structures with distinct molecular components at the front versus the back, or at the top versus the bottom. In this way, the cytoskeleton acts to transduce polarity signals to generate whole-cell organization and behavior. Carefully controlled cell-polarization processes are also required for oriented cell divisions in tissues and for development of a coherent, organized multicellular organism.

Genetic studies in yeast, flies, and worms have provided most of our current understanding of the molecular basis of cell polarity. As we shall see, with increasing complexity of a cellular system comes greater elaboration of polarity-determining mechanisms. However, many of the molecular components have been evolutionarily conserved, and in all cases the cytoskeleton plays a central role.

Cell Polarity Is Governed by Small GTPases in Budding Yeast

The establishment of cell polarity often begins with local regulation of the actin cytoskeleton by external or internal signals. Many polarity signals converge just beneath the plasma membrane through activation of a group of closely related small monomeric GTPases that are members of the **Rho family**—*Cdc42*, *Rac*, and *Rho*. Like other monomeric GTPases, the Rho proteins act as molecular switches that cycle between an active GTP-bound state and an inactive GDP-bound state (see Figure 3–63). The state of each GTPase depends on dedicated regulatory proteins. Guanine nucleotide exchange factors (GEFs) are required to activate

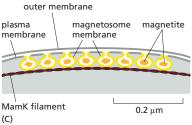

Figure 16-74 MamK organizes chains of magnetosomes. (A) Threedimensional reconstruction of a wild-type Magnetospirillum magneticum cell showing the cell membrane (gray), magnetosomes (yellow), and magnetosome-associated MamK filaments (green). (B) Magnetosomes appear disordered in a mamk deletion mutant, and no filaments are observed. (C) Magnetosomes are formed from invaginations of the plasma membrane and form chains along MamK filaments. (A and B, adapted from A. Komeili et al., Science 311:242-245, 2006. Figure 16-75 The dramatic effects of Cdc42, Rac, and Rho on actin organization in fibroblasts. In each case, the actin filaments have been labeled with fluorescent phalloidin. (A) Serum-starved fibroblasts have actin filaments primarily in the cortex and relatively few stress fibers. (B) Microinjection of a constitutively activated form of Cdc42 results in many long filopodia at the cell periphery. (C) Microiniection of a constitutively activated form of Rac causes the formation of an enormous lamellipodium that extends from the entire circumference of the cell. (D) Microinjection of a constitutively activated form of Rho causes the rapid assembly of many prominent stress fibers. (From A. Hall, Science 279:509-514, 1998. With permission from Catherine Nobes.)

the GTPase by replacing tightly bound GDP with GTP, whereas GTPase activating proteins (GAPs) inactivate the GTPase by promoting GTP hydrolysis, which is otherwise very slow. In addition, guanine nucleotide dissociation inhibitors (GDIs) can bind to the GDP-bound form of a GTPase and inhibit GTP exchange by a GEF.

When the GTP-bound form of each Rho family GTPase is introduced into a fibroblast cell, dramatic changes in cell shape are observed. Active Cdc42 leads to the formation of many long filopodia at the cell surface. Activation of Rac promotes actin polymerization at the cell periphery, leading to the formation of sheet-like lamellipodial protrusions. Activation of Rho promotes both the bundling of actin filaments with myosin II filaments into stress fibers and the clustering of integrins and associated proteins to form focal adhesions (Figure 16–75). These dramatic and complex structural changes occur because each of these three molecular switches has numerous downstream target proteins that affect actin organization and dynamics. Normally, however, these GTPase pathways are not activated uniformly throughout the cell as in this experiment, but are deployed with precise spatial and temporal regulation to generate polarized subcellular structures, which in turn give rise to changes in cell shape and behavior.

Cdc42 is the most highly conserved of all the Rho family GTPases and a master regulator of cell polarity in many cell types. Its importance in the establishment of cell polarity is illustrated by its role in the budding yeast *Saccharomyces cerevisiae*, which undergoes a highly polarized cell division. The formation of a new bud begins with the selection of a single bud site on the cell surface. It is crucial that only a single site is selected, because producing more than one bud would be detrimental to cell division. Before bud site selection, inactive GDP-bound Cdc42 is uniformly distributed on the cell membrane. Occasionally, a Cdc42 molecule will release its GDP and bind GTP, leading to the formation of multiple GTP-Cdc42 foci at random locations in the membrane. Eventually, one of these Cdc42 molecules recruits a protein kinase called PAK, which in turn recruits a scaffold protein together with the Cdc42 GEF. The GEF-containing complex promotes activation of neighboring GDP-bound Cdc42 molecules, resulting in positive feedback. The clustering of Cdc42-GTP molecules at a single site depletes the cytoplasmic pool of

MBOC7_ptr_ch16_949-1026.indd 1017 02/12/21 2:16 PM

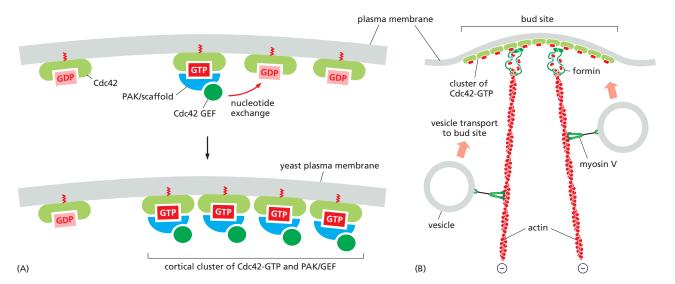

Figure 16–76 Cdc42 establishes yeast-cell polarity. (A) A positive feedback loop by which Cdc42-GTP recruits its own GEF to the plasma membrane to generate a focal site of Cdc42 activity. (B) Local activation of a formin protein by Cdc42-GTP nucleates actin filament assembly. Transport of vesicles along these actin filaments toward their plus ends by myosin V delivers cargoes necessary for growth of the bud.

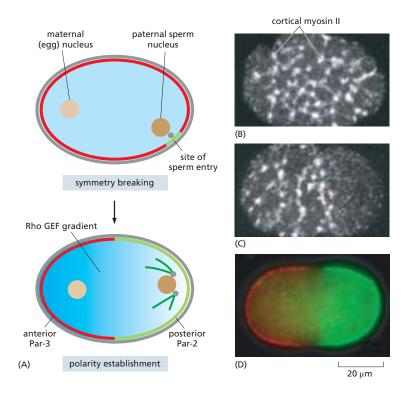

the Cdc42 GEF, thereby ensuring the formation of just one localized site of Cdc42 activation (Figure 16–76A). This cluster of Cdc42-GTP then transmits a signal that polarizes the cytoskeleton by recruiting and activating a formin protein. Recall that formins stimulate rapid assembly of long, straight actin filaments and remain tethered at their plus ends (see Figure 16–13). The resulting actin filaments enable bud growth through the delivery of secretory vesicles and other cargoes to the polarity site by type V myosins (Figure 16–76B; see also Figure 16–36). In addition, both PAK and formin contribute to assembly of septin filaments at the bud neck (see Figure 16–68A). Thus, a low level of Cdc42 activity is locally amplified by positive feedback to initiate the polarized assembly of actin and septins at a single site on the mother cell. Downstream effectors then contribute to bud growth and polarized cell division to produce a daughter cell.

PAR Proteins Generate Anterior-Posterior Polarity in Embryos

Most animal cells do not polarize toward a single membrane site like budding yeast, but instead form complementary cortical domains that mark opposite ends of the cell. This form of polarity has been studied extensively in the early stages of embryonic development of the nematode *Caenorhabditis elegans*. The unfertilized egg is symmetrical, but the fertilized egg, or zygote, rapidly establishes the anterior-posterior axis. The first cell division then occurs asymmetrically along this axis, giving rise to two daughter cells that are of different sizes, compositions, and fates (see Figure 17–50). Genetic screens for mutants defective in this asymmetrical cell division identified *partitioning defective* (*par*) genes that encode the so-called *PAR proteins*. Subsequent studies revealed that other factors are also involved, and the precise molecular mechanisms by which anterior-posterior polarity is established in this system remain under active investigation.

The initial events leading to polarization of the zygote depend on regulation of the cortical actin cytoskeleton by the GTPase Rho. Egg symmetry is first broken when the sperm enters the egg, which marks the location of the posterior end of the embryo. The centrosome associated with the sperm nucleates a microtubule aster, which through an unknown mechanism depletes the Rho GEF from the acto-myosin cortex in that region of the cell. Local loss of Rho activity decreases myosin II-dependent cortical contractility, resulting in greater tension toward the

MBOC7_ptr_ch16_949-1026.indd 1018 02/12/21 2:16 PM

other end of the cell. This asymmetry then sets up localization of the PAR proteins so that they occupy separate cortical domains.

One set of PAR proteins, the anterior PAR proteins, includes Par-3, Par-6, Cdc42, and atypical protein kinase C (aPKC). Initially unpolarized at the cortex, these proteins move toward the anterior because of the change in contractility that causes flow within the membrane. Enrichment of the anterior PAR proteins actively displaces another set of proteins (the posterior PAR proteins, including Par-1 and Par-2), which then bind to the posterior cortex (Figure 16-77). These complementary cortical domains are maintained by mutual antagonism between the anterior and posterior components, which occurs through multiple mechanisms. For example, phosphorylation by aPKC in the anterior region excludes the posterior PAR proteins, while the posterior PAR proteins suppress aPKC activity in their domain. It remains unclear how PAR proteins then direct the trafficking and localization of other proteins to define the cortical domains. As in yeast, the master polarity regulator Cdc42, which is activated exclusively at the anterior cortex, likely plays a key role.

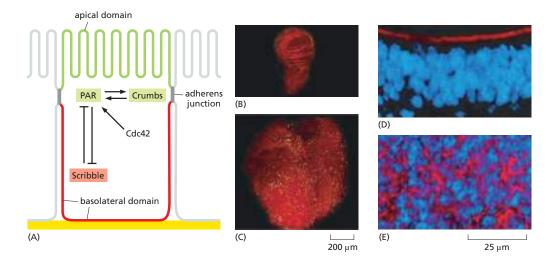

In all animal species, mechanisms that establish polarity in the embryo determine the overall body plan (see Chapter 21). Subsequent polarized cell divisions produce daughter cells that are destined to become different tissues in the organism. In this way, the establishment of intracellular polarity early in development sets the stage for polarity throughout the adult animal.

Conserved Complexes Polarize Epithelial Cells and Control Their Growth

All animal cells are polarized in some way, perhaps most prominently in the epithelial cells that make up many tissues. Epithelia are sheets of tightly connected cells that line the surface of organs and act as highly selective barriers, such as the barriers between the skin and the outside environment or between the lumen of the gut and its surrounding tissues. Epithelial cells have two distinct domains: the *apical* domain at the upper surface, which faces the outside environment, and

Figure 16-77 PAR proteins establish two distinct cortical domains in C. elegans (A) Symmetry breaking and polarity establishment occur in the fertilized egg before the maternal and paternal nuclei meet. After sperm entry, its centrosome duplicates and nucleates microtubules that decrease Rho GEF activity at what will become the posterior end of the embryo. This leads to accumulation of the anterior PAR proteins (including Par-3), allowing posterior PAR proteins (including Par-2) to bind the cortex at the posterior end. (B) Prior to fertilization, bundles of fluorescently labeled myosin II (white) are distributed throughout the cortex of the unpolarized egg because of the uniform distribution of activated Rho all along the plasma membrane, resulting in uniform cortical acto-myosin contractility. (C) After fertilization, local depletion of the Rho GEF near the sperm entry site (at right in this image) reduces myosin levels and contractility in the posterior cortex of the cell. (D) Par complex localization after polarization with Par-3 (red) at the anterior and Par-2 (green) at the posterior of the zygote. Multiple mechanisms operate to maintain this asymmetry through mutual antagonism between anterior and posterior PAR proteins. (B and C, from L. Rose and P. Gönczy, The C. elegans Research Community, WormBook, 2014, doi 10.1895/wormbook.1.30.2; D, from J. Nance and J.A. Zallen, Development 138:799-809, 2011. MBOC7_ptr_ch16_949-1026.indd 1019 02/12/21 2:16 PM

the *basolateral* domain at the bottom and side surfaces, which face the underlying matrix and adjacent cells (see Figure 16–4). Cell polarization is initiated by cues from the adjacent cells or the extracellular matrix. An important early step is the formation of cell-cell junctions that separate the apical and basolateral domains and hold the epithelial sheet together (see Chapter 19). In addition, as discussed earlier (see Figure 16–44), microtubules become aligned with their minus ends anchored at the apical surface and their plus ends pointing basally. This arrangement helps to polarize the secretory system so that nascent secreted and membrane proteins are transported to the appropriate domain. For example, digestive enzymes must be secreted exclusively into the lumen of the gut to avoid extensive damage to the surrounding tissues.

Much of what we know about the regulators of epithelial polarity comes from genetic screens that identified polarity-deficient mutants in *Drosophila*. These screens revealed some familiar proteins, including Cdc42 and the anterior PAR proteins, which in this system localize to the apical domain. In addition, two other protein groups were identified, termed *Crumbs* and *Scribble*, which are located in the apical and basolateral domains, respectively. Cells cannot form an apical domain in the absence of PAR or Crumbs proteins. In contrast, the apical domain is greatly expanded in the absence of Scribble proteins. This and other evidence indicate that mutual antagonism between apical and basolateral regulators helps maintain cell polarity and junctional contacts (**Figure 16–78A**). Downstream of the PAR, Crumbs, and Scribble modules, the organization of epithelial cell junctions, cytoskeleton, and secretory pathway is mediated by Rho family GTPases; the mechanisms underlying this regulation are not well understood.

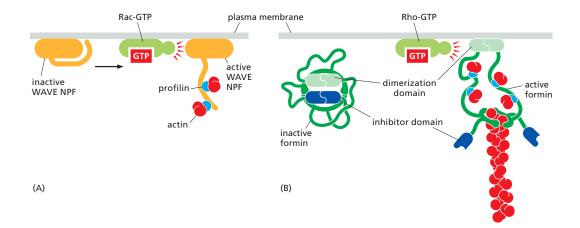

Disruption of these polarity modules can lead to cellular growth defects, often through misregulation of a signaling system called the Hippo pathway (see Figure 21–67). For example, mutation of Scribble in epithelia of the developing fly larva not only leads to the loss of polarized cell organization but also promotes massive and invasive overgrowth, all characteristics of malignant tumors (Figure 16–78B, C, D, and E). Because Scribble proteins also help maintain polarity and normal growth in human epithelial tissues, they act as tumor suppressors (see Chapter 20).

Cell Migration Requires Dynamic Cell Polarity

Whereas epithelial cells maintain a polarized state throughout their lifetime to perform an essential barrier function within tissues, migrating cells display a dynamic polarity that requires continual long-distance communication and coordination between one end of a cell and the other. In addition to driving local mechanical processes such as protrusion at the front and retraction at the rear,

Figure 16–78 Cell-polarity protein modules identified in *Drosophila*.

(A) PAR and Crumbs proteins cooperate to assemble the apical domain and junctional complexes, whereas Scribble defines the basolateral domain. Scribble and PAR are mutually antagonistic, whereas PAR and Crumbs reinforce each other, Cdc42 helps to recruit PAR proteins. (B) Fluorescence micrograph of a wild-type Drosophila larval epithelial tissue called the imaginal disc stained for actin (red) shows the wellorganized, folded monolayer epithelium. (C) In a Scribble mutant, the imaginal disc has lost its normal morphology and grown dramatically larger because of hyperproliferation. Actively dividing cells are labeled yellow. (D) Higher-magnification image of a wild-type disc shows the polarized localization of actin (red) to the apical domain. (E) Actin organization is disrupted in the absence of Scribble. Nuclei are stained blue. (B and C, courtesy of David Bilder: D and E. from D. Bilder et al., Science 289:113-116, 2000. With permission from AAAS.)

the cytoskeleton is responsible for coordinating cell shape, organization, and mechanical properties along its entire length, a distance that is typically tens of micrometers for animal cells. As we shall see, the Rho family GTPases and several cell-polarity proteins that we have already introduced are central to this process.

Cell locomotion requires an initial polarization of the cell to propel it in a particular direction. Once again, Cdc42 appears to be critical, as it sets up the overall polarity of a migrating cell. The downstream effectors of Cdc42-GTP include the polarity protein Par-3, and Cdc42 is also thought to stimulate extension of filopodia (see Figure 16-75) that help sense and respond to extracellular cues. Once polarized, protrusion of the leading edge of the cell is driven through nucleation of branched actin filaments by the Arp2/3 complex (see Figure 16-12). This process depends on Rac-GTP, which stimulates members of the WAVE family of actin nucleation-promoting factors (NPFs). A WAVE protein, present in a large regulatory complex, can exist in an inactive folded conformation and an activated open conformation. Association with Rac-GTP recruits WAVE to the plasma membrane and stabilizes the open conformation (Figure 16-79A). Active WAVE then stimulates nucleation of new actin filaments by Arp2/3 along the sides of existing filaments (see Figures 16-12 and 16-14A). In this way, Rac-GTP-dependent WAVE promotes the formation of branched actin networks that drive lamellipod formation at the leading edge of migrating cells (Figure 16-80A).

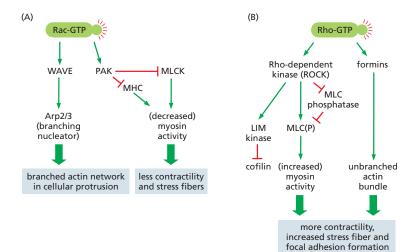

Rho-GTP is equally important for cell migration and has a very different set of targets. Instead of activating the Arp2/3 complex to build branched actin networks, Rho-GTP induces formin proteins to construct parallel actin bundles. Similar to the effects of Rac-GTP on WAVE, association of formins with Rho-GTP stabilizes an open, active conformation (Figure 16-79B). As discussed previously, formins stimulate both the nucleation and elongation of straight actin filaments (see Figures 16-13 and 16-14B). At the same time, Rho-GTP activates the Rho-associated kinase (ROCK), which stimulates another kinase called LIM, which phosphorylates and inhibits the activity of the actin-destabilizing protein cofilin. The resulting stable, unbranched actin filaments are ideal for interacting with myosin II. Furthermore, ROCK activates myosin II by inhibiting a phosphatase acting on myosin light chains (see Figure 16-34). The consequent increase in the net amount of myosin light-chain phosphorylation increases the level of contractile myosin motor-protein activity in the cell, enhancing the formation of tension-dependent structures such as stress fibers and focal adhesions (Figure 16-80B).

Spatial and temporal separation between the Rac and Rho pathways is thought to facilitate maintenance of the large-scale differences between the cell front and the cell rear during migration. Whereas Rac is activated exclusively at the leading edge of the cell, Rho activation predominates at the rear. Furthermore, the two pathways are mutually antagonistic. For example, Rac inhibits Rho activity through one of its effectors, the kinase PAK, which inhibits myosin II and therefore

Figure 16-79 Regulation of nucleationpromoting factors and formins by Rho family GTPases. (A) Members of the WAVE family of nucleation-promoting factors are activated upon binding to Rac-GTP at the plasma membrane. A conformational change in WAVE opens up the protein, allowing domains that were previously inaccessible to interact with both the Arp2/3 complex and profilinbound actin subunits. For clarity, the WAVE regulatory complex is not shown. (B) The activity of some formin proteins is inhibited by an autoinhibitory interaction in the absence of an active GTPase. Binding to Rho-GTP exposes a binding site for the plus end of an actin filament, as well as profilin-actin binding domains.

1022

contractility. Rac and Rho also modulate the activities of the other's GEFs, GAPs, or GDIs to reinforce spatial separation of their activities.

External Signals Can Dictate the Direction of Cell Migration

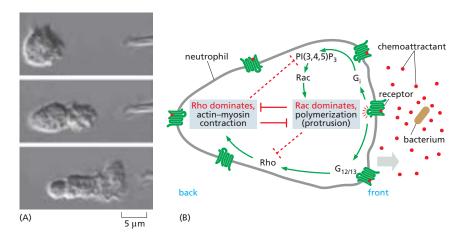

Chemotaxis is the movement of a cell toward or away from a source of some diffusible chemical. These external signals act through cell surface receptors that trigger Rho family proteins to polarize and orient the cell motility apparatus, enabling directed cell migration. One well-studied example is the chemotactic movement of a class of white blood cells, called *neutrophils*, toward a source of bacterial infection. Receptor proteins on the surface of neutrophils enable them to detect very low concentrations of *N*-formylated peptides that are derived from bacterial proteins (only prokaryotes begin protein synthesis with *N*-formylmethionine). Using these receptors, neutrophils are guided to bacterial targets by their ability to detect a difference of only 1% in the concentration of these diffusible peptides on one side of the cell versus the other (Figure 16–81A).

In this case, and in the chemotaxis of *Dictyostelium* amoebae toward a source of cyclic AMP, binding of the chemoattractant to its G-protein-coupled receptor activates phosphoinositide 3-kinases (PI3Ks) (see Figure 15-53), which generate a signaling molecule $[PI(3,4,5)P_3]$ that in turn activates the Rac GTPase. Rac then activates the Arp2/3 complex leading to lamellipodial protrusion. Through an unknown mechanism, accumulation of the polarized actin network at the leading edge causes further local enhancement of PI3K activity in a positive feedback loop, strengthening the induction of protrusion. The PI(3,4,5)P₃ that activates Rac cannot diffuse far from its site of synthesis, because it is rapidly converted back into PI(4,5)P2 by a constitutively active lipid phosphatase. At the same time, binding of the chemoattractant ligand to its receptor activates another signaling pathway that turns on Rho and enhances myosin-based contractility. As described in the previous section, these two pathways directly inhibit each other, such that Rac activation dominates in the front of the cell and Rho activation dominates in the rear (Figure 16-81B). This enables the cell to maintain its functional polarity with protrusion at the leading edge and contraction at the back.

Nondiffusible chemical cues attached to the extracellular matrix or to the surface of cells can also influence the direction of cell migration. When these signals activate receptors, they can cause increased cell adhesion and directed actin polymerization. Most long-distance cell migrations in animals, including neural-crest-cell migration and the travels of neuronal growth cones, depend on a combination of diffusible and nondiffusible signals to steer the locomoting cells or growth cones to their proper destinations.

Figure 16–80 The contrasting effects of Rac and Rho activation on actin organization. (A) Activation of the small GTPase Rac leads to alterations in actin accessory proteins that promote the formation of protrusive actin networks in lamellipodia and pseudopodia. Several different pathways contribute independently. Rac-GTP activates members of the WAVE protein family, which in turn activate actin nucleation and branched network formation by the Arp2/3 complex. In a parallel pathway, Rac-GTP activates the protein kinase PAK, which has several targets including the myosin light-chain kinase (MLCK), which is inhibited by phosphorylation. Inhibition of MLCK results in decreased phosphorylation of the myosin regulatory light chain and leads to myosin II filament disassembly and a decrease in contractile activity. In some cells. PAK also directly inhibits myosin II activity by phosphorylation of the myosin heavy chain (MHC). (B) Activation of the related GTPase Rho leads to nucleation of actin filaments by formins and increases contraction by myosin II, promoting the formation of contractile actin bundles at the rear of the cell and assembly of stress fibers. Activation of myosin II by Rho requires a Rho-associated kinase called ROCK. This kinase inhibits the phosphatase that removes the activating phosphate groups from myosin Il light chains (MLC); it may also directly phosphorylate the myosin light chains in some cell types. ROCK also activates other protein kinases, such as LIM kinase, which in turn contributes to the formation of stable contractile actin filament bundles by inhibiting the actindepolymerizing factor cofilin. A similar signaling pathway is important for forming the contractile ring necessary for cytokinesis (see Figure 17-45).

Communication Among Cytoskeletal Elements Supports Whole-Cell Polarity and Locomotion

The interconnected cytoskeleton is crucial for cell polarity and migration. Although polarity signals are frequently transduced by Rho family GTPases that act primarily on the actin cytoskeleton and myosin contractility, microtubules, septins, and intermediate filaments also participate. For example, vimentin intermediate filament networks associate with integrins at focal adhesions, and vimentin-deficient fibroblasts display impaired mechanical stability, migration, and contractile capacity. Furthermore, disruption of linker proteins that connect different cytoskeletal elements, including several plakins and KASH proteins, leads to defects in cell polarization and migration. Thus, interactions among cytoplasmic filament systems, as well as mechanical linkage to the nucleus, are required for complex, whole-cell behaviors such as migration.

Cells also use microtubules to support cell polarity and to organize persistent movement in a specific direction. Cross-linking proteins connect microtubule minus and plus ends to actin at the apical and basal cortex of epithelial cells, respectively. They also link the plus ends of microtubules and actin at the front of migrating cells. An example of such a cross-linker is the formin proteins, a subset of which binds to microtubules in addition to regulating actin filament assembly. These interactions enable microtubules to influence actin rearrangements and cell adhesion. By extending from the centrosome into the protrusive region of a migrating cell, microtubules can also serve as a compass to aid in directed cell migration. Microtubules also influence actin and focal adhesions by serving as tracks for motor-dependent transport of cargoes to and from the cell periphery. They can also deliver regulatory proteins, such as Rac GEFs, which bind to the +TIPs traveling on growing microtubule ends. Thus, microtubules reinforce the polarity information that the actin cytoskeleton receives from the outside world, allowing a sensitive response to weak signals and enabling motility to persist in the same direction for a prolonged period.

Summary

Cell polarity and migration require large-scale shaping and structuring of cells. This involves the coordinated activities of all three basic filament systems along with a large variety of regulatory and motor proteins. Rho family proteins work together with cell-polarity proteins to establish stable cytoskeletal structures necessary to generate higher levels of polarity within an organism or to maintain epithelial tissues. These same factors also operate during the dynamic polarization required for directed cell migration—a widespread behavior important in embryonic development and also in wound healing, tissue maintenance, and immune system function in the adult animal—providing a prime example of complex, coordinated cytoskeletal action influenced by external cues.

Figure 16-81 Neutrophil polarization and chemotaxis. (A) The pipette tip at the right is leaking a small amount of the bacterial peptide formyl-Met-Leu-Phe, which is recognized by the human neutrophil as the product of a foreign invader. The neutrophil quickly extends a new lamellipodium toward the source of the chemoattractant peptide (top). It then extends this lamellipodium and polarizes its cytoskeleton so that contractile myosin Il is located primarily at the rear, opposite the position of the lamellipodium (middle). Finally, the cell crawls toward the source of the peptide (bottom). If a real bacterium were the source of the peptide, rather than an investigator's pipette, the neutrophil would engulf the bacterium and destroy it (see also Figure 16-3 and Movie 16.17). (B) Binding of bacterial molecules to G-protein-coupled receptors on the neutrophil stimulates directed motility. These receptors are found all over the surface of the cell, but are more likely to be bound to the bacterial ligand at the front. Two distinct signaling pathways contribute to the cell's polarization. At the front of the cell, stimulation of the Rac pathway leads, via the trimeric G protein G_i, to growth of protrusive actin networks. Second messengers within this pathway are short-lived, so protrusion is limited to the region of the cell closest to the stimulant. The same receptor also stimulates a second signaling pathway, via the trimeric G proteins G₁₂ and G₁₃, that triggers the activation of Rho. The two pathways are mutually antagonistic. Because Rac-based protrusion is active at the front of the cell, Rho is activated only at the rear of the cell, stimulating contraction of the cell rear and assisting directed movement. (A, from O.D. Weiner et al., Nat. Cell Biol. 1:75-81, published 1999 by Macmillan Magazines Ltd. Reproduced with permission of SNCSC.)

PROBLEMS

Which statements are true? Explain why or why not.

- **16–1** The role of ATP hydrolysis in actin polymerization is similar to the role of GTP hydrolysis in tubulin polymerization: both serve to weaken subunit bonds in the polymer and thereby promote depolymerization.
- **16–2** Motor neurons trigger action potentials in muscle cell membranes that open voltage-gated Ca²⁺ channels in T tubules, allowing extracellular Ca²⁺ to enter the cytosol, bind to troponin C, and initiate rapid muscle contraction.
- **16–3** In most animal cells, minus end-directed microtubule motors deliver their cargo to the periphery of the cell, whereas plus end-directed microtubule motors deliver their cargo to the interior of the cell.
- **16–4** Because bacteria are very small and lack the elaborate networks of intracellular membrane-enclosed organelles typical of eukaryotic cells, they do not require cytoskeletal filaments.

Discuss the following problems.

- 16–5 A scallop is a hinged bivalve that swims by slowly opening its two-part shell and then rapidly closing it, forcing a jet of water out the back and propelling itself forward. Imagine a bacterium constructed analogously. Could it swim in its low-Reynolds-number environment using the same mechanism as the scallop? Why or why not?
- 16–6 The plus and minus ends of actin filaments grow at different rates and have different critical concentrations (C_c). Between these critical concentrations, the filaments grow at their plus ends but shrink at their minus ends, a property termed treadmilling (Figure Q16–1). Is there any concentration of actin subunits at which the filament length does not change? If so, describe the concentration at which it occurs.

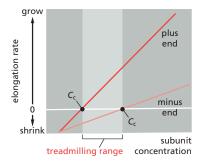

Figure Q16–1 Treadmilling at intermediate concentrations of free actin subunits (Problem 16–6).
