16–7 Cofilin preferentially binds to older actin filaments and promotes their disassembly. How does cofilin distinguish old filaments from new ones?

16–8 How is the unidirectional motion of a lamellipodium maintained?

16–9 Detailed measurements of sarcomere length and tension during isometric contraction in striated muscle provided crucial early support for the sliding-filament model of muscle contraction. On the basis of your understanding of the sliding-filament model and the structure of a sarcomere, propose a molecular explanation for the relationship of tension to sarcomere length in the portions of **Figure Q16–2** marked I, II, III, and IV. (In this muscle, the length of the myosin filament is 1.6 μ m, and the lengths of the actin thin filaments that project from the Z discs are 1.0 μ m.)

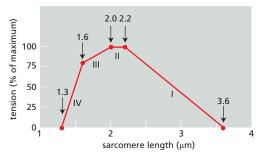

Figure Q16–2 Tension as a function of sarcomere length during isometric contraction (Problem 16–9).

16–10 At 1.4 mg/mL pure tubulin, microtubules grow at a rate of about 2 μ m/min. At this growth rate, how many $\alpha\beta$ -tubulin dimers (8 nm in length) are added to the ends of a microtubule each second?

16–11 The movements of single motor-protein molecules can be analyzed directly. Using polarized laser light, it is possible to create interference patterns that exert a centrally directed force, ranging from zero at the center to a few piconewtons at the periphery (about 200 nm from the center). Individual molecules that enter the interference pattern are rapidly pushed to the center, allowing them to be captured and moved at the experimenter's discretion.

These so-called optical tweezers can be used to position single kinesin molecules on a microtubule that is fixed to a coverslip. Although a single kinesin molecule cannot be seen optically, it can be tagged with a silica bead and tracked indirectly by following the bead (Figure Q16–3A). In the absence of ATP, the kinesin molecule remains at the center of the interference pattern, but with ATP it moves toward the plus end of the microtubule. As kinesin moves along the microtubule, it encounters the force of the interference pattern, which simulates the load kinesin carries during its actual function in the cell. Moreover, the pressure against the silica bead counters the effects of Brownian (thermal) motion,

REFERENCES 1025

so that the position of the bead more accurately reflects the position of the kinesin molecule on the microtubule.

A trace of the movements of a kinesin molecule along a microtubule is shown in Figure Q16-3B.

(A) EXPERIMENTAL SETUP

(B) POSITION OF KINESIN

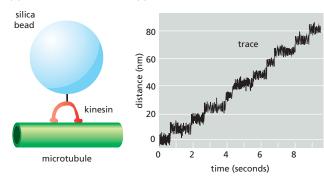

Figure Q16–3 Movement of kinesin along a microtubule (Problem 16–11). (A) Experimental setup, with kinesin linked to a silica bead, moving along a microtubule. (B) Position of kinesin (as visualized by the position of the silica bead) relative to the center of the interference pattern, as a function of time of movement along the microtubule. The jagged nature of the trace results from Brownian motion of the bead.

- A. As shown in Figure Q16-3B, all movement of kinesin is in one direction (toward the plus end of the microtubule). What supplies the free energy needed to ensure a unidirectional movement along the microtubule?
- **B.** What is the average rate of movement of kinesin along the microtubule?
- **C.** What is the length of each step that kinesin takes as it moves along the microtubule?
- D. Kinesin has two globular domains that can each bind to β -tubulin, and it moves along a single protofilament

in a microtubule. In each protofilament, the β -tubulin subunit repeats at 8-nm intervals. Given the step length and the interval between β -tubulin subunits, how do you suppose a kinesin molecule moves along a microtubule?

E. Is there anything in the data in Figure Q16–3 that tells you how many ATP molecules are hydrolyzed per step?

16–12 A mitochondrion 1 μ m long can travel the 1-meter length of the axon from the spinal cord to the big toe in a day. The Olympic men's freestyle swimming record for 200 meters is 1.72 minutes. In terms of body lengths per day, who is moving faster: the mitochondrion or the Olympic record holder? (Assume that the swimmer is 2 meters tall.)

16–13 Why is it that intermediate filaments have identical ends and lack polarity, whereas actin filaments and microtubules each have two distinct ends with a defined polarity?

16–14 Once cell polarity has been established in the fertilized egg of *C. elegans* (Figure Q16–4), the female pronucleus migrates along the microtubules emanating from the centrosomes adjacent to the paternal nucleus, which leads to fusion of the haploid genomes. What motor is likely involved in nuclear migration?

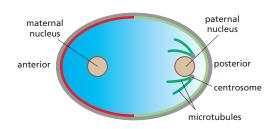

Figure Q16–4 Polarity establishment in a fertilized *C. elegans* egg prior to nuclear fusion (Problem 16–14).

The Cell Cycle

CHAPTER

17

The only way to make a new cell is to duplicate a cell that already exists. This simple fact, first established in the middle of the nineteenth century, carries with it a profound message for the continuity of life. All living organisms, from the unicellular bacterium to the multicellular mammal, are products of repeated rounds of cell growth and division extending back in time to the beginnings of life on Earth more than 3 billion years ago.

A cell reproduces by performing an orderly sequence of events in which it duplicates its contents and then divides in two. This cycle of duplication and division, known as the **cell cycle**, is the essential mechanism by which all living things reproduce. In unicellular species, such as bacteria and yeasts, each cell division produces a complete new organism. In multicellular species, long and complex sequences of cell divisions are required to produce a functioning organism. Even in the adult body, cell division is usually needed to replace cells that die. In fact, each of us must manufacture many millions of cells every second simply to survive: if all cell division were stopped—by exposure to a very large dose of x-rays, for example—we would die within a few days.

The details of the cell cycle vary from organism to organism and at different times in an organism's life. Certain characteristics, however, are universal. At a minimum, the cell must accomplish its most fundamental task: the passing on of its genetic information to the next generation of cells. To produce two genetically identical daughter cells, the DNA in each chromosome is replicated faithfully to produce two complete copies. The replicated chromosomes are then distributed (*segregated*) to the two daughter cells, so that each receives a copy of the entire genome (Figure 17–1). In addition to duplicating their genome, most cells also duplicate their other organelles and macromolecules; otherwise, daughter cells would get smaller with each division. To maintain their size, dividing cells coordinate their growth (that is, their increase in cell mass) with their division.

This chapter describes the events of the eukaryotic cell cycle and how they are controlled and coordinated. We begin with a brief overview of the cell cycle. We then describe the *cell-cycle control system*, a complex network of regulatory proteins that triggers the different events of the cycle. We next consider in detail the major stages of the cell cycle, in which the chromosomes are duplicated and then segregated into the two daughter cells. Finally, we consider how extracellular signals govern the rates of cell growth and division and how these two processes are coordinated.

OVERVIEW OF THE CELL CYCLE

The most basic function of the cell cycle is to duplicate the vast amount of DNA in the chromosomes and then segregate the copies into two genetically identical daughter cells. These processes define the two major phases of the cell cycle. Chromosome duplication occurs during *S phase* (S for DNA *s*ynthesis), which requires 10–12 hours and occupies about half of the cell-cycle time in a typical mammalian cell. After S phase, chromosome segregation and cell division occur

Control of Cell Division and Cell Growth

MBOC7_ptr_ch17_1027-1088.indd 1027 02/12/21 2:14 PM

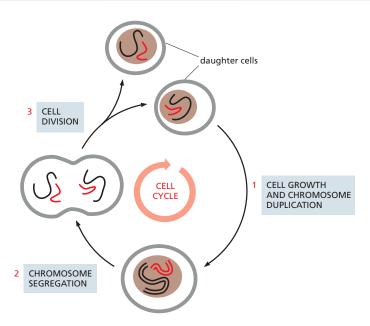

Figure 17–1 The cell cycle. The division of a hypothetical eukaryotic cell with two chromosomes (one *red*, and one *black*) is shown to illustrate how two genetically identical daughter cells are produced in each cycle. Each of the daughter cells will often continue to divide by going through additional cell cycles.

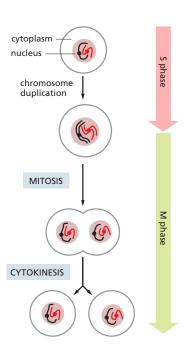

in *M phase* (M for *m*itosis), which requires much less time (less than an hour in a mammalian cell). M phase comprises two major events: nuclear division, or *mitosis*, during which the copied chromosomes are distributed into a pair of daughter nuclei; and cytoplasmic division, or *cytokinesis*, when the cell itself divides in two (Figure 17–2).

At the end of S phase, the DNA molecules in each pair of duplicated chromosomes remain intertwined and held tightly together by specialized protein linkages. Early in mitosis, at a stage called *prophase*, the two DNA molecules are disentangled and condensed into pairs of rigid, compact rods called **sister chromatids**, which remain linked by *sister-chromatid cohesion*. When the nuclear envelope then disassembles, the sister-chromatid pairs become attached to the *mitotic spindle*, a giant bipolar array of microtubules (discussed in Chapter 16). Sister chromatids are attached to opposite poles of the spindle and, eventually, align at the spindle equator in a stage called *metaphase*. The destruction of sister-chromatid cohesion at the start of *anaphase* separates the sister chromatids, which are pulled to opposite poles of the spindle. The spindle is then disassembled, and the segregated chromosomes are packaged into separate nuclei at *telophase*. Cytokinesis then cleaves the cell in two, so that each daughter cell inherits one of the two nuclei (Figure 17–3).

The Eukaryotic Cell Cycle Usually Consists of Four Phases

Most cells require much more time to grow and double their mass of proteins and organelles than they require to duplicate their chromosomes and divide. Partly to allow time for growth, most cell cycles have *gap phases*—a **G**₁ **phase** between M phase and S phase and a **G**₂ **phase** between S phase and mitosis. Thus, the eukaryotic cell cycle is traditionally divided into four sequential phases: G₁, S, G₂, and M. G₁, S, and G₂ together are called **interphase** (**Figure 17–4**, and see Figure 17–3). In a typical human cell proliferating in culture, interphase might

Figure 17–2 The major events of the cell cycle. The major chromosomal events of the cell cycle occur in S phase, when the chromosomes are duplicated, and M phase, when the duplicated chromosomes are segregated into a pair of daughter nuclei (in mitosis), after which the cell itself divides into two (cytokinesis).

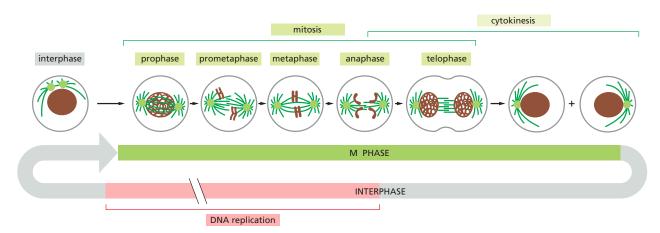

Figure 17–3 The events of eukaryotic cell division as seen under a microscope. The easily visible processes of nuclear division (mitosis) and cell division (cytokinesis), collectively called M phase, typically occupy only a small fraction of the cell cycle. The other, much longer, part of the cycle is known as interphase, which includes S phase and the gap phases.

occupy 23 hours of a 24-hour cycle, with 1 hour for M phase. Cell growth occurs throughout the cell cycle.

The two gap phases are more than simple time delays to allow cell growth. They also provide time for the cell to monitor the internal and external environment to ensure that conditions are suitable and preparations are complete before the cell commits itself to the complex events of S phase and mitosis. The G_1 phase is especially important in this respect. Its length can vary greatly depending on external conditions and extracellular signals from other cells. If extracellular conditions are unfavorable, for example, cells delay progress through G_1 and may even enter a specialized resting state known as G_0 (G zero), in which they can remain for days, weeks, or even years. Indeed, many cells remain permanently in G_0 until the organism dies. If extracellular conditions become favorable or signals to grow and divide are introduced, cells in G_0 progress through a commitment point in G_1 known as **Start** (in yeasts) or the **restriction point** (in mammalian cells). We will use the term "Start" for both yeast and animal cells. After passing this point, cells are committed to DNA replication, even if the extracellular signals that stimulate cell growth and division are removed.

Not all cells undergo the conventional four-phase cell cycle. The early cleavage divisions of vertebrate embryos, for example, are not accompanied by cell growth, and these rapid divisions simply include alternating S and M phases without intervening gaps. Another important and common variation is the **endocycle**, also known as *endoreduplication*, in which multiple rounds of S phase occur without intervening M phases, resulting in cells with many copies

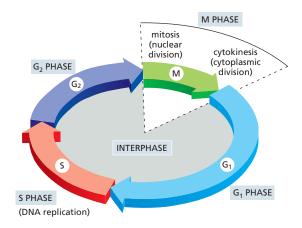

Figure 17–4 The four phases of the cell cycle. In most cells, gap phases separate the major events of S phase and M phase. G_1 is the gap between M phase and S phase, while G_2 is the gap between S phase and M phase.

MBOC7_ptr_ch17_1027-1088.indd 1029 02/12/21 2:14 PM

of the genome—thereby enabling rapid increases in the production of numerous gene products. Finally, as we describe later, some cell types undergo mitosis without cytokinesis, resulting in large cells with multiple nuclei.

Cell-Cycle Control Is Similar in All Eukaryotes

Some features of the cell cycle, including the time required to complete certain events, vary greatly from one cell type to another, even in the same organism. The basic organization of the cycle, however, is essentially the same in all eukaryotic cells, and all eukaryotes appear to use similar machinery and control mechanisms to drive and regulate cell-cycle events. The proteins of the cell-cycle control system, for example, first appeared more than a billion years ago. Remarkably, they have been so well conserved over the course of evolution that many of them function perfectly when transferred from a human cell to a yeast cell. We can therefore study the cell cycle and its regulation in a variety of organisms and use the findings from all of them to assemble a unified picture of how eukaryotic cells divide.

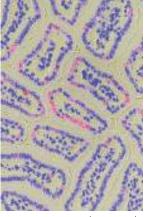

Several model organisms are used in the analysis of the eukaryotic cell cycle. The budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe* are simple eukaryotes in which powerful molecular and genetic approaches can be used to identify and characterize the genes and proteins that govern the fundamental features of cell division. The early embryos of certain animals, particularly those of the frog *Xenopus laevis*, are excellent tools for biochemical dissection of cell-cycle control mechanisms, while the fruit fly *Drosophila melanogaster* is useful for the genetic analysis of mechanisms underlying the control and coordination of cell growth and division in multicellular organisms. Cultured human cells provide an excellent system for the molecular and microscopic exploration of the complex processes by which our own cells divide.

Cell-Cycle Progression Can Be Studied in Various Ways

How can we tell what stage a cell has reached in the cell cycle? One way is simply to look at living cells with a microscope. A glance at a population of mammalian cells proliferating in culture reveals that a fraction of the cells have rounded up and are in mitosis (cell rounding allows the mitotic spindle to function more effectively). Other cells can be observed in the process of cytokinesis. We can gain additional clues about cell-cycle position by staining cells with DNA-binding fluorescent dyes (which reveal the condensation of chromosomes in mitosis) or with antibodies that recognize specific cell components such as the microtubules (revealing the mitotic spindle). S-phase cells can be identified in the microscope by supplying them with visualizable molecules that are incorporated into newly synthesized DNA, such as the artificial thymidine analog 5-ethynyl-2'-deoxyuridine (EdU); cell nuclei that have incorporated EdU are then revealed by treatment with a fluorescent dye that attaches covalently to EdU (Figure 17–5).

Typically, in a population of cultured mammalian cells that are all proliferating rapidly but asynchronously, about 30–40% will be in S phase at any instant and become labeled by a brief pulse of EdU. From the proportion of cells in such a population that are labeled, we can estimate the duration of S phase as a fraction of the whole cell-cycle duration. Similarly, from the proportion of cells in

Figure 17–5 Labeling S-phase cells. A fluorescence micrograph of EdU-labeled cells of the mouse small intestine, showing intestinal villi in transverse section. The mouse was injected with a single brief dose of EdU, which then became incorporated into the newly synthesized DNA of any cell that was progressing through S phase at the time of injection. Ninety-six hours later, the tissue was fixed and labeled with a fluorescent dye that attaches to EdU (red), thereby labeling cells that were in S phase 96 hours earlier. All the cell nuclei are stained with a blue fluorescent dye. (From A. Salic and T.J. Mitchison, Proc. Natl. Acad. Sci. USA 105:2415–2420, 2008. With permission from National Academy of Sciences.)

100 μm

MBOC7_ptr_ch17_1027-1088.indd 1030 02/12/21 2:14 PM

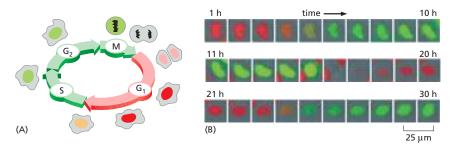

Figure 17–6 Measuring cell-cycle timing in live cells. (A) The method shown here depends on fluorescent proteins that are present only at specific cell-cycle stages, as illustrated in the diagram. First, a protein called geminin is labeled with a green fluorescent protein. This protein is targeted for degradation by the APC/C, a ubiquitin ligase that is active from metaphase to the end of G_1 (as discussed later). Thus, the green fluorescence of this protein is seen from early S phase to mid-mitosis. A second protein, called Cdt1, is tagged with a red fluorescent protein. This protein is targeted for ubiquitylation and destruction from late G_1 to telophase of mitosis. Cells therefore glow red from the end of mitosis to the end of G_1 . (B) Fluorescence microscopy of a single mammalian cell expressing these two proteins reveals alternating red and green fluorescence as the cell progresses through the cell cycle. These images were obtained every hour over a 30-hour period. The cell was in late mitosis and cytokinesis at the 16- and 17-hour time points, and only one of the daughter cells is shown in subsequent images. This method is called Fucci (fluorescent ubiquitylation-based cell-cycle indicator). (From A. Sakaue-Sawano et al., Cell 132:487–498, 2008. With permission from Elsevier.)

mitosis (the *mitotic index*), we can estimate the duration of M phase. The timing of cell-cycle phases can also be measured in living cells using fluorescently labeled proteins that appear and disappear at specific stages (Figure 17–6).

Another way to assess the stage that a cell has reached in the cell cycle is by measuring its DNA content, which doubles during S phase. This approach is greatly facilitated by the use of fluorescent DNA-binding dyes and a *flow cytometer*, which allows the rapid and automatic analysis of large numbers of cells (**Figure 17–7**). We can use flow cytometry to determine the fraction of cells in G_1 , S, and $G_2 + M$ phases by measuring DNA content in a cell population.

Summary

Cell division usually begins with duplication of the cell's contents, followed by distribution of those contents into two daughter cells. Chromosome duplication occurs during S phase of the cell cycle, whereas most other cell components are duplicated continually throughout the cycle. During M phase, the replicated chromosomes are segregated into individual nuclei (mitosis), and the cell then splits in two (cytokinesis). S phase and M phase are usually separated by gap phases called G_1 and G_2 , when various intracellular and extracellular signals regulate cell-cycle progression. Cell-cycle organization and control have been highly conserved during evolution, and studies in a wide range of organisms have led to a unified view of eukaryotic cell-cycle control.

THE CELL-CYCLE CONTROL SYSTEM

For many years, cell biologists watched the puppet show of DNA synthesis, mitosis, and cytokinesis but had no idea of what lay behind the curtain controlling these events. It was not even clear whether there was a separate control system or whether the processes of DNA synthesis, mitosis, and cytokinesis somehow controlled themselves. A major breakthrough came in the late 1980s with the identification of the key proteins of the control system, along with the realization that they are distinct from the proteins that perform the processes of DNA replication, chromosome segregation, and so on.

In this section, we first consider the basic principles upon which the cell-cycle control system operates. We then discuss the protein components of the system and how they work together to time and coordinate the events of the cell cycle.

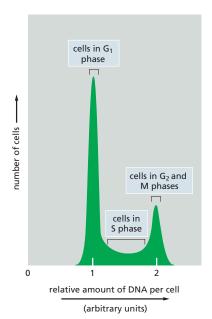

Figure 17-7 Analysis of DNA content with a flow cytometer. This graph shows typical results obtained for a proliferating cell population when the DNA content of its individual cells is determined in a flow cytometer. (A flow cytometer, also called a fluorescence-activated cell sorter. or FACS, can also be used to sort cells according to their fluorescence.) The cells analyzed here were stained with a dye that becomes fluorescent when it binds to DNA, so that the amount of fluorescence is directly proportional to the amount of DNA in each cell. The cells fall into three categories: those that have an unreplicated complement of DNA and are therefore in G₁, those that have a fully replicated complement of DNA (twice the G₁ DNA content) and are in G2 or M phase, and those that have an intermediate amount of DNA and are in S phase. The distribution of cells indicates that there are greater numbers of cells in G₁ than in G₂ + M phase, showing that G₁ is longer than G₂ + M in this population.

MBOC7_ptr_ch17_1027-1088.indd 1031 02/12/21 2:14 PM

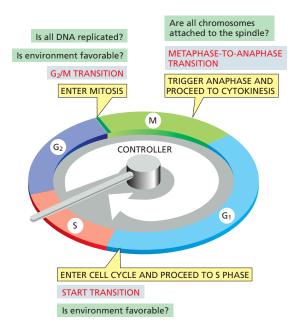

Figure 17–8 The control of the cell cycle. A cell-cycle control system triggers the essential processes of the cycle—such as DNA replication, mitosis, and cytokinesis. The control system is represented here as a central arm—the controller—that rotates clockwise, triggering essential processes when it reaches specific transitions on the outer dial (yellow boxes). Information about the completion of cell-cycle events, as well as signals from the environment, can cause the control system to arrest the cycle at these transitions.

The Cell-Cycle Control System Triggers the Major Events of the Cell Cycle

The **cell-cycle control system** operates much like a timer that triggers the events of the cell cycle in a set sequence (**Figure 17-8**). In its simplest form—as seen in the stripped-down cell cycles of early animal embryos, for example—the control system is rigidly programmed to provide a fixed amount of time for the completion of each cell-cycle event. The control system in these early embryonic divisions is independent of the events it controls, so that its timing mechanisms continue to operate even if those events fail. In most cells, however, the control system does respond to information received back from the processes it controls. If some malfunction prevents the successful completion of DNA synthesis, for example, signals are sent to the control system to delay progression to M phase. Such delays provide time for the machinery to be repaired and also prevent the disaster that might result if the cycle progressed prematurely to the next stage—and segregated incompletely replicated chromosomes, for example.

The cell-cycle control system is based on a connected series of biochemical switches, each of which initiates a specific cell-cycle event. This system of switches possesses many important features that increase the accuracy and reliability of cell-cycle progression. First, the switches are generally *binary* (on/off) and launch events in a complete, irreversible fashion. It would clearly be disastrous, for example, if events such as chromosome condensation or nuclear-envelope breakdown were only partially begun but not completed. Second, the cell-cycle control system is remarkably robust and reliable, allowing the system to operate effectively under a variety of conditions and even if some components fail. Finally, the control system is highly adaptable and can be modified to suit specific cell types or to respond to specific intracellular or extracellular signals.

In most eukaryotic cells, the cell-cycle control system governs cell-cycle progression at three major regulatory transitions (see Figure 17–8). The first is Start (or the restriction point) in late G_1 , when the cell commits to cell-cycle entry and chromosome duplication. The second is the G_2/M transition, when the control system triggers the early mitotic events that lead to chromosome alignment on the mitotic spindle in metaphase. The third is the **metaphase-to-anaphase transition**, when the control system stimulates sister-chromatid separation, leading to the completion of mitosis and cytokinesis. The control system blocks progression

MBOC7_ptr_ch17_1027-1088.indd 1032 02/12/21 2:14 PM

through each of these transitions if it detects problems inside or outside the cell. If the control system senses problems in the completion of DNA replication, for example, it will hold the cell at the G_2/M transition until those problems are solved. Similarly, if extracellular conditions are not appropriate for cell proliferation, the control system blocks progression through Start, thereby preventing cell division until conditions become favorable.

The Cell-Cycle Control System Depends on Cyclically Activated Cyclin-dependent Protein Kinases

Central components of the cell-cycle control system are members of a family of protein kinases known as **cyclin-dependent kinases** (Cdks). The activities of these kinases rise and fall as the cell progresses through the cycle, leading to cyclical changes in the phosphorylation of intracellular proteins that initiate or regulate the major events of the cell cycle. An increase in Cdk activity at the G_2/M transition, for example, increases the phosphorylation of proteins that control chromosome condensation, nuclear-envelope breakdown, spindle assembly, and other events that occur in early mitosis.

Cyclical changes in Cdk activity are controlled by a complex array of other proteins. The most important of these Cdk regulators are proteins known as **cyclins**. Cdks, as their name implies, depend on cyclins for their activity: unless they are bound tightly to a cyclin, they have no protein kinase activity (**Figure 17–9**). Cyclins were originally named because they undergo a cycle of synthesis and degradation in each cell cycle. The levels of the Cdk proteins, by contrast, are constant. Cyclical changes in cyclin protein levels result in the cyclic assembly and activation of **cyclin-Cdk complexes** at specific stages of the cell cycle.

There are three major classes of cyclins, each defined by the stage of the cell cycle at which they bind Cdks and carry out their functions (Figure 17–10):

- 1. G_1/S -cyclins activate Cdks in late G_1 and thereby help trigger progression through Start, resulting in a commitment to cell-cycle entry. Their levels fall in S phase.
- S-cyclins bind Cdks soon after progression through Start and help stimulate chromosome duplication. S-cyclin levels remain elevated until mitosis, and these cyclins also contribute to the control of some early mitotic events.
- 3. M-cyclins activate Cdks that stimulate entry into mitosis at the G_2/M transition. M-cyclin levels fall in mid-mitosis.

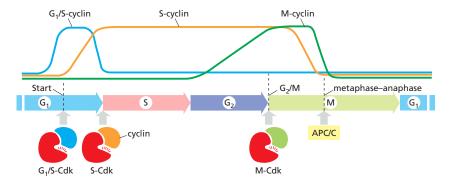

Figure 17–10 Cyclin–Cdk complexes of the cell-cycle control system. The concentrations of the three major cyclin types oscillate during the cell cycle, while the concentrations of Cdks (not shown) exceed cyclin amounts and do not change. In late G_1 , rising G_1/S -cyclin levels lead to the formation of G_1/S -Cdk complexes that trigger progression through the Start transition. S-Cdk complexes form later in G_1 and trigger DNA replication, as well as some early mitotic events. M-Cdk complexes form during G_2 but are held in an inactive state; they are activated at the end of G_2 and trigger entry into mitosis at the G_2/M transition. A separate regulatory protein complex, the APC/C, initiates the metaphase-to-anaphase transition, as we discuss later.

Figure 17–9 Two key components of the cell-cycle control system. When cyclin forms a complex with Cdk, the protein kinase is activated to trigger specific cell-cycle events. Without cyclin, Cdk is inactive

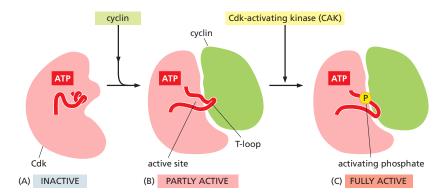

Figure 17–11 The structural basis of Cdk activation. These drawings are based on three-dimensional structures of human Cdk2 and cyclin A, as determined by x-ray crystallography. The location of the bound ATP is indicated. The enzyme is shown in three states. (A) In the inactive state, without cyclin bound, the active site is blocked by a region of the protein called the T-loop (red). (B) The binding of cyclin causes the T-loop to move out of the active site, resulting in partial activation of Cdk2. (C) Phosphorylation of Cdk2 (by CAK) at a threonine residue in the T-loop further activates the enzyme by changing the shape of the T-loop, improving the ability of the enzyme to bind its protein substrates (Movie 17.1).

In most cells, a fourth class of cyclins, the G_1 -cyclins, helps govern the activities of the G_1 /S-cyclins, thereby controlling progression through Start in late G_1 . Extracellular signals that stimulate cell proliferation act in part by increasing the production of G_1 -cyclins, as we discuss later in the chapter.

In yeast cells, a single Cdk protein binds all classes of cyclins and triggers different cell-cycle events by changing cyclin partners at different stages of the cycle. In vertebrate cells, by contrast, there are four Cdks. Two interact with G_1 -cyclins, one with G_1 /S- and S-cyclins, and one with S- and M-cyclins. In this chapter, we simply refer to the different cyclin–Cdk complexes as G_1 -Cdk, G_1 /S-Cdk, S-Cdk, and M-Cdk. Table 17–1 lists the names of the individual Cdks and cyclins.

Cyclin binding alone does not fully activate the associated Cdk. Complete activation requires a separate kinase, the Cdk-activating kinase (CAK), which phosphorylates an amino acid near the entrance of the Cdk active site. This causes a conformational change that greatly increases the activity of the Cdk subunit (Figure 17–11). CAK activity is constant through the cell cycle, and this modification therefore occurs constitutively throughout the cycle.

At certain cell-cycle stages, phosphorylation at a pair of amino acids near the kinase active site, by a protein kinase known as **Weel**, inhibits Cdk activity. Dephosphorylation of these sites by a phosphatase known as **Cdc25** increases Cdk activity (**Figure 17–12**). This regulatory mechanism is particularly important

TABLE 17-1 The Major Cyclins and Cdks of Vertebrates and Budding Yeast						
	Vertebrates		Budding yeast

G ₁ -Cdk	Cyclin D*	Cdk4, Cdk6	Cln3	Cdk1**		
G ₁ /S-Cdk	Cyclin E	Cdk2	Cln1, 2	Cdk1		
S-Cdk	Cyclin A	Cdk2, Cdk1**	Clb5, 6	Cdk1		
M-Cdk	Cyclin B	Cdk1	Clb1, 2, 3, 4	Cdk1		

^{*}There are three D cyclins in mammals (cyclins D1, D2, and D3).

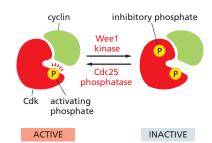

Figure 17–12 The regulation of Cdk activity by inhibitory phosphorylation. The active cyclin–Cdk complex is turned off when the kinase Wee1 phosphorylates two closely spaced sites above the active site. Removal of these phosphates by the phosphatase Cdc25 activates the cyclin–Cdk complex. For simplicity, only one inhibitory phosphate is shown. CAK adds the activating phosphate, as shown in Figure 17–11.

^{**}The original name of Cdk1 was Cdc2 in vertebrates and fission yeast and Cdc28 in budding yeast.

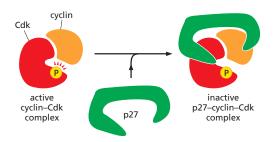

Figure 17–13 The inhibition of a cyclin–Cdk complex by a CKI. This drawing is based on the three-dimensional structure of the human cyclin A–Cdk2 complex bound to the CKI p27, as determined by x-ray crystallography. The p27 binds to both the cyclin and Cdk in the complex, distorting the active site of the Cdk. It also inserts into the ATP-binding site, further inhibiting the enzyme activity.

for generating the rapid activation of M-Cdk activity at the onset of mitosis, as we discuss later.

The activities of G_1/S - and S-Cdks early in the cell cycle are governed in part by **Cdk inhibitor proteins (CKIs)**. These small proteins wrap around the cyclin-Cdk complex, promoting a rearrangement in the Cdk active site that renders it inactive (**Figure 17–13**).

Protein Phosphatases Reverse the Effects of Cdks

As we learned in Chapters 3 and 15, protein phosphorylation is not controlled simply by the protein kinases that attach phosphate but also by the protein phosphatases that remove it. Phosphatases that reverse the effects of Cdks and other kinases are therefore key players in the cell-cycle control system.

We can think about the level of protein phosphorylation like the level of water in a sink, which depends on the rate of water flow in through the tap (protein kinase activity) and the rate of flow out of the drain (phosphatase activity). The fastest way to raise the water level is to plug the drain at the same time as you increase the flow through the tap. Indeed, we will see that the activity of phosphatases tends to decline when Cdk activity increases, resulting in a more robust increase in the protein phosphorylation state.

Protein phosphatase 2A (PP2A) is a particularly critical regulator of Cdk substrates during the cell cycle. This three-subunit enzyme comes in multiple forms, depending on the identity of a subunit called the regulatory subunit, or B subunit (**Figure 17–14**). The B subunit influences the substrate selectivity, localization, and regulation of the enzyme. Two B subunits, B55 and B56, are the most important.

The cell-cycle regulation of PP2A associated with the B55 subunit is particularly well understood and illustrates how opposing Cdk and phosphatase activities are coordinated during the cell cycle. PP2A-B55 activity is high during interphase but inhibited during early mitosis when M-Cdk activity rises. The underlying mechanism is conceptually simple: M-Cdk turns off PP2A-B55 via the phosphorylation of an intermediary protein kinase called *Greatwall* (Figure 17–15). As a result, the kinase activity of M-Cdk goes relatively unopposed in early mitosis, contributing to the rapid phosphorylation of M-Cdk substrates. When anaphase is initiated and M-Cdk activity declines after cyclin destruction, the system works in reverse: PP2A-B55 is reactivated to promote rapid dephosphorylation of Cdk substrates during anaphase and telophase.

Hundreds of Cdk Substrates Are Phosphorylated in a Defined Order

Cdks catalyze the phosphorylation of hundreds of different proteins in the cell. Clearly, however, these proteins are not all phosphorylated at the same time: proteins that trigger DNA replication in early S phase, for example, are phosphorylated much earlier than proteins that promote spindle assembly in early mitosis. How is the correct ordering of substrate phosphorylation achieved?

The answer is only partly understood. First, it is clear that cyclins do not simply activate the Cdk partner but also direct it to specific target proteins. The surface of each cyclin contains a binding site for short amino acid sequences that

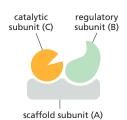

Figure 17–14 Structure of the phosphatase PP2A. PP2A is composed of three subunits. The two core subunits include the small catalytic subunit and a large structural subunit called the scaffold. This dimer associates with one of several different regulatory subunits, which are positioned next to the active site of the catalytic subunit and can influence its interaction with substrates.

MBOC7_ptr_ch17_1027-1088.indd 1035

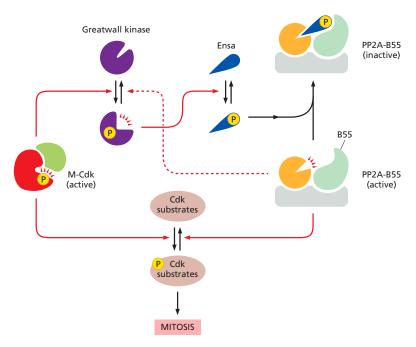

Figure 17–15 Control of PP2A-B55 activity in mitosis. Prior to mitosis, PP2A-B55 is active, helping to reduce the phosphorylation of M-Cdk targets. When M-Cdk activity begins to rise at the beginning of mitosis, it phosphorylates and thereby activates another protein kinase called Greatwall. This kinase in turn phosphorylates a small protein called Ensa, which binds tightly to PP2A-B55 and inhibits phosphatase activity. M-Cdk thereby inactivates its opponent. As an added twist, PP2A-B55 can dephosphorylate Greatwall (dashed line), thereby inhibiting its own inhibitor—a form of positive feedback. We discuss the implications of this feedback in a later section.

are found on certain Cdk substrates. As a result, each cyclin–Cdk complex interacts more tightly with specific targets: S-Cdk, for example, has a high affinity for DNA replication proteins and therefore phosphorylates those proteins at a high rate while essentially ignoring low-affinity mitotic targets. It is likely, therefore, that the ordering of substrate phosphorylation depends in part on the activation timing of each cyclin–Cdk complex.

Cyclin specificity is not the whole story, however. Even the same cyclin–Cdk complex can induce different effects at different times in the cycle, indicating that a single enzyme phosphorylates different targets in a specific order. This ordering is likely to result from differences in the affinities of the interactions between the Cdk active site and the substrate: high-affinity substrates are phosphorylated earlier. The total amount of enzyme activity is also important: M-Cdk activity, for example, continues to rise as the cell progresses through mitosis, and higher activity might be required for the phosphorylation of certain low-affinity targets that are phosphorylated later in mitosis.

Finally, we must not forget that the timing of protein phosphorylation also depends on the opposing phosphatases, each of which will have differing activation times, localization, and affinities for specific targets. With all these factors at play, it is easy to see that a combination of mechanisms is likely to generate the perfectly timed choreography of protein phosphorylation during the cell cycle. Disentangling these mechanisms is a major goal of current research.

Positive Feedback Generates the Switchlike Behavior of Cell-Cycle Transitions

As mentioned earlier, a key feature of the cell-cycle control system is its ability to generate switchlike, binary decisions: progression through each major cell-cycle transition is a complete, irreversible commitment. The cell-cycle control system

MBOC7_ptr_ch17_1027-1088.indd 1036 02/12/21 2:14 PM

achieves this behavior through the use of positive feedback. As we discussed in Chapters 8 and 15, positive feedback is used frequently in cell regulation to generate robust, all-or-none regulatory effects, and this mechanism is well suited for generating the switchlike behavior that is so critical in cell-cycle progression.

The activation of M-Cdk at the G_2/M transition provides the best-understood example of positive feedback in cell-cycle control. M-Cdk activation begins with the accumulation of M-cyclin during G_2 , which leads to a corresponding accumulation of M-Cdk complexes as the cell approaches mitosis. Although the Cdk subunit in these complexes is phosphorylated at an activating site by the Cdk-activating kinase (CAK), as discussed earlier, the protein kinase Weel holds it in an inactive state by inhibitory phosphorylation at two neighboring sites (see Figure 17–12). Thus, by the time the cell reaches the end of G_2 , it contains an abundant stockpile of M-Cdk that is primed and ready to act but is suppressed by phosphates that block the kinase active site.

What, then, causes the activation of the M-Cdk stockpile? The crucial event is activation of the protein phosphatase Cdc25, which removes the inhibitory phosphates that restrain M-Cdk (**Figure 17–16**). At the same time, the inhibitory activity of the kinase Wee1 is suppressed, further ensuring that M-Cdk activity increases. Notably, Cdc25 is activated, at least in part, by its target, M-Cdk. M-Cdk also inhibits the inhibitory kinase Wee1. The ability of M-Cdk to activate its own activator (Cdc25) and inhibit its own inhibitor (Wee1) results in positive feedback (see Figure 17–16). The result is that all M-Cdk complexes in the cell are rapidly and irreversibly activated, leading to rapid phosphorylation of the many proteins that drive the early events of mitosis.

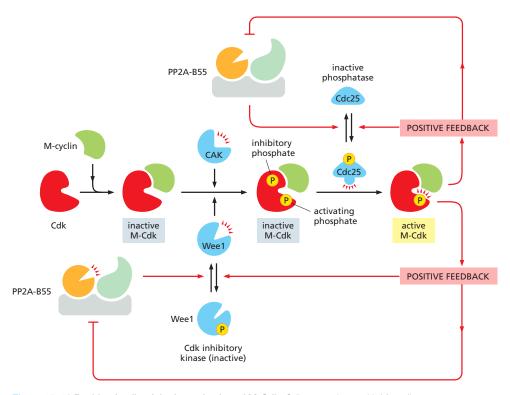

Figure 17–16 Positive feedback in the activation of M-Cdk. Cdk1 associates with M-cyclin as the levels of M-cyclin gradually rise. The resulting M-Cdk complex is phosphorylated on an activating site by Cdk-activating kinase (CAK) and on a pair of inhibitory sites by Wee1 kinase (for simplicity, only one inhibitory phosphate is shown). The resulting inactive M-Cdk complex is then activated at the end of G_2 by the phosphatase Cdc25. Cdc25 is further stimulated by active M-Cdk, resulting in positive feedback. This feedback is enhanced by the ability of M-Cdk to inhibit Wee1. The phosphorylation of both Cdc25 and Wee1 is reversed by the phosphatase PP2A-B55. As described earlier, this phosphatase is inactivated by M-Cdk (see Figure 17–15), providing another mechanism by which M-Cdk activates itself.

MBOC7_ptr_ch17_1027-1088.indd 1037 02/12/21 2:14 PM

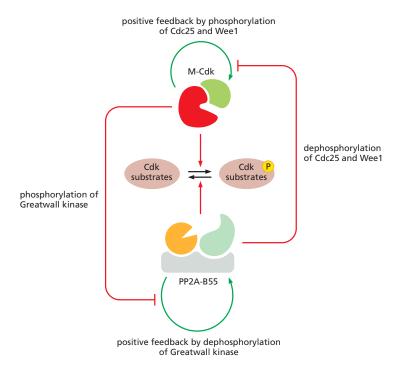

Figure 17–17 The mitotic regulatory circuit. This diagram summarizes the interactions described in Figures 17–15 and 17–16. M-Cdk and PP2A-B55 are each activated by positive feedback (green). They also inhibit each other (red). The result is an integrated system of multiple positive feedback loops. Much remains to be learned about other mechanisms and molecules that feed into this system in early and late mitosis.

As in all positive feedback systems, there must be some external trigger mechanism that first unleashes the feedback loop, in this case by causing a small increase in Cdc25 activity. The mitotic trigger is not well understood, but a likely possibility is that the S-Cdks that are active in G_2 and early prophase help initiate Cdc25 activation.

As we discussed earlier, increased protein phosphorylation in early mitosis also depends on the ability of M-Cdk to inhibit the phosphatase PP2A-B55 through the protein kinase Greatwall (see Figure 17–15). Notably, PP2A-B55 can fight back by dephosphorylating and thereby inhibiting its inhibitor, Greatwall. This *mutual antagonism* is essentially a form of positive feedback: when a small amount of Greatwall activation is triggered by increasing M-Cdk, the resulting inhibition of PP2A-B55 increases Greatwall phosphorylation and activation, and the system switches abruptly to a state of low PP2A-B55 activity.

A fascinating feature of this system is that PP2A-B55 is also an inhibitor of M-Cdk activation, because it dephosphorylates Cdc25 (causing its inactivation) and Wee1 (causing its activation) (see Figure 17–16). M-Cdk and PP2A-B55 are thus mutual antagonists, producing yet another layer of positive feedback. The overall result is a remarkable regulatory circuit in which two positive feedback loops are themselves linked by positive feedback (Figure 17–17). Highly integrated feedback systems of this sort generate a robust biochemical switch that can operate even when some components fail.

Dephosphorylation of M-Cdk substrates is crucial for the completion of mitosis and cytokinesis. The positive feedback loops that promote phosphorylation in early mitosis can be flipped to the alternate dephosphorylation state in anaphase, when M-Cdk is abruptly inactivated by destruction of cyclins. We discuss the mechanisms of cyclin destruction next.

The Anaphase-promoting Complex/Cyclosome (APC/C) Triggers the Metaphase-to-Anaphase Transition

Whereas activation of specific cyclin–Cdk complexes drives progression through the Start and G_2/M transitions (see Figure 17–10), progression through the metaphase-to-anaphase transition is triggered not by protein phosphorylation but by protein destruction, leading to the final stages of cell division.

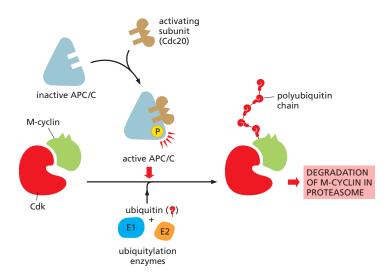

Figure 17–18 The control of proteolysis by the APC/C. The APC/C is activated in metaphase by association with Cdc20, which recognizes specific amino acid sequences on M-cyclin and other target proteins. With the help of two additional proteins called E1 and E2 (see Chapter 3), the APC/C assembles polyubiquitin chains on the target protein. The polyubiquitylated target is then recognized and degraded in a proteasome.

The key regulator of the metaphase-to-anaphase transition is the **anaphase-promoting complex**, **or cyclosome (APC/C)**, a member of the ubiquitin ligase family of enzymes. As discussed in Chapter 3, ubiquitin ligases are used in numerous cell processes to stimulate the proteolytic destruction of specific regulatory proteins. They polyubiquitylate specific target proteins, resulting in their destruction in proteasomes. Other ubiquitin ligases mark proteins for purposes other than destruction (discussed in Chapter 3).

The APC/C catalyzes the ubiquitylation and destruction of two major proteins. The first is *securin*; its destruction in metaphase activates a protease that separates the sister-chromatid pairs and unleashes anaphase, as described later. The S- and M-cyclins are the second major targets of the APC/C. Destroying these cyclins inactivates most Cdks in the cell (see Figure 17–10). As a result, the many proteins phosphorylated by Cdks from S phase to early mitosis are dephosphorylated by PP2A and other phosphatases in the anaphase cell. This dephosphorylation of Cdk targets is required for the completion of M phase, including the final steps in mitosis and then cytokinesis.

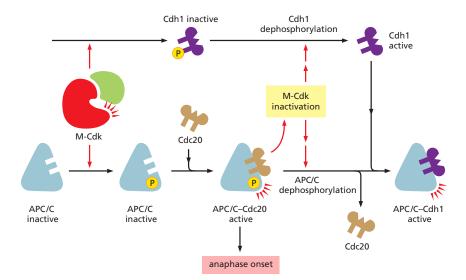

APC/C activity increases in mid-mitosis and remains high through G_1 . Activation depends primarily on association with one of two activating subunits, **Cdc20** or **Cdh1**. These subunits are essential for APC/C activity for two reasons. First, their binding causes a conformational change that enhances enzyme activity. Second, they provide the main binding site for the enzyme's protein substrates. Activators interact with short amino acid sequences on APC/C substrates, holding them in place while the APC/C builds polyubiquitin chains on the target (**Figure 17–18**).

The two APC/C activator subunits interact sequentially with the APC/C. Cdc20 acts first, in metaphase, to trigger the destruction of securin and cyclins, resulting in chromosome segregation in anaphase. Cdc20 is then replaced by Cdh1, which maintains APC/C activity through late mitosis and G_1 , ensuring that cyclins and other proteins are kept at low levels until the following cell cycle.

Sequential activation of the APC/C by Cdc20 and Cdh1 is based on the opposing effects of M-Cdk: phosphorylation activates APC/C-Cdc20 and inhibits APC/C-Cdh1. As a result, APC/C-Cdc20 is turned on when M-Cdk levels rise in early mitosis, whereas APC/C-Cdh1 activation occurs only after M-Cdk activity declines due to cyclin destruction in anaphase (Figure 17–19).

The cell-cycle control system also employs another ubiquitin ligase called SCF (see Figure 3–67). Its major role in the cell cycle is to ubiquitylate certain CKI proteins in late G_1 , thereby helping to control the activation of S-Cdks and DNA replication. SCF is also responsible for the destruction of G_1 /S-cyclins in early S phase. SCF activity depends on substrate-binding subunits called F-box proteins. Unlike APC/C activity, however, SCF activity is constant during the cell

MBOC7_ptr_ch17_1027-1088.indd 1039 02/12/21 2:14 PM

cycle. Ubiquitylation by SCF is controlled instead by changes in the phosphorylation state of its target proteins, as F-box subunits recognize only specifically phosphorylated proteins.

The G₁ Phase Is a Stable State of Cdk Inactivity

A key regulatory event in late M phase is the inactivation of Cdks, which resets the cell-cycle control system as the cell prepares to enter a new cell cycle. In most cells, this state of Cdk inactivity generates a stable G_1 gap phase, during which the cell grows and monitors its environment before committing to a new cell cycle.

Cells employ several mechanisms to suppress Cdk activity after mitosis. One mechanism, as we have just seen, depends on the late mitotic activation of APC/C–Cdh1, which ensures that cyclin destruction continues throughout G_1 . A second mechanism for Cdk suppression depends on the increased production of CKIs, the Cdk inhibitor proteins discussed earlier. Budding yeast cells, in which this mechanism is best understood, contain a CKI protein called Sic1, which binds to and inactivates M-Cdk in late mitosis and G_1 . Like Cdh1, Sic1 is inhibited by M-Cdk, which phosphorylates Sic1 during mitosis and thereby promotes its ubiquitylation by SCF. Thus, Sic1 and M-Cdk, like Cdh1 and M-Cdk, inhibit each other, resulting in more examples of positive feedback. As a result, the decline in M-Cdk activity that occurs in late mitosis causes the Sic1 protein to accumulate, and this CKI helps keep M-Cdk activity low after mitosis. A CKI protein called p27 may serve similar functions in animal cells.

In many cells, decreased transcription of M-cyclin genes helps reduce M-Cdk activity in late mitosis. In budding yeast, for example, M-Cdk promotes the expression of these genes, resulting in another positive feedback loop. This loop is turned off as cells exit from mitosis: the inactivation of M-Cdk by Cdh1 and Sic1 leads to decreased M-cyclin gene transcription and thus decreased M-cyclin synthesis. Gene regulatory proteins that promote the expression of G_1/S - and S-cyclins are also inhibited during G_1 .

Thus, APC/C-Cdh1 activity, CKI accumulation, and decreased cyclin gene expression act together to ensure that G_1 phase is a time when most Cdk activity is suppressed. As in many other aspects of cell-cycle control, the use of multiple regulatory mechanisms allows the system to operate with reasonable efficiency even if one mechanism is defective. So how does the cell escape from this stable G_1 state to initiate a new cell cycle? The answer is that G_1 /S-Cdk activity, which rises in late G_1 , releases all of the braking mechanisms that suppress Cdk activity, as we describe later in this chapter when we discuss the control of cell proliferation.

Figure 17-19 Sequential activation of APC/C by Cdc20 and Cdh1. M-Cdk phosphorylates the APC/C, thereby enhancing its association with Cdc20. Thus, M-Cdk not only triggers the early mitotic events leading up to metaphase, but it also sets the stage for progression into anaphase and the destruction of cyclins. This creates a negative feedback loop: M-Cdk sets in motion a regulatory process that leads to its own inactivation. More negative feedback then follows: APC/C-Cdc20 also turns itself off by inactivating Cdks, which allows APC/C dephosphorylation. APC/C-Cdc20 is thereby inactivated in anaphase. The APC/C remains active through mitosis and beyond because the second activator, Cdh1, is regulated in a completely different fashion: Cdh1 phosphorylation by Cdks inhibits its binding to the APC/C. keeping it inactive from late G₁ to anaphase. When cyclins are destroyed in anaphase, Cdk inactivation allows Cdh1 dephosphorylation, which activates Cdh1 and thereby stimulates formation of APC/C-Cdh1. APC/C-Cdh1 remains active until Cdh1 is phosphorylated and thereby inactivated by G₁/S- and S-Cdks at the beginning of the next cell cycle.

MBOC7_ptr_ch17_1027-1088.indd 1040 02/12/21 2:14 PM

The Cell-Cycle Control System Functions as a Linked Series of Biochemical Switches

Table 17–2 summarizes some of the major components of the cell-cycle control system. These proteins are functionally linked to form a robust network, which operates essentially autonomously to activate a series of biochemical switches, each of which triggers specific cell-cycle events.

When conditions for cell proliferation are right, various external and internal signals stimulate the activation of G_1 -Cdk, which in turn stimulates the expression of genes encoding G_1/S - and S-cyclins (Figure 17–20). The resulting activation of G_1/S -Cdk then drives progression through the Start transition, in part by releasing many of the inhibitory mechanisms, discussed above, that restrain Cdk activity in G_1 . By mechanisms we discuss later, G_1/S -Cdks also unleash a wave of S-Cdk

General name	Functions and comments	
	Protein kinases and protein phosphatases that modify Cdks	
Cdk-activating kinase (CAK)	Phosphorylates an activating site in Cdks	
Wee1 kinase	Phosphorylates inhibitory sites in Cdks; primarily involved in suppressing Cdk1 activity before mitosis; animals also contain a related kinase, Myt1, with similar functions	
Cdc25 phosphatase	Removes inhibitory phosphates from Cdks; three family members (Cdc25A, B, C) in mammals; primarily involved in controlling Cdk1 activation at the onset of mitosis	
Protein phosph	atases that dephosphorylate substrates of Cdks and other cell-cycle kinases	
PP2A-B55	One of two major forms of PP2A involved in Cdk substrate regulation	
PP2A-B56	Second of two major forms of PP2A involved in Cdk substrate regulation	
PP1	Second major class of phosphatase involved in Cdk substrate regulation	
	Cdk inhibitor proteins (CKIs)	
Sic1 (budding yeast)	Suppresses Cdk1 activity in G_1 ; phosphorylation by Cdk1 at the end of G_1 triggers its destruction	
p27 (mammals)	Suppresses G_1/S -Cdk and S-Cdk activities in G_1 ; helps cells withdraw from cell cycle when they terminally differentiate; phosphorylation by Cdk2 triggers its ubiquitylation by SCF	
p21 (mammals)	Suppresses G ₁ /S-Cdk and S-Cdk activities after DNA damage	
p16 (mammals)	Suppresses G ₁ -Cdk activity in G ₁ ; frequently inactivated in cancer	
	Ubiquitin ligases and their activators	
APC/C	Catalyzes ubiquitylation of regulatory proteins involved primarily in exit from mitosis, including securin and S-cyclins and M-cyclins; regulated by association with activating subunits Cdc20 or Cdh1	
Cdc20	APC/C-activating subunit in all cells; triggers initial activation of APC/C at metaphase-to-anaphase transition; stimulated by M-Cdk activity	
Cdh1	APC/C-activating subunit that maintains APC/C activity after anaphase and throughout G inhibited by Cdk activity	
SCF	Employs various substrate-binding (F-box) subunits to catalyze ubiquitylation of regulatory proteins involved in G ₁ control, including some CKIs (Sic1 in budding yeast, p27 in mammals); phosphorylation of target protein usually required for this activity	
CRL4-Cdt2	Related to SCF: catalyzes ubiquitylation of the replication regulator Cdt1 during S phase, thereby suppressing further loading of Mcm helicase at origin; target recognition depends on association with proteins at the replication fork	

MBOC7_ptr_ch17_1027-1088.indd 1041 02/12/21 2:14 PM

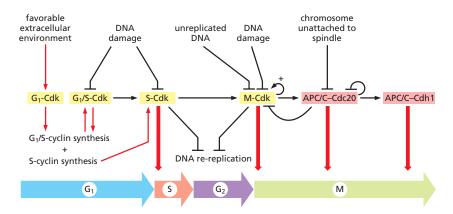

Figure 17–20 Sequential activation of Cdks during the cell cycle. The core of the cell-cycle control system consists of a series of cyclin–Cdk complexes (yellow). The activity of each complex is also influenced by various inhibitory mechanisms, which provide information about the extracellular environment, DNA damage, and spindle assembly (top). We will discuss the mechanisms underlying these inhibitory effects later in this chapter.

activity, which initiates chromosome duplication in S phase and also contributes to M-Cdk activation and some early events of mitosis. M-Cdk then triggers progression through the G_2/M transition and the events of early mitosis, leading to the alignment of sister-chromatid pairs on the mitotic spindle. Finally, M-Cdk also activates APC/C-Cdc20, thereby triggering the destruction of securin and cyclins—leading to sister-chromatid segregation and late mitotic events. Cdk inactivation also leads to activation of APC/C-Cdh1 and other mechanisms that suppress Cdk activity, resulting in a stable G_1 phase. We are now ready to discuss these cell-cycle stages in more detail, starting with S phase.

Summary

The cell-cycle control system triggers the events of the cell cycle and ensures that they are properly timed and coordinated with each other. Central components of the control system are the cyclin-dependent protein kinases (Cdks), which depend on cyclin subunits for their activity. Oscillations in the activities of different cyclin-Cdk complexes control various cell-cycle events. Thus, activation of S-phase cyclin-Cdk complexes (S-Cdk) initiates S phase, whereas activation of M-phase cyclin-Cdk complexes (M-Cdk) triggers mitosis. The mechanisms that control the activities of cyclin-Cdk complexes include phosphorylation of the Cdk subunit and binding of Cdk inhibitor proteins (CKIs). Protein phosphatases, including PP2A, oppose the actions of Cdks and thereby help control Cdk substrate phosphorylation and thus cell-cycle progression. The cell-cycle control system also depends crucially on a ubiquitin ligase called the APC/C, which catalyzes the ubiquitylation and consequent destruction of cyclins and other regulatory proteins that control progression through late mitosis. Together, the many components of the cell-cycle control system are assembled into a complex regulatory system containing a linked series of biochemical switches that drive stepwise progression through the phases of the cell cycle.

S PHASE

The linear chromosomes of eukaryotic cells are vast and dynamic assemblies of DNA and protein, and their duplication is a complex process that takes up a major fraction of the cell cycle. Not only must the long DNA molecule of each chromosome be duplicated accurately—a remarkable feat in itself—but the chromatin proteins in each region of that DNA must also be reproduced, ensuring that the daughter cells inherit all features of chromosome structure.

MBOC7_ptr_ch17_1027-1088.indd 1042 02/12/21 2:14 PM

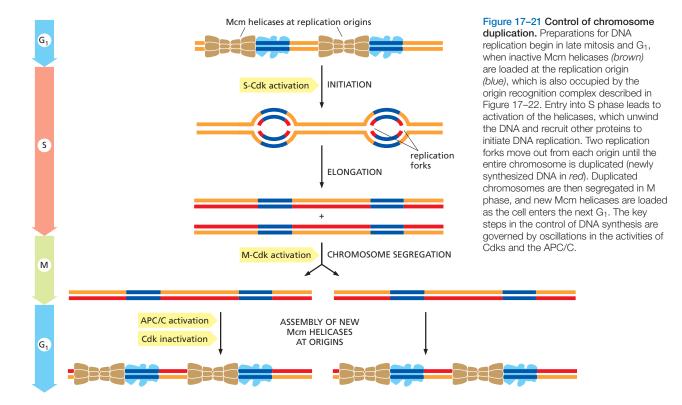

S PHASE 1043

The central event of chromosome duplication—DNA replication—poses two problems for the cell. First, replication must occur with extreme accuracy to minimize the risk of mutations in the next cell generation. Second, every nucleotide in the genome must be copied once, but only once, to prevent the damaging effects of gene amplification. In Chapter 5, we discuss the sophisticated protein machinery that performs DNA replication with astonishing speed and accuracy. In this section, we consider the elegant mechanisms by which the cell-cycle control system initiates the replication process and, at the same time, prevents it from happening more than once per cycle.

S-Cdk Initiates DNA Replication Once Per Cell Cycle

As we discussed in Chapter 5, DNA replication in eukaryotic cells begins at *origins* of *replication*, which are scattered at numerous locations in every chromosome. During S phase, DNA replication is initiated at these origins when a *DNA helicase* unwinds the double helix and DNA replication enzymes are loaded onto the two single-stranded templates. This leads to the *elongation* phase of replication, when the replication machinery moves outward from the origin at two *replication forks*.

To ensure that chromosome duplication occurs only once per cell cycle, the initiation of DNA replication is divided into two distinct steps that occur at different times in the cell cycle (Figure 17–21). The first step occurs only in late mitosis or early G_1 , when two inactive DNA helicases, called Mcm helicases, are loaded onto the DNA at the replication origin. This step is sometimes called *licensing* of replication origins because initiation of DNA synthesis is permitted only at origins that are preloaded with Mcm helicases. The second step occurs in S phase, when the Mcm helicases are activated, primarily by S-Cdks, resulting in DNA unwinding and the initiation of DNA synthesis. Once a replication origin has been activated in this way, it cannot be reused until new Mcm helicases are loaded at that origin, which can occur only when the cell reaches late mitosis or G_1 . As a result, origins can be activated only once per cell cycle, ensuring that the DNA is replicated once and only once.

MBOC7_ptr_ch17_1027-1088.indd 1043 02/12/21 2:14 PM

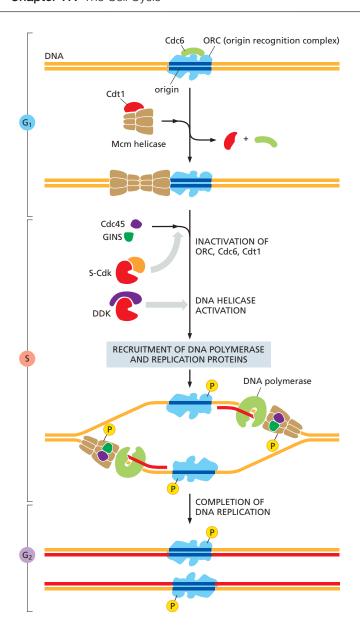

Figure 17-22 Control of the initiation of DNA replication. The replication origin is bound by the origin recognition complex (ORC) throughout the cell cycle, but ORC functions only in late mitosis and early G₁ when it associates with Cdc6, ORC-Cdc6 binds the Mcm helicase, which contains six closely related subunits arranged in a barrel shape. The helicase also associates with a protein called Cdt1. Using energy provided by ATP hydrolysis, the ORC and Cdc6 proteins load two copies of the Mcm helicase around the DNA next to the origin. At the onset of S phase, S-Cdk stimulates the assembly of several accessory proteins, including Cdc45 and GINS on each Mcm helicase. Another protein kinase, DDK, phosphorylates subunits of the Mcm helicase. The result is a large protein complex called the CMG helicase (for Cdc45-Mcm-GINS), which unwinds the DNA at the origin. DNA polymerase and other replication proteins arrive at the origin, and DNA replication begins. For clarity, this diagram does not show synthesis of the lagging strand (discussed in Chapter 5). The ORC is displaced by the replication machinery, but new ORCs bind to both replication origins after their replication. S-Cdk and other mechanisms also inactivate the loading factors ORC, Cdc6, and Cdt1, thereby preventing loading of new Mcm helicases at the origins until the end of mitosis.

Figure 17–22 illustrates some of the molecular details underlying the control of the two steps in the initiation of DNA replication. A key player is a large multiprotein complex called the **origin recognition complex (ORC)**, which binds to replication origins. In late mitosis and early G_1 , the proteins Cdc6 and Cdt1 collaborate with the ORC to load the Mcm helicases around the DNA next to the origin. The origin is now licensed for replication.

At the onset of S phase, S-Cdk triggers origin activation by phosphorylating specific accessory proteins, which bind and thereby activate the Mcm helicases at the origin. The two DNA strands are separated, and an active helicase is loaded around each strand. The DNA synthesis machinery is recruited to the origin and DNA synthesis begins. Another protein kinase called *DDK* is also activated in S phase and helps drive origin activation by phosphorylating specific subunits of the Mcm helicase.

At the same time as S-Cdk initiates DNA replication, it employs several mechanisms to prevent the loading of new Mcm helicases at origins. S-Cdk phosphorylates and thereby inhibits the ORC and Cdc6 proteins. Inactivation of

MBOC7_ptr_ch17_1027-1088.indd 1044 02/12/21 2:14 PM

S PHASE 1045

APC/C-Cdh1 in late G_1 also helps prevent Mcm helicase loading, as follows. In late mitosis and early G_1 , APC/C-Cdh1 triggers the destruction of a Cdt1 inhibitor called **geminin**, thereby allowing Cdt1 to be active. When APC/C-Cdh1 is turned off in late G_1 , geminin accumulates and inhibits the Cdt1 that is not associated with DNA. Also, the association of Cdt1 with a protein at active replication forks stimulates Cdt1 ubiquitylation by a ubiquitin ligase called CRL4-Cdt2, leading to Cdt1 degradation. In these various ways, Mcm complex loading is blocked from S phase to mid-mitosis. Thus, once an origin is used, it cannot be reloaded with a new Mcm complex in the same cell cycle.

How, then, is the cell-cycle control system reset to allow replication in the next cell cycle? In late mitosis, APC/C activation leads to the inactivation of Cdks and the destruction of geminin. ORC and Cdc6 are dephosphorylated and Cdt1 is activated, allowing Mcm helicase loading to prepare the cell for the next S phase.

Chromosome Duplication Requires Duplication of Chromatin Structure

The DNA of the chromosomes is complexed with a variety of protein components, including histones and various regulatory proteins involved in the control of gene expression (discussed in Chapter 4). Thus, duplication of a chromosome is not simply a matter of replicating the DNA at its core but also requires the duplication of these chromatin proteins and their proper assembly on the DNA.

The production of chromatin proteins increases during S phase to provide the raw materials needed to package the newly synthesized DNA. Most important, S-Cdks stimulate a large increase in the synthesis of the four histone subunits that form the histone octamers at the core of each nucleosome. These subunits are assembled into nucleosomes on the DNA by nucleosome assembly factors, which typically associate with the replication fork and distribute nucleosomes on both strands of the DNA as they emerge from the DNA synthesis machinery.

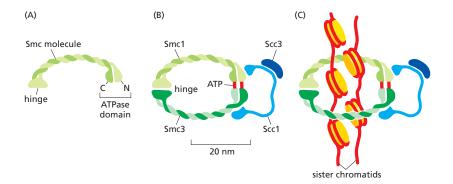

Chromatin packaging helps to control gene expression. In some parts of the chromosome, the chromatin is highly condensed and is called *heterochromatin*, whereas in other regions it has a more open structure called *euchromatin* (discussed in Chapter 4). These differences in chromatin structure depend on a variety of mechanisms, including modification of histone tails and the presence of non-histone proteins. Because these differences are important in gene regulation, it is crucial that chromatin structure, like the DNA within, is reproduced accurately during S phase. How chromatin structure is reproduced is not well understood, however. During DNA synthesis, histone-modifying enzymes and various non-histone proteins are probably deposited onto the two new DNA strands as they emerge from the replication fork, and these proteins are thought to reproduce the local chromatin structure of the parent chromosome (see Figure 4–44).

Cohesins Hold Sister Chromatids Together

At the end of S phase, each replicated chromosome consists of a pair of identical sister chromatids glued together along their length. This sister-chromatid cohesion sets the stage for a successful mitosis because it greatly facilitates the attachment of the two sister chromatids to opposite poles of the mitotic spindle. Imagine how difficult it would be to achieve bipolar spindle attachment if sister chromatids were allowed to drift apart after S phase. Indeed, defects in sister-chromatid cohesion—in yeast mutants, for example—lead inevitably to major errors in chromosome segregation.

Sister-chromatid cohesion depends on a large protein complex called **cohesin**, which forms a ring structure that surrounds the two chromatids (**Figure 17–23**). Cohesin is first loaded around unduplicated chromosomes before S phase, with assistance from a specialized loading complex. During S

MBOC7_ptr_ch17_1027-1088.indd 1045 02/12/21 2:14 PM

phase, by mechanisms that remain obscure, the cohesin ring is held in place during passage of the replication fork, such that the cohesin ring encircles the pair of new sister chromatids as they are being synthesized. Also during S phase, an acetyltransferase modifies a subpopulation of cohesins, locking them around the sisters to provide the stable sister-chromatid cohesion that is required to hold the sisters together until mitosis.

Sister-chromatid cohesion also results, at least in part, from the intertwining of sister DNA molecules that occurs when two replication forks meet during DNA synthesis. The enzyme topoisomerase II gradually disentangles the sister DNAs between S phase and early mitosis by cutting one DNA molecule, passing the other through the break, and then resealing the cut DNA (see Figure 5–23). Once the intertwining has been removed, sister-chromatid cohesion depends on cohesin. The loss of sister cohesion at the metaphase-to-anaphase transition therefore depends primarily on disruption of these complexes, as we describe later.

Summary

Duplication of the chromosomes in S phase involves the accurate replication of the entire DNA molecule in each chromosome, as well as the duplication of the chromatin proteins that associate with the DNA and govern various aspects of chromosome function. Chromosome duplication is triggered by the activation of S-Cdk, which activates proteins that unwind the DNA and initiate its replication at replication origins. Once a replication origin is activated, S-Cdk also inhibits proteins that are required to allow that origin to initiate DNA replication again. Thus, each origin is fired once and only once in each S phase and cannot be reused until the next cell cycle. During S phase, the duplicated chromosomes are linked together by cohesin, which provides the sister-chromatid cohesion that is required for alignment of the sister-chromatid pairs on the bipolar spindle in mitosis.

MITOSIS

Following the completion of S phase and transition through G_2 , the cell undergoes the dramatic changes of M phase. This begins with mitosis, during which the sister chromatids are separated and distributed (*segregated*) to a pair of identical daughter nuclei, each with its own copy of the genome. Mitosis is traditionally divided into five stages—*prophase*, *prometaphase*, *metaphase*, *anaphase*, and *telophase*—defined primarily on the basis of chromosome behavior as seen in a microscope. As mitosis is completed, the second major event of M phase—cytokinesis—divides the cell into two halves, each with an identical nucleus. Panel 17-1 summarizes the major events of M phase (Movie 17.2, Movie 17.3, Movie 17.4, and Movie 17.5).

From a regulatory point of view, mitosis can be divided into two major parts, each governed by distinct components of the cell-cycle control system. First, an increase in M-Cdk activity at the G_2/M transition triggers the events of early

Figure 17-23 Cohesin. Cohesin is a protein complex with four subunits. (A) Two subunits of cohesin are members of a large family of proteins called SMC proteins (for structural maintenance of chromosomes). These subunits, Smc1 and Smc3, are coiled-coil proteins whose N- and C-terminal regions fold together to form a globular ATPase domain. (B) The Scc1 subunit contains two globular domains separated by a long disordered region that binds an additional subunit called Scc3. Binding of the globular domains of Scc1 to the Smc1 and Smc3 subunits results in a ring structure that encircles the sister chromatids as shown in (C). ATP binding promotes the interaction of the ATPase domains as shown here, while ATP hydrolysis dissociates the ATPase domains. Loading and unloading of cohesin on DNA requires ATP hydrolysis and is expected to involve the opening of one of the three intersubunit gates, but this process remains poorly understood. During S phase, acetylation of the ATPase domain of Smc3 (not shown) prevents the opening of the ring, thereby locking the cohesin ring around the sister chromatids. In metaphase, proteolytic cleavage of sites in the disordered region of Scc1 triggers sister-chromatid separation, as discussed later.

mitosis (prophase, prometaphase, and metaphase). M-Cdk and other mitotic protein kinases phosphorylate a variety of proteins, leading to the assembly of the mitotic spindle and its attachment to the sister-chromatid pairs. The second major part of mitosis begins at the metaphase-to-anaphase transition, when the APC/C triggers the destruction of securin, liberating a protease that cleaves cohesin and thereby initiates separation of the sister chromatids. The APC/C also promotes the destruction of cyclins, which leads to Cdk inactivation and the dephosphorylation of Cdk targets, which is required for the events of late M phase, including the completion of anaphase, the disassembly of the mitotic spindle, and the division of the cell by cytokinesis.

M-Cdk and Other Protein Kinases Drive Entry into Mitosis

One of the most remarkable features of cell-cycle control is that a single protein kinase, M-Cdk, brings about so many of the diverse and complex cell rearrangements that occur in the early stages of mitosis. At a minimum, M-Cdk must induce the assembly of the mitotic spindle and ensure that each sister chromatid in a pair is attached to the opposite pole of the spindle. It also triggers *chromosome condensation*, the large-scale reorganization of the intertwined sister chromatids into compact, rodlike structures. In animal cells, M-Cdk also promotes the breakdown of the nuclear envelope and rearrangements of the actin cytoskeleton and the Golgi apparatus. Each of these processes is initiated when M-Cdk phosphorylates specific proteins involved in the process. Many of these Cdk substrates have been identified, and in many cases we understand in considerable detail how their phosphorylation alters their function.

M-Cdk directly phosphorylates many of the proteins involved in mitotic processes, but it also acts indirectly by phosphorylating and thereby activating other protein kinases that carry out some mitotic functions. Two families of protein kinases, the *Polo-like kinases* and the *Aurora kinases*, make particularly important contributions to the control of early mitotic events. The Polo-like kinase Plk1, for example, is required for the normal assembly of a bipolar mitotic spindle, in part because it phosphorylates proteins involved in separation of the spindle poles early in mitosis. The Aurora kinase Aurora-A also helps control proteins that govern the assembly and stability of the spindle, whereas Aurora-B controls attachment of sister chromatids to the spindle, as we discuss later.

Condensin Helps Configure Duplicated Chromosomes for Separation

At the end of S phase, the immensely long DNA molecules of the sister chromatids are tangled in a mass of partially intertwined DNA and proteins. Any attempt to pull the sisters apart in this state would undoubtedly lead to breaks in the chromosomes. To avoid this disaster, the cell devotes a great deal of time and energy in early mitosis to reorganizing the sister chromatids into relatively short, distinct structures that can be pulled apart more easily in anaphase. These chromosomal changes involve two overlapping processes: *chromosome condensation*, in which the chromatids are dramatically compacted; and *sister-chromatid resolution*, whereby the two sisters are resolved into distinct, separable units (Figure 17–24A). Resolution results from the disentangling of the sister DNAs, accompanied by the partial removal of cohesin molecules along the chromosome arms. As a result, when the cell reaches metaphase, the sister chromatids appear in the microscope as compact, rodlike structures that are joined tightly at their centromeric regions and only loosely along their arms.

The condensation and resolution of sister chromatids depend, at least in part, on a five-subunit protein complex called **condensin**, which is concentrated along the central axes of mitotic chromosomes (**Figure 17–24B**). Condensin structure is related to that of the cohesin complex that holds sister chromatids together (see Figure 17–23). It contains two SMC subunits like those of cohesin, plus

1048 PANEL 17-1: The Principal Stages of M Phase (Mitosis and Cytokinesis) in an Animal Cell

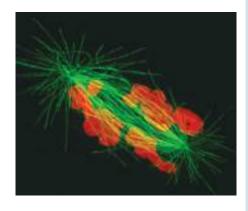

At prophase, the replicated chromosomes, each consisting of two closely associated sister chromatids, condense. Outside the nucleus, the mitotic spindle assembles between the two centrosomes, which have replicated and moved apart. For simplicity, only three chromosomes are shown. In diploid cells, there would be two copies of each chromosome present. In the fluorescence micrograph, chromosomes are stained orange and microtubules are green.

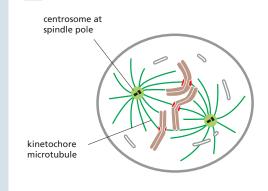

2 PROMETAPHASE

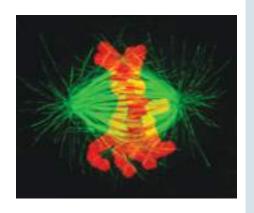

Prometaphase starts abruptly with the breakdown of the nuclear envelope. Chromosomes can now attach to spindle microtubules via their kinetochores and undergo active movement.

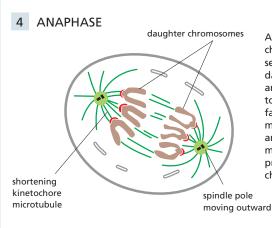

3 METAPHASE

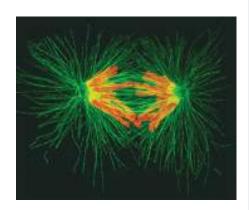

At metaphase, the chromosomes are aligned at the equator of the spindle, midway between the spindle poles. The kinetochore microtubules attach sister chromatids to opposite poles of the spindle.

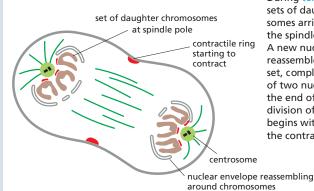

MBOC7_ptr_ch17_1027-1088.indd 1048 02/12/21 2:14 PM

At anaphase, the sister chromatids synchronously separate to form two daughter chromosomes, and each is pulled slowly toward the spindle pole it faces. The kinetochore microtubules get shorter, and the spindle poles also move apart; both processes contribute to chromosome segregation.

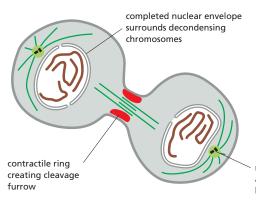

5 TELOPHASE

During telophase, the two sets of daughter chromosomes arrive at the poles of the spindle and decondense. A new nuclear envelope reassembles around each set, completing the formation of two nuclei and marking the end of mitosis. The division of the cytoplasm begins with contraction of the contractile ring.

6 CYTOKINESIS

During cytokinesis, the cytoplasm is divided in two by a contractile ring of actin and myosin filaments, which pinches the cell in two to create two daughters, each with one nucleus.

MBOC7_ptr_ch17_1027-1088.indd 1049 02/12/21 2:14 PM

Figure 17–25 Condensin. (A) Condensin is a five-subunit protein complex that resembles cohesin (see Figure 17–23). The ATPase head domains of its two major subunits, Smc2 and Smc4, are held together by a linker protein called Brn1, which is associated with two additional proteins called Ycs4 and Ycg1. (B) These diagrams illustrate a mechanism by which condensin might generate DNA loops, thereby promoting the compaction of a chromosome. For an alternative model, see Figure 4–56. In the model shown here, the process begins when the Ycg1 subunit interacts tightly with a strand of chromosome DNA, anchoring the condensin firmly in place on the DNA. The nearby DNA curls around to interact with the hinge domain. By mechanisms that remain unclear, the hinge and ATPase domains work together, using energy from ATP hydrolysis, to move leftward along the top DNA strand (red arrow), thereby generating a chromosome loop. Such loops are common structural elements in chromosome packaging (discussed in Chapter 4).

three non-SMC subunits (Figure 17–25A). Like cohesin, condensin forms a ring that encircles DNA. In addition, condensin has the ability to use energy provided by ATP hydrolysis to promote the compaction of sister chromatids. There is evidence that the ATPase domains of condensin act as a motor that moves DNA through the ring, thereby allowing it to create chromosome loops (Figure 17–25B). Much remains to be learned, however, before we understand how the local coordination of condensin, cohesin, and histone proteins is choreographed by M-Cdk to generate the efficient packaging and resolution of the sister chromatids.

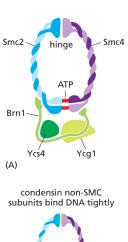

The Mitotic Spindle Is a Dynamic Microtubule-based Machine

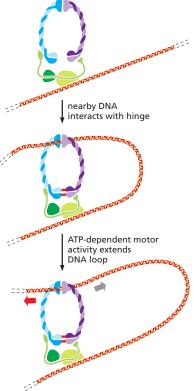

The central event of mitosis—chromosome segregation—depends in all eukaryotes on a complex and beautiful machine called the **mitotic spindle** (see Panel 17–1). The spindle is a bipolar array of microtubules, which pulls sister chromatids apart in anaphase, thereby segregating the two sets of chromosomes to opposite ends of the cell, where they are packaged into daughter nuclei (Movie 17.6). M-Cdk triggers the assembly of the spindle early in mitosis, in parallel with the chromosome restructuring just described. Before we consider how the spindle assembles and how its microtubules attach to sister chromatids, we briefly review the key features of metaphase spindle structure.

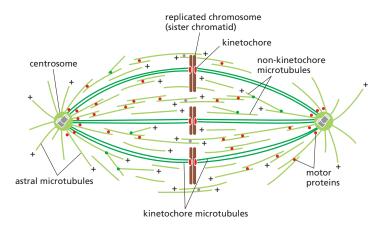

As we discussed in Chapter 16, microtubules are dynamic polar polymers with plus and minus ends that display distinct behaviors. The metaphase spindle of an animal cell contains many thousands of microtubules radiating from two spindle poles, with minus ends oriented toward the pole and plus ends directed outward (Figure 17–26). The kinetochore microtubules are the central players in chromosome segregation: their plus ends are attached to sister-chromatid pairs at large protein structures called *kinetochores*, which are located at the *centromere* of each sister chromatid. Each kinetochore binds large numbers of microtubules that are cross-linked to form thick microtubule bundles called *K-fibers*. These fibers are responsible for moving separated sister chromatids toward the poles in anaphase.

The second major type of spindle microtubule, and by far the most numerous, are the **non-kinetochore microtubules** (also known as interpolar microtubules). These relatively short and unstable microtubules are densely packed between the poles, cross-linked by various proteins to form a dynamic and adaptable scaffolding network that provides structural stability to the spindle. Some of these microtubules are embedded in the spindle poles, but many are found away from the poles, sometimes with minus ends attached to the sides of other microtubules. Near the spindle equator, they are often cross-linked with antiparallel microtubules oriented with minus ends directed toward the opposite spindle pole.

In most animal cells, spindles also contain **astral microtubules** that radiate outward from the poles and contact the cell cortex, helping to position the spindle in the cell. Each of the two poles in these spindles is focused at a large protein organelle called the **centrosome**. As described in Chapter 16 (see Figures 16–42 and 16–43), the centrosome consists of a cloud of amorphous material (called the *pericentriolar material*) that surrounds a pair of *centrioles* (**Figure 17–27**). The pericentriolar material nucleates a radial array of microtubules, with their dynamic plus ends projecting outward and their minus ends associated with

the centrosome. Some cells—notably the cells of higher plants and the oocytes of many vertebrates—do not have centrosomes and therefore do not have astral microtubules. Thus, as we discuss later, centrosomes are not essential for spindle assembly.

The assembly and function of a bipolar spindle depend on hundreds of different microtubule-associated proteins that can be placed in three general categories: nucleating factors that govern the formation of new microtubules, regulatory proteins that control rates of polymerization and depolymerization at both ends of the microtubules, and motor proteins that cross-link and move microtubules relative to each other. We briefly describe each of these important microtubule regulators in the following sections, after which we discuss how these components collaborate in the assembly of the spindle.

Microtubules Are Nucleated in Multiple Regions of the Spindle

Microtubules are the building blocks of the spindle, and spindle assembly requires the synthesis of enormous numbers of new microtubules. Mature metaphase spindles contain tens or hundreds of thousands of microtubules, most of which are turning over rapidly, resulting in the need for a constant supply of new

Figure 17-26 The metaphase mitotic spindle in an animal cell. Bundles of parallel kinetochore microtubules (K-fibers) connect the spindle poles with the kinetochores of sister chromatids. Nonkinetochore microtubules are scattered throughout the spindle with their minus ends directed toward the nearest pole; these microtubules are cross-linked by various microtubule-associated proteins to form a dynamic, interconnected meshwork. Near the spindle equator, antiparallel microtubules are cross-linked by specific motor and other proteins (light purple dots). In other regions of the spindle, parallel microtubules are cross-linked (red dots) Some microtubules grow from nucleating factors in the centrosome, while others originate in nucleating factors on the sides of other microtubules (green dots), as we discuss later. Astral microtubules radiate out from the poles into the cytoplasm and are not present in spindles lacking centrosomes.

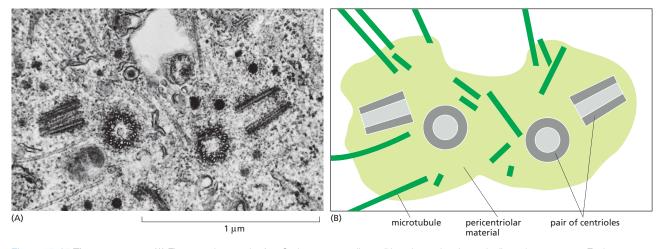

Figure 17–27 The centrosome. (A) Electron micrograph of an S-phase mammalian cell in culture, showing a duplicated centrosome. Each centrosome contains a pair of centrioles; although the centrioles have duplicated, they remain together in a single complex, as shown in the drawing of the micrograph in (B). One centriole of each centriole pair has been cut in cross section, while the other is cut in longitudinal section, indicating that the two members of each pair are aligned at right angles to each other. The two halves of the replicated centrosome, each consisting of a centriole pair surrounded by pericentriolar material, will split and migrate apart to initiate the formation of the two poles of the mitotic spindle when the cell enters M phase (see Figures 16–42 and 16–43). (A, from M. McGill et al., J. Ultrastruct. Res. 57:43–53, 1976. With permission from Academic Press.)

microtubules. To meet this need, the spindle contains large numbers of microtubule nucleating factors. By far the most important of these is the γ -tubulin ring complex (γ -TuRC; see Figure 16–41), which nucleates microtubule assembly from the minus end, leaving the plus end to grow rapidly.

In the many animal cell types that contain centrosomes, large numbers of γ -TuRCs are anchored and activated in the pericentriolar material and drive the formation of microtubules that radiate outward from the centrosome (see Figure 16-42). The number of γ -TuRCs in each centrosome increases greatly at the beginning of mitosis, in a process called *centrosome maturation*.

Microtubule formation also occurs within the metaphase spindle between the poles. A large protein complex called *augmin* anchors active γ -TuRC to the side of a microtubule, resulting in the nucleation of a new microtubule that branches off the other (see Figure 16-47). Augmin binds to the microtubule in such a way that it orients the new microtubule with its plus end pointing in the same direction as the microtubule to which it binds; as a result, the new microtubule has the correct orientation when it is released and repositioned in the spindle microtubule network.

Spindle assembly also depends on increased microtubule synthesis in the vicinity of the chromosomes. Mitotic chromosomes generate local signals that activate γ -TuRC and thereby promote microtubule formation. As we describe later, this mechanism, together with microtubule sorting by various motor proteins, allows chromosomes to make a major contribution to the formation of a bipolar spindle—particularly in the absence of centrosomes.

Microtubule Instability Increases Greatly in Mitosis

As discussed in Chapter 16, microtubules are in a state of *dynamic instability*, in which individual microtubules are either growing or shrinking and stochastically switch between the two states. New microtubules are continually being created to balance the loss of those that disappear completely by depolymerization.

Entry into mitosis signals an abrupt change in the cell's microtubules. During prophase, and particularly in prometaphase and metaphase (see Panel 17-1), the average lifetime of a microtubule decreases dramatically—particularly the lifetime of non-kinetochore microtubules, which exist for only 15–30 seconds. This increase in microtubule instability, coupled with the increased ability of the spindle to nucleate microtubules as mentioned above, results in a remarkably dense and dynamic array of spindle microtubules.

Microtubule dynamics are controlled in the cell by a variety of regulatory proteins, including microtubule-associated proteins (MAPs) that promote stability and depolymerization factors that destabilize microtubule plus ends. Changes in the activities of these proteins are responsible for the changes in microtubule dynamics that occur during mitosis. Many of these changes result from phosphorylation of specific proteins by M-Cdk and other mitotic protein kinases.

Microtubule-based Motor Proteins Govern Spindle Assembly and Function

The assembly and function of the mitotic spindle depend on numerous microtubule-dependent motor proteins. As discussed in Chapter 16, these proteins belong to two families—the large family of kinesin-related proteins, which usually move toward the plus end of microtubules, and dyneins, which move toward the minus end. Two motor proteins—*kinesin-5* and *cytoplasmic dynein*—are particularly important in spindle assembly and function, and many others, including *kinesin-14* and *kinesins-4/10*, are also involved (Figure 17–28).

Kinesin-5 is a large tetramer containing two dimeric motor domains at each end. The motor domains both move toward the plus end of a microtubule but can be oriented in opposite directions; as a result, they can associate with two antiparallel microtubules and slide them in opposite directions. When this occurs near the center of the spindle, the result is that the minus ends of the microtubule

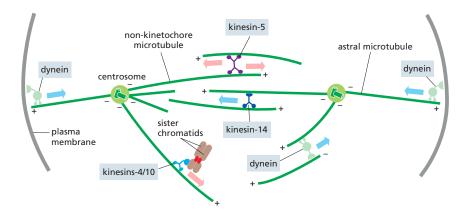

Figure 17-28 Major motor proteins of the spindle. Microtubule-dependent motor proteins contribute to spindle assembly and function (see text). The colored arrows indicate the direction of motor protein movement along a microtubule—blue toward the minus end and light red toward the plus end. Because non-kinetochore microtubules are extensively cross-linked to each other in the spindle and at the poles, it is thought that microtubule sliding like that shown here can alter spindle length. (From D.O. Morgan, The Cell Cycle: Principles of Control, p. 117. London: New Science Press, 2007. With permission from Oxford University Press.)

are pushed toward the poles. This process is fundamentally important in generating bipolarity in the spindle.

Cytoplasmic dynein is a minus end-directed motor that, together with associated proteins, organizes microtubules at various locations in the cell. By attaching to the minus end of one microtubule and transporting it toward the minus end of a second microtubule, dynein functions to connect new microtubules formed in the body of the spindle to microtubules nucleated at a centrosome, and to focus the spindle poles. Dynein is also present on the plus ends of astral microtubules at the cell cortex. By moving toward the minus end of astral microtubules, dynein motors pull the spindle poles toward the cell cortex and away from each other.

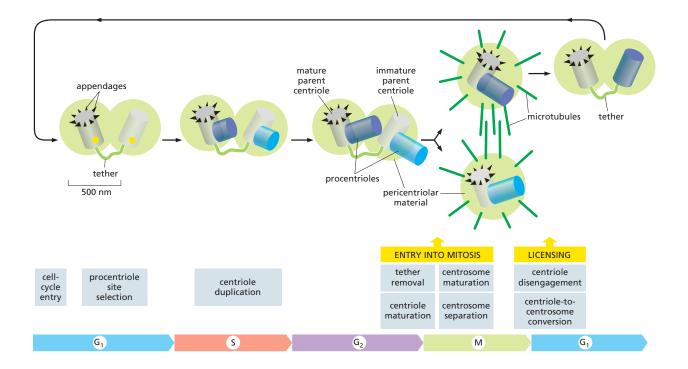

Kinesin-14, unlike most kinesins, is a minus end-directed motor. It contains a dimeric motor domain and a second domain that can bind to a neighboring microtubule in a specific orientation, enabling it to cross-link antiparallel microtubules at the center of the spindle and pull the poles together. Kinesin-4 and kinesin-10 proteins, also called *chromokinesins*, are plus end-directed motors that associate with chromosome arms and push the attached chromosome away from the pole (or the pole away from the chromosome).

Bipolar Spindle Assembly in Most Animal Cells Begins with Centrosome Duplication

The mitotic spindle must have two poles if it is to pull the two sets of sister chromatids to opposite ends of the cell in anaphase. In most animal cells, several mechanisms ensure the bipolarity of the spindle. One depends on centrosomes. A typical animal cell enters mitosis with a pair of centrosomes, each of which nucleates a radial array of microtubules. The two centrosomes provide prefabricated spindle poles that greatly facilitate bipolar spindle assembly. The other mechanisms depend on the ability of mitotic chromosomes to nucleate and stabilize microtubules and on the ability of motor proteins to organize microtubules into a bipolar array. We will discuss these "self-organization" mechanisms later in this section.

In interphase, most animal cells contain a single centrosome that nucleates most of the cell's cytoplasmic microtubules. The centrosome duplicates when the cell enters the cell cycle, so that by the time the cell reaches mitosis there are two centrosomes. Centrosome duplication begins at about the same time as the cell enters S phase. The G_1/S -Cdk (a complex of cyclin E and Cdk2 in animal cells; see Table 17–1) that triggers cell-cycle entry also helps initiate centrosome duplication, together with another protein kinase called Plk4. Each of the two centrioles in the centrosome nucleates the formation of a new centriole, which is gradually constructed in S phase to generate a closely linked pair of centrosomes (Figure 17–29). This centrosome pair remains together on one side of the nucleus until the cell enters mitosis, when the two centrosomes undergo numerous changes to form the poles of the spindle.

There are interesting parallels between centrosome duplication and chromosome duplication. Both use a semiconservative mechanism of duplication, in

which the two halves separate and serve as templates for construction of a new half. Centrosomes, like chromosomes, must replicate once and only once per cell cycle, to ensure that the cell enters mitosis with precisely two copies: an incorrect number of centrosomes can lead to defects in spindle assembly and thus errors in chromosome segregation.

We are beginning to unravel the complex mechanisms that limit centrosome duplication to once and only once per cell cycle. These mechanisms are reminiscent of those that restrict DNA replication to once per cell cycle: after duplication has occurred in S phase, passage through mitosis is required for the "licensing" of centrosome duplication in the next cell cycle (see Figure 17–29).

Spindle Assembly in Animal Cells Requires Nuclear-Envelope Breakdown

In cells that contain centrosomes, spindle assembly begins when the two centrosomes move apart along the nuclear envelope in prophase, pulled by dynein motor proteins that link astral microtubules to the cell cortex (see Figure 17–28). The plus ends of the microtubules between the centrosomes interdigitate to form an array of antiparallel microtubules, and kinesin-5 motor proteins cross-link these microtubules and push the centrosomes apart.

Centrosomes and microtubules are located in the cytoplasm, where they have no access to the sister-chromatid pairs inside the nucleus. Thus, the attachment of the nascent spindle to sister-chromatid pairs requires the removal of the nuclear envelope. In addition, many of the motor proteins and microtubule regulators that promote spindle assembly are associated with the chromosomes inside the nucleus, and they require nuclear-envelope breakdown to carry out their functions.

Nuclear-envelope breakdown is a complex, multistep process, which is thought to begin when M-Cdk phosphorylates several subunits of the nuclear pore complexes in the nuclear envelope. This phosphorylation initiates the disassembly of nuclear pore complexes and their dissociation from the envelope. M-Cdk also phosphorylates components of the nuclear lamina, the structural framework beneath the envelope, resulting in nuclear lamina disassembly. In parallel, phosphorylation of several inner-nuclear-envelope proteins leads to detachment of

Figure 17-29 The centrosome cycle. In early G₁, the centrosome consists of two centrioles linked by a protein tether, as well as associated pericentriolar material for nucleation of microtubules (light green). One centriole, the mature parent, carries protein appendages required for certain centrosome functions. Upon entry into the cell cycle, G₁/S-Cdk and Plk4 initiate centriole duplication, whereby a new centriole (procentriole) is assembled at a single site on the side of each parent centriole (yellow dots). The elongation of the procentrioles is usually completed in G₂. The two centriole pairs remain close together in a single centrosomal complex until entry into mitosis, when the protein kinases M-Cdk, Plk1, and other regulators trigger numerous changes: the tether between centrosomes is removed. the immature parent centriole acquires appendages (centriole maturation), the pericentriolar material expands to enable more microtubule nucleation (centrosome maturation), and the centrosomes separate, forming a new spindle between them. After the completion of mitosis, the two centrioles in each centrosome detach (centriole disengagement), and the new centriole acquires pericentriolar material (centriole-to-centrosome conversion). These two processes are required for centriole duplication in the subsequent cell cycle; thus, progression through mitosis is required for duplication, helping to ensure that centrioles (and centrosomes) duplicate only once per cell cycle.

Figure 17–30 Activation of the GTPase Ran around mitotic chromosomes. The Ran protein, like other members of the small GTPase family (discussed in Chapter 15), can exist in two conformations depending on whether it is bound to GDP (inactive state) or GTP (active state). The localization of active Ran in mitosis was determined using a protein that emits fluorescence at a specific wavelength when it is activated by Ran-GTP. In the metaphase human cell shown here, Ran activity (yellow and red) is highest around the chromosomes, between the poles of the mitotic spindle (indicated by asterisks). (From P. Kaláb et al., Nature 440:697–701, published 2006 by Nature Publishing Group. Reproduced with permission from SNCSC.)

lamin proteins and chromosomes from the nuclear envelope, which is then incorporated into the membranes of the endoplasmic reticulum.

Mitotic Chromosomes Promote Bipolar Spindle Assembly

When they are present, centrosomes drive spindle assembly. Centrosomes are very efficient microtubule nucleators that also act to organize the spindle poles, rapidly generating a bipolar microtubule array that rains down on the chromosomes when the nuclear envelope is removed. However, chromosomes are not just passive passengers in the process of spindle assembly. By creating a local environment that favors both microtubule nucleation and microtubule stabilization, they play an active part in spindle formation. The influence of the chromosomes can be demonstrated by using a fine glass needle to reposition them after the spindle has formed. For some cells in metaphase, if a single chromosome is tugged out of alignment, a mass of new spindle microtubules rapidly appears around the newly positioned chromosome, while the spindle microtubules at the chromosome's former position depolymerize. This property of the chromosomes seems to depend, at least in part, on a guanine nucleotide exchange factor (GEF) that is bound to chromatin; the GEF stimulates a small GTPase in the cytosol called Ran to bind GTP in place of GDP. The activated Ran-GTP, which is also involved in nuclear transport (discussed in Chapter 12), releases microtubuleregulatory proteins from protein complexes in the cytosol, thereby stimulating the local nucleation and stabilization of microtubules around chromosomes (Figure 17-30). The best-understood mechanism depends on the release of a protein called TPX2, which then binds and activates the protein kinase Aurora-A. Aurora-A phosphorylates regulatory proteins that activate γ-TuRCs, leading to an increase in local formation of new microtubules. TPX2 might also activate augmin to promote the formation of new microtubule branches on the sides of existing microtubules. Local microtubule stabilization is also promoted by the protein kinase Aurora-B, which associates with mitotic chromosomes.

In the absence of centrosomes, spindle assembly is thought to begin with the formation of microtubules around the chromosomes. Various microtubule-associated proteins then organize the microtubules into a bipolar spindle (Figure 17–31). Two motor proteins that we discussed earlier are particularly

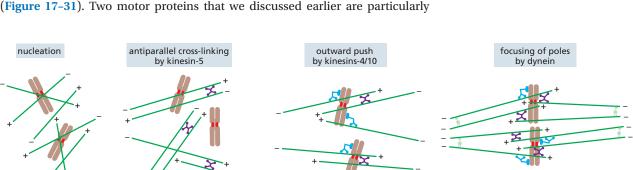

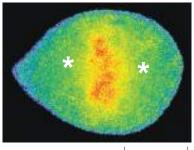

Figure 17–31 Spindle self-organization by motor proteins. Mitotic chromosomes stimulate the local activation of proteins that promote the formation of microtubules in the vicinity of the chromosomes. Kinesin-5 motor proteins (see Figure 17–28) organize these microtubules into antiparallel bundles, while plus end–directed kinesin-4 and kinesin-10 link the microtubules to chromosome arms and push minus ends away from the chromosomes. Dynein, together with numerous other proteins, focuses these minus ends into a pair of spindle poles.

10 um

important. Kinesin-5, by cross-linking antiparallel microtubules and pushing their minus ends outward, is essential for the bipolar character of the spindle. Dynein, by transporting one microtubule minus end toward the minus end of another, is required for the focusing of minus ends in a discrete pole at each end of the bipolar array. Many other microtubule regulators, including other motor proteins and augmin, also contribute to spindle assembly.

Cells that normally lack centrosomes, such as those of higher plants and many animal oocytes, use chromosome-based self-organization mechanisms to form spindles. These mechanisms also assemble spindles in experimental systems where centrosomes are removed—such as in certain animal embryos that have been induced to develop from eggs without fertilization (called *parthenogenesis*). As the sperm normally provides the centrosome when it fertilizes an egg, the mitotic spindles in these parthenogenetic embryos develop without centrosomes (Figure 17–32). Although the resulting acentrosomal spindle can segregate chromosomes normally, it lacks astral microtubules, which are responsible for positioning the spindle in animal cells; as a result, the spindle can be mispositioned in the cell.

Kinetochores Attach Sister Chromatids to the Spindle

After the assembly of a bipolar microtubule array, the second major step in spindle formation is the attachment of the array to the sister-chromatid pairs. Spindle microtubules become attached to each chromatid at its **kinetochore**, a giant, multilayered protein structure that is built at the centromeric region of the chromatid (**Figure 17–33**; also see Chapter 4). In metaphase, the plus ends of kinetochore microtubules are embedded head-on in specialized microtubule-attachment sites within the outer region of the kinetochore, furthest from the DNA. The kinetochore of an animal cell can bind 10–40 microtubules, whereas a budding yeast kinetochore can bind only one. Attachment of each microtubule depends on multiple copies of a rod-shaped protein complex called the Ndc80 complex, which is anchored in the kinetochore at one end and interacts with the

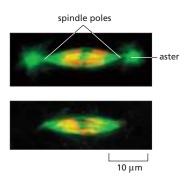

Figure 17-32 Bipolar spindle assembly without centrosomes in parthenogenetic embryos of the insect Sciara (or fungus gnat). The microtubules are stained green, the chromosomes red. The top fluorescence micrograph shows a normal spindle formed with centrosomes in a normally fertilized Sciara embryo. The bottom micrograph shows a spindle formed without centrosomes in an embryo that initiated development without fertilization. Note that the spindle with centrosomes has an aster at each pole of the spindle, whereas the spindle formed without centrosomes does not. Both types of spindles are able to segregate the replicated chromosomes. (© 1998 B. de Saint Phalle and W. Sullivan. Originally published in J. Cell Biol. https://doi.org/10.1083/jcb.141.6.1383. Figure 17–34 Microtubule attachment sites in the kinetochore. (A) In this electron micrograph of a mammalian kinetochore, the chromosome is on the right, and the plus ends of multiple microtubules are embedded in the outer kinetochore on the left. (B) Electron tomography (discussed in Chapter 9) was used to construct a low-resolution three-dimensional image of the outer kinetochore in A. Several microtubules (in multiple colors) are embedded in fibrous material of the kinetochore, which is thought to be composed of the Ndc80 complex and other proteins. (C) Each microtubule is attached to the kinetochore by interactions with multiple copies of the Ndc80 complex (blue). This complex binds to the sides of the microtubule near its plus end, allowing polymerization and depolymerization to occur while the microtubule remains attached to the kinetochore. The opposite end of the Ndc80 complex is attached through intermediary proteins to centromeric nucleosomes containing a specialized version of histone H3 called CENP-A (see Chapter 4). Budding yeast kinetochores contain a single centromeric nucleosome and thus a single microtubule-binding site like that shown here, while animal kinetochores (like those in B) contain large arrays of these binding sites distributed over large numbers of centromeric nucleosomes. (A and B, from Y. Dong et al., Nat. Cell Biol. 9:516–522, published 2007 by Nature Publishing Group. Reproduced with permission of SNCSC.)

sides of the microtubule at the other, thereby linking the microtubule to the kinetochore while still allowing the addition or removal of tubulin subunits at this end (Figure 17–34). Regulation of plus-end polymerization and depolymerization at the kinetochore is critical for the control of chromosome movement on the spindle, as we discuss later.

Kinetochore attachment to the spindle occurs by a complex sequence of events. At the end of prophase in animal cells, the centrosomes of the growing spindle generally lie on opposite sides of the nuclear envelope. Thus, when the envelope breaks down, the sister-chromatid pairs are bombarded by dynamic microtubule plus ends coming from two directions. However, the kinetochores do not instantly achieve the correct "end-on" microtubule attachment to both spindle poles. Instead, detailed studies with light and electron microscopy show that most initial attachments are unstable *lateral* attachments, in which a kinetochore attaches to the side of a passing microtubule, with assistance from dynein motor proteins in the outer kinetochore. Eventually, microtubule plus ends are captured by one and then the other kinetochore in the correct end-on orientation.

Another attachment mechanism also plays a part, particularly in the absence of centrosomes. Short microtubules in the vicinity of the chromosomes become embedded in the plus end-binding sites of the kinetochore. Polymerization at these plus ends then results in growth of the microtubules away from the kinetochore. The minus ends of these kinetochore microtubules are eventually cross-linked to other minus ends and focused by dynein motor proteins at the spindle pole (see Figure 17–31).

Bi-orientation Is Achieved by Trial and Error

The success of mitosis demands that sister chromatids in a pair attach to opposite poles of the mitotic spindle, so that they move to opposite ends of the cell when they separate in anaphase. How is this mode of attachment, called **bi-orientation**, achieved? What prevents the attachment of both kinetochores to the same spindle pole or the attachment of one kinetochore to both spindle poles? Part of the answer is that sister kinetochores are constructed in a back-to-back orientation

MBOC7_ptr_ch17_1027-1088.indd 1057 02/12/21 2:14 PM

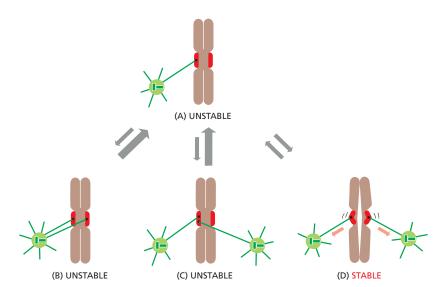

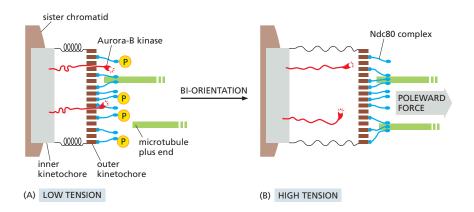

Figure 17–35 Alternative forms of kinetochore attachment to the spindle poles. (A) Initially, a single microtubule from a spindle pole binds to one kinetochore in a sister-chromatid pair. Additional microtubules can then bind to the chromosome in various ways. (B) A microtubule from the same spindle pole can attach to the other sister kinetochore, or (C) microtubules from both spindle poles can attach to the same kinetochore. These incorrect attachments are unstable, however, so that one of the two microtubules tends to dissociate. (D) When a microtubule from the opposite pole binds to the second kinetochore, the sister kinetochores are thought to sense tension across their microtubule-binding sites. This triggers an increase in microtubule binding affinity, thereby locking the correct attachment in place. Occasionally (not shown), attachments can form that are a combination of C and D; that is, the two sister kinetochores are attached to opposite poles and are under tension, but there is also an inappropriate microtubule link between one kinetochore and both spindle poles. This combination is stable, and cells that progress to anaphase with such an attachment risk moving both sister chromatids to the same daughter, which is usually lethal for the cell.

that reduces the likelihood that both kinetochores can face the same spindle pole. Nevertheless, incorrect attachments do occur, and elegant regulatory mechanisms have evolved to correct them.

Incorrect attachments are corrected by a system of trial and error that is based on a simple principle: most incorrect attachments are highly unstable and do not last, whereas correct attachments are held in place. How does the kinetochore sense a correct attachment? The answer appears to be tension (Figure 17-35). When a sister-chromatid pair is properly bi-oriented on the spindle, the two kinetochores are pulled in opposite directions by strong poleward forces. Sister-chromatid cohesion resists these poleward forces, creating high levels of tension within the kinetochores. When chromosomes are incorrectly attached—when both sister chromatids are attached to the same spindle pole, for example-tension is low and the kinetochore generates an inhibitory signal that loosens the grip of its microtubule attachment site, allowing detachment to occur. When bi-orientation occurs, the high tension at the kinetochore shuts off the inhibitory signal, strengthening microtubule attachment. In animal cells, tension not only increases the affinity of the attachment site but also leads to the attachment of additional microtubules to the kinetochore. This results in the formation of a thick kinetochore fiber composed of multiple microtubules.

The tension-sensing mechanism depends on the protein kinase Aurora-B, which is associated with the kinetochore and is thought to generate the inhibitory signal that reduces the strength of microtubule attachment in the absence of tension. It phosphorylates several components of the microtubule attachment site, including the Ndc80 complex, decreasing the site's affinity for a microtubule plus end. When bi-orientation occurs, the resulting tension reduces

MBOC7_ptr_ch17_1027-1088.indd 1058 02/12/21 2:14 PM

phosphorylation by Aurora-B, thereby increasing the affinity of the attachment site (Figure 17–36).

After their attachment to the two spindle poles, the chromosomes are tugged back and forth, eventually assuming a position equidistant between the two poles, a position called the **metaphase plate**. In vertebrate cells, the chromosomes then oscillate gently at the metaphase plate, awaiting the signal for the sister chromatids to separate. The signal is produced, with a predictable lag time, after the bi-oriented attachment of the last sister-chromatid pair.

Multiple Forces Act on Chromosomes in the Spindle

The metaphase spindle, with the sister chromatids aligned at the metaphase plate, appears as a stable bipolar structure of a fixed length, but appearances can be deceiving. The spindle is a highly dynamic assembly that exists at a steady state that depends on the precise balance of numerous forces generated by various motor proteins and by microtubule polymerization and depolymerization. These forces move chromosomes once they are attached to the spindle and produce the tension that is so important for the stabilization of correct attachments. In anaphase, similar forces pull the separated chromatids to opposite ends of the spindle. Three major spindle forces are particularly critical, although their strength and importance vary at different stages of mitosis.

The first major force pulls the kinetochore and its associated chromatid along the kinetochore microtubule toward the spindle pole. This force is generated by depolymerization at the plus end of the microtubule. It pulls on chromosomes during prometaphase and metaphase but is particularly important for moving sister chromatids toward the poles after they separate in anaphase. Notably, this kinetochore-generated poleward force does not require ATP or motor proteins. This might seem implausible at first, but it has been shown that purified kinetochores in a test tube, with no ATP present, can remain attached to depolymerizing microtubules and thereby move. The energy that drives the movement is stored in the microtubule and is released when the microtubule depolymerizes; it ultimately comes from the hydrolysis of GTP that occurs after a tubulin subunit adds to the end of a microtubule (discussed in Chapter 16).

How does plus-end depolymerization drive the kinetochore toward the pole? As we discussed earlier (see Figure 17–34C), Ndc80 complexes in the kinetochore make multiple low-affinity attachments along the side of the microtubule. Because the attachments are constantly breaking and re-forming at new sites, the kinetochore remains attached to a microtubule even as the microtubule depolymerizes. In principle, this could move the kinetochore toward the spindle pole.

A second poleward force is provided in some cell types by **microtubule flux**, whereby the microtubules themselves are pulled toward the spindle poles and dismantled at their minus ends. The mechanism underlying this poleward movement is not clear, although it is likely to depend on forces generated by motor proteins and minus-end depolymerization at the spindle pole. In metaphase, the addition

Figure 17-36 How tension might increase microtubule attachment to the kinetochore. These diagrams illustrate one speculative mechanism by which bi-orientation might increase microtubule attachment to the kinetochore. A single kinetochore is shown for clarity; the spindle pole is on the right. (A) When a sisterchromatid pair is unattached to the spindle or attached to just one spindle pole, there is little tension between the outer and inner kinetochores. The protein kinase Aurora-B is tethered to the inner kinetochore and phosphorylates the microtubule attachment sites, including the Ndc80 complex (blue), in the outer kinetochore as shown. thereby reducing the affinity of microtubule binding. Microtubules therefore associate and dissociate rapidly, and attachment is unstable. (B) When bi-orientation is achieved, the forces pulling the kinetochore toward the spindle pole are resisted by forces pulling the other sister kinetochore toward the opposite pole, and the resulting tension pulls the outer kinetochore away from the inner kinetochore. As a result, Aurora-B is unable to reach the outer kinetochore, and microtubule attachment sites are not phosphorylated. Microtubule binding affinity is therefore increased, resulting in the stable attachment of multiple microtubules to both kinetochores. The dephosphorylation of outer kinetochore proteins depends on a phosphatase that is not shown here.

MBOC7_ptr_ch17_1027-1088.indd 1059 02/12/21 2:14 PM

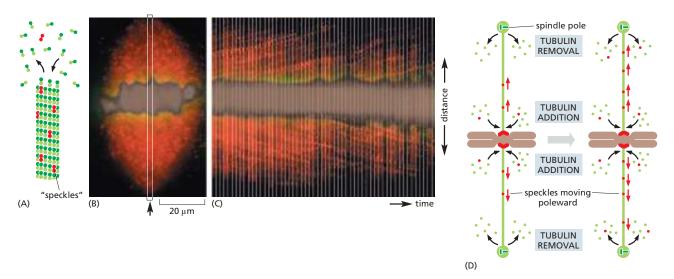

Figure 17–37 Microtubule flux in the metaphase spindle. (A) To observe microtubule flux, a small amount of fluorescent tubulin is injected into living cells or cell extracts so that individual microtubules form with a small proportion of fluorescent tubulin. Such microtubules have a speckled appearance when viewed by fluorescence microscopy. (B) Much of what we know about mitotic spindle behavior comes from studies in extracts of the eggs of the frog *X. laevis*. These extracts carry out many cell-cycle processes in a test tube, including mitotic spindle assembly. This image shows a fluorescence micrograph of a mitotic spindle in an extract mixed with a small amount of fluorescent tubulin. Because there are no centrosomes in these extracts, the spindle does not have astral microtubules. The chromosomes are colored *brown*, and the tubulin speckles are *red*. (C) The movement of individual speckles can be followed by time-lapse video microscopy. Images of the thin vertical boxed region (*arrow*) in B, taken every 10 seconds, are aligned here to show that individual speckles move toward the poles at a rate of about 0.75 μm/min, indicating that the microtubules are moving poleward. (D) The length of a kinetochore microtubule does not change significantly during this experiment because new tubulin subunits are added at the microtubule plus end at the same rate as tubulin subunits are removed from the minus end. (B and C, from T.J. Mitchison and E.D. Salmon, *Nat. Cell Biol.* 3:E17–21, published 2001 by Nature Publishing Group. Reproduced with permission of SNCSC.)

of new tubulin at the plus end of a microtubule compensates for the loss of tubulin at the minus end, so that microtubule length remains constant despite the movement of microtubules toward the spindle pole (Figure 17–37). Any kinetochore that is attached to a microtubule undergoing such flux experiences a poleward force, which contributes to the generation of tension at the kinetochore in metaphase. Together with the kinetochore-based forces discussed above, flux also contributes to the poleward forces that move sister chromatids after they separate in anaphase.

A third force acting on chromosomes is the *polar ejection force*, or *polar wind*. Plus end-directed kinesin-4 and kinesin-10 motors on chromosome arms interact with microtubules and transport the chromosomes away from the spindle poles (see Figure 17–28). This force is particularly important in prometaphase and metaphase, when it helps push chromosome arms out from the spindle. This force might also help align the sister-chromatid pairs at the metaphase plate.

The APC/C Triggers Sister-Chromatid Separation and the Completion of Mitosis

The cell cycle reaches its most dramatic moment with the separation of the sister chromatids at the metaphase-to-anaphase transition (Figure 17–38). Although M-Cdk activity sets the stage for this event, the anaphase-promoting complex, or cyclosome (APC/C), discussed earlier throws the switch that initiates sister-chromatid separation by ubiquitylating several mitotic regulatory proteins and thereby triggering their destruction (see Figure 17–18).

As we discussed earlier, cohesins hold sister-chromatid pairs together after S phase. In early mitosis, the resolution of the sister chromatids is accompanied by the removal of most cohesin from the chromosome arms via a mechanism that depends on a protein that pulls open the cohesin ring at the junction of its Smc3 and Scc1 subunits (see Figure 17–23). When the cell reaches metaphase, cohesins

MBOC7_ptr_ch17_1027-1088.indd 1060 02/12/21 2:14 PM

Figure 17–38 Sister-chromatid separation at anaphase. In the transition from metaphase (A) to anaphase (B), sister chromatids suddenly and synchronously separate and move toward opposite poles of the mitotic spindle—as shown in these light micrographs of *Haemanthus* (lily) endosperm cells that were stained with gold-labeled antibodies against tubulin (pink). (Courtesy of Andrew Bajer.)

remain primarily at the centromeric regions of the chromosomes, adjacent to the kinetochores, where they serve to resist the poleward forces that pull the sister chromatids apart. Anaphase begins with the abrupt removal of the remaining cohesin, which allows the sisters to separate and move to opposite poles of the spindle. The APC/C initiates the process by targeting the inhibitory protein **securin** for destruction. Before anaphase, securin binds to and inhibits the activity of a protease called **separase**. The destruction of securin in metaphase releases separase, which is then free to cleave the Scc1 subunit of cohesin (see Figure 17–23). The cohesins fall away, and the sister chromatids separate (**Figure 17–39**).

We saw earlier that phosphorylation of various proteins by M-Cdk promotes spindle assembly, chromosome condensation, and nuclear-envelope breakdown in early mitosis. It is thus not surprising that the dephosphorylation of these same proteins is required for spindle disassembly and the re-formation of daughter nuclei in telophase. Dephosphorylation of Cdk targets depends in part on the inactivation of most Cdks in the cell, which results when the APC/C targets S- and M-cyclins for destruction. Protein dephosphorylation also results

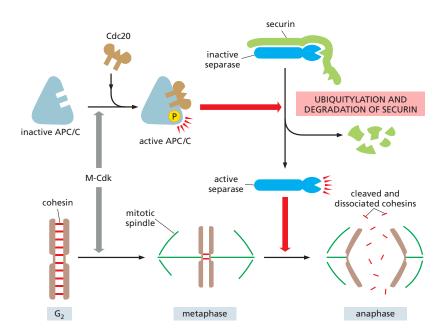

Figure 17-39 The initiation of sisterchromatid separation by the APC/C. The activation of APC/C by Cdc20 leads to the ubiquitylation and destruction of securin, which normally holds separase in an inactive state. The destruction of securin allows separase to cleave Scc1, a subunit of the cohesin complex holding the sister chromatids together (see Figure 17–23). The forces of the mitotic spindle then pull the sister chromatids apart. In animal cells, phosphorylation by Cdks also inhibits separase (not shown). Thus, Cdk inactivation in anaphase (resulting from cyclin destruction) also promotes separase activation by allowing its dephosphorylation.

Figure 17–40 Mad2 protein on unattached kinetochores. This fluorescence micrograph shows a mammalian cell in prometaphase, with the mitotic spindle in *green* and the sister chromatids in *blue*. One sister-chromatid pair is attached to only one pole of the spindle. Staining with anti-Mad2 antibodies indicates that Mad2 is bound to the kinetochore of the unattached sister chromatid (*red dot*, indicated by *red arrow*). A small amount of Mad2 is associated with the kinetochore of the sister chromatid that is attached to the spindle pole (*pale dot*, indicated by *white arrow*). © 1998 J. Waters et al. Originally published in *J. Cell Biol.* https://doi.org/10.1083/jcb.141.5.1181. With permission from Rockefeller University Press.)

from activation of phosphatases. Recall from our earlier discussions, for example, that the phosphatase PP2A-B55 is inactivated by M-Cdk (see Figures 17–15 and 17–17). When Cdk activity declines after cyclin destruction, PP2A and other phosphatases are activated, further driving protein dephosphorylation and the completion of mitosis.

Unattached Chromosomes Block Sister-Chromatid Separation: The Spindle Assembly Checkpoint

Drugs that destabilize microtubules, such as colchicine or vinblastine (discussed in Chapter 16), arrest cells in mitosis for hours or even days. This observation led to the identification of a **spindle assembly checkpoint** mechanism that is activated by the drug treatment and blocks progression through the metaphase-to-anaphase transition. The checkpoint mechanism ensures that cells do not enter anaphase until all chromosomes are correctly bi-oriented on the mitotic spindle.

The spindle assembly checkpoint depends on a sensor mechanism that monitors microtubule attachment at the kinetochore. Any kinetochore that is not properly attached to microtubules sends out a diffusible negative signal that blocks APC/C-Cdc20 activation throughout the cell and thus blocks the metaphase-to-anaphase transition. When the last sister-chromatid pair is properly attached and bi-oriented, this block is removed, allowing sister-chromatid separation to occur.

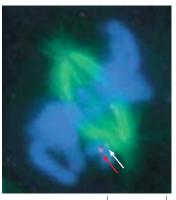

The negative checkpoint signal depends on several proteins, including *Mad2*, which are recruited to unattached kinetochores (**Figure 17–40**). The unattached kinetochore acts as an enzyme that catalyzes a change in the conformation of Mad2, so that Mad2 then interacts with other proteins to form a large multiprotein complex that binds and thereby inhibits APC/C-Cdc20. When proper microtubule attachment is achieved, these inhibitory complexes are disassembled, and APC/C-Cdc20 inhibition is thereby relieved.

In mammalian cells, the spindle assembly checkpoint determines the normal timing of anaphase. The destruction of securin in these cells begins moments after the last sister-chromatid pair becomes bi-oriented on the spindle, and anaphase begins about 20 minutes later. Experimental inhibition of the checkpoint mechanism causes premature sister-chromatid separation and anaphase.

Chromosomes Segregate in Anaphase A and B

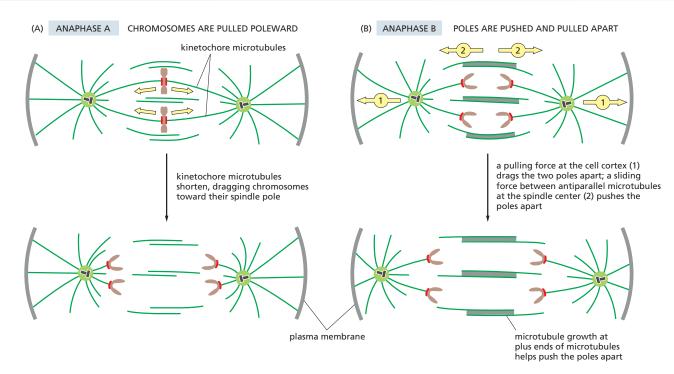

The sudden loss of sister-chromatid cohesion at the onset of anaphase leads to sister-chromatid separation, which allows the forces of the mitotic spindle to pull the sisters to opposite poles of the cell—called *chromosome segregation*. The chromosomes move by two independent and overlapping processes. The first, **anaphase A**, is the initial poleward movement of the chromosomes, which is accompanied by shortening of the kinetochore microtubules. The second, **anaphase B**, is the separation of the spindle poles themselves, which begins after the sister chromatids have separated and the daughter chromosomes have moved some distance apart (**Figure 17–41**).

Chromosome movement in anaphase A depends on a combination of the two major poleward forces described earlier. The first is the force generated by microtubule depolymerization at the kinetochore, which results in the loss of tubulin subunits at the plus end as the kinetochore moves toward the pole. The second is

20 um

MBOC7_ptr_ch17_1027-1088.indd 1062 02/12/21 2:14 PM

provided by microtubule flux, which is the poleward movement of the microtubules toward the spindle pole (see Figure 17–37). The relative importance of these two forces during anaphase varies in different cell types: in embryonic cells, chromosome movement depends mainly on microtubule flux, for example, whereas movement in yeast and vertebrate somatic cells results primarily from forces generated at the kinetochore.

Spindle-pole separation during anaphase B depends on motor-driven mechanisms similar to those that separate the two centrosomes in early mitosis. Dynein motor proteins that anchor astral microtubule plus ends to the cell cortex pull the poles apart. Kinesin-5, which cross-links antiparallel microtubules at the center of the spindle, pushes the poles apart (see Figure 17–28).

Although sister-chromatid separation initiates the chromosome movements of anaphase A, other mechanisms also ensure correct chromosome movements in anaphase A and spindle elongation in anaphase B. Most important, the completion of a normal anaphase depends on the dephosphorylation of Cdk substrates, which in most cells results from the APC/C-dependent destruction of cyclins. If M-cyclin destruction is prevented—by the production of a mutant form that is not recognized by the APC/C, for example—sister-chromatid separation generally occurs, but the chromosome movements and microtubule behavior of anaphase are abnormal.

The relative contributions of anaphase A and anaphase B to chromosome segregation vary greatly, depending on the cell type. In mammalian cells, anaphase B begins shortly after anaphase A and stops when the spindle is about twice its metaphase length; in contrast, the spindles of yeasts and certain protozoa primarily use anaphase B to separate the chromosomes at anaphase, and their spindles elongate to up to 15 times their metaphase length.

Segregated Chromosomes Are Packaged in Daughter Nuclei at Telophase

By the end of anaphase, the daughter chromosomes have segregated into two equal groups at opposite ends of the cell. In **telophase**, the final stage of mitosis, the two sets of chromosomes are packaged into a pair of daughter nuclei. The first major event of telophase is the disassembly of the mitotic spindle, followed by

Figure 17–41 The two processes of anaphase in mammalian cells. (A) Separated sister chromatids move toward the poles in anaphase A. (B) In anaphase B, the two spindle poles move apart.

MBOC7_ptr_ch17_1027-1088.indd 1063 02/12/21 2:14 PM

the re-formation of the nuclear envelope. This process occurs in multiple stages. First, proteins on the surface of the chromosomes promote their interaction with each other, resulting in a compact cluster of all the chromosomes. Next, fragments of endoplasmic reticulum membrane containing inner nuclear-envelope proteins associate with the surface of the chromosome cluster, eventually fusing to re-form the complete nuclear envelope. Nuclear pore complexes are incorporated into the envelope, and the nuclear lamina re-forms. The pore complexes pump in nuclear proteins, the nucleus expands, and the mitotic chromosomes are reorganized into their less-condensed interphase state. A new nucleus has been created, and mitosis is complete. All that remains is for the cell to complete its division into two.

Summary

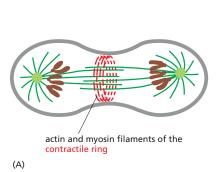

M-Cdk triggers the events of early mitosis, including chromosome condensation, assembly of the mitotic spindle, and bipolar attachment of the sister-chromatid pairs to microtubules of the spindle. Spindle assembly in animal cells depends on the nucleation of microtubules at multiple locations. Centrosomes, which are duplicated before mitosis and then separated in early mitosis, nucleate microtubules to help form the poles of the spindle. Spindle formation also depends on the ability of mitotic chromosomes to stimulate local microtubule formation and the ability of motor proteins to organize microtubules into a bipolar array. Anaphase is triggered by the APC/C, which stimulates the destruction of the proteins that hold the sister chromatids together. The APC/C also promotes cyclin destruction and thus the inactivation of M-Cdk. The resulting dephosphorylation of Cdk targets is required for the events that complete mitosis, including the disassembly of the spindle and the re-formation of the nuclear envelope.

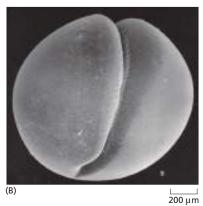

CYTOKINESIS

The final step in the cell cycle is **cytokinesis**, the division of the cytoplasm in two. In most cells, cytokinesis follows every mitosis, although some cells, such as early *Drosophila* embryos and some mammalian hepatocytes and heart muscle cells, undergo mitosis without cytokinesis and thereby acquire multiple nuclei. In most animal cells, cytokinesis begins in anaphase and ends shortly after the completion of mitosis in telophase.

Cytokinesis begins in an animal cell with the appearance of a *cleavage furrow* on the cell surface. The furrow rapidly deepens and spreads around the cell until it completely divides the cell in two. The structure underlying this process is the *contractile ring*—a dynamic assembly composed of actin filaments, myosin II filaments, and many structural and regulatory proteins. During anaphase, the ring assembles just beneath the plasma membrane (Figure 17–42; see also Panel 17–1). The ring gradually contracts, and, at the same time, fusion of intracellular vesicles

Figure 17–42 Cytokinesis. (A) The actinmyosin bundles of the contractile ring are oriented as shown, so that their contraction pulls the membrane inward. (B) In this low-magnification scanning electron micrograph of a cleaving frog egg, the cleavage furrow is especially prominent, as the cell is unusually large. The furrowing of the cell membrane is caused by the activity of the contractile ring underneath it. (C) The surface of a furrow at higher magnification. (B and C, from H.W. Beams and R.G. Kessel, Am. Sci. 64:279–290, 1976. With permission from Sigma Xi.)

CYTOKINESIS 1065

with the plasma membrane inserts new membrane. This addition of membrane compensates for the increase in surface area that accompanies cytoplasmic division. When ring contraction is completed, the contractile ring is disassembled, and the narrow membrane bridge between the daughter cells is severed.

Actin and Myosin II in the Contractile Ring Guide the Process of Cytokinesis

In interphase cells, actin and myosin II filaments form a cortical network underlying the plasma membrane. In some cells, they also form large cytoplasmic bundles called stress fibers (discussed in Chapter 16). As cells enter mitosis, these arrays of actin and myosin disassemble; much of the actin reorganizes, and myosin II filaments are released. As the sister chromatids separate in anaphase, actin and myosin II begin to accumulate in the rapidly assembling contractile ring (Figure 17-43), which also contains numerous other proteins that provide structural support or assist in ring assembly. Assembly of the contractile ring results in part from the local formation of new actin filaments, which depends on formin proteins that nucleate the assembly of parallel arrays of linear, unbranched actin filaments (discussed in Chapter 16). After anaphase, the overlapping arrays of actin and myosin II filaments contract to generate the force that divides the cytoplasm in two. Once contraction begins, the ring exerts a force large enough to bend a fine glass needle that is inserted in its path. As the ring constricts, it maintains the same thickness, suggesting that its total volume and the number of filaments it contains decrease steadily. Moreover, unlike actin in muscle, the actin filaments in the ring are highly dynamic, and their arrangement changes continually during cytokinesis.

The contractile ring is finally dispensed with altogether when cleavage ends and the plasma membrane of the cleavage furrow narrows to form the **midbody**. The midbody persists as a tether between the two daughter cells and contains the remains of the *central spindle*, a large protein structure derived from the antiparallel microtubules of the spindle midzone, packed tightly together within a dense matrix material (**Figure 17–44**). Cytokinesis is completed by a process called *abscission*: the membranes on both sides of the midbody are constricted and severed by filaments formed from a polymeric protein called ESCRT-III.

Local Activation of RhoA Triggers Assembly and Contraction of the Contractile Ring

RhoA, a small GTPase of the Ras superfamily (see Table 15–5), controls the assembly and function of the contractile ring at the site of cleavage. RhoA is attached to the inner surface of the cell membrane at the future division site, where it promotes actin filament formation, myosin II assembly, and ring contraction. It

Figure 17–43 The contractile ring.

(C) Fluorescence micrographs of a dividing slime mold amoeba stained for actin (red) and myosin II (green). Whereas all of the visible myosin II has redistributed to the contractile ring, only some of the actin has done so; the rest remains in the cortex of the nascent daughter cells. (B, from H.W. Beams and R.G. Kessel, Am. Sci. 64:279–290, 1976. With permission from Sigma Xi. C, courtesy of Yoshio Fukui.)

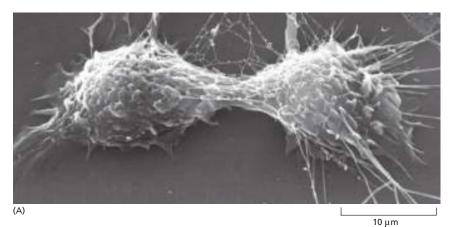

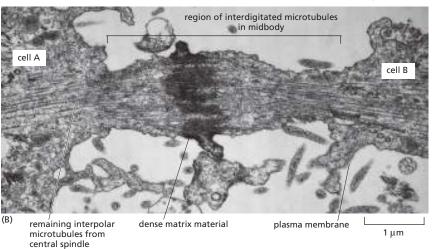

Figure 17–44 The midbody. (A) A scanning electron micrograph of a cultured animal cell dividing; the midbody still joins the two daughter cells. (B) A conventional electron micrograph of the midbody of a dividing animal cell. Cleavage is almost complete, but the daughter cells remain attached by this thin strand of cytoplasm containing the remains of the central spindle. Abscission results when the membranes on both sides of the dense midbody are constricted and severed. (A, courtesy of Guenter Albrecht-Buehler; B, courtesy of J.M. Mullins.)

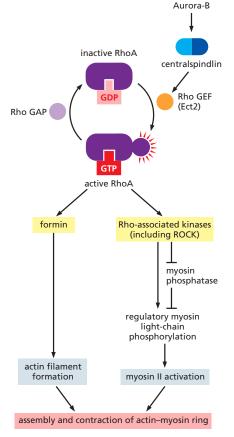

stimulates actin filament formation by activating formins, and it promotes myosin II assembly and contractions by activating multiple protein kinases, including the Rho-associated kinase (ROCK) (Figure 17–45). These kinases phosphorylate the regulatory myosin light chain, a subunit of myosin II, thereby stimulating bipolar myosin II filament formation and motor activity.

RhoA is activated by a guanine nucleotide exchange factor (GEF) called Ect2, which stimulates the release of GDP and binding of GTP to RhoA (see Figure 17–45). Ect2 is localized to the division site and activated by complex mechanisms involving spindle microtubules, as we discuss next.

The Microtubules of the Mitotic Spindle Determine the Plane of Animal Cell Division

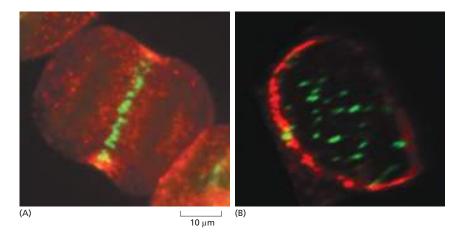

The central problem in cytokinesis is how to ensure that division occurs at the right time and in the right place. Cytokinesis must occur only after the two sets of chromosomes are fully segregated from each other, and the site of division must

Figure 17–45 Regulation of the contractile ring by the GTPase RhoA. Like other Rho family GTPases, RhoA is activated by a Rho GEF protein (called Ect2) and inactivated by a Rho GTPase-activating protein (Rho GAP). By binding formins, activated RhoA promotes the assembly of actin filaments in the contractile ring. By activating Rho-associated protein kinases, such as ROCK, it stimulates myosin II filament formation and activity, thereby promoting contraction of the ring. Activation of RhoA at the future cleavage site depends on Ect2 activation by another protein complex called centralspindlin, discussed in the next section.

human cell. (A) At center is a cultured human cell at the beginning of cytokinesis, showing the locations of the GTPase RhoA (red) and a protein called Cyk4 (green), which is one of two subunits of centralspindlin, a protein complex that is concentrated at the overlapping plus ends of antiparallel microtubules. (B) When the same three-dimensional image is viewed in the plane of the contractile ring, as shown here, RhoA (red) is seen as a ring beneath the cell surface, while the centralspindlin subunit Cyk4 (green) is associated with microtubule bundles scattered throughout the equatorial plane of the cell. Note that the small population of centralspindlin at the cell cortex is not readily detected in these images. (Courtesy of Alisa Piekny and Michael Glotzer.)

Figure 17–46 Localization of cytokinesis regulators at the central spindle of the

be placed between the two sets of daughter chromosomes, thereby ensuring that each daughter cell receives a complete set. The correct timing and positioning of cytokinesis in animal cells are achieved by mechanisms that depend on the mitotic spindle. During anaphase, the spindle generates signals that initiate furrow formation at a position midway between the spindle poles, thereby ensuring that division occurs between the two sets of separated chromosomes. Because these signals originate in the anaphase spindle, this mechanism also contributes to the correct timing of cytokinesis in late mitosis.

Studies of the fertilized eggs of marine invertebrates first revealed the importance of spindle microtubules in determining the placement of the contractile ring. After fertilization, these embryos cleave rapidly without intervening periods of growth. In this way, the original egg is progressively divided into smaller and smaller cells. Because the cytoplasm is clear, the spindle can be observed in real time with a microscope. If the spindle is tugged into a new position with a fine glass needle in early anaphase, the incipient cleavage furrow disappears, and a new one develops in accord with the new spindle site—supporting the idea that signals generated by the spindle induce local furrow formation.

How does the mitotic spindle specify the site of division? The key mechanism appears to be that the midzone of the anaphase spindle generates a signal that promotes furrow formation at the cell cortex. The central component of this regulatory system is a two-subunit protein complex called *centralspindlin*, which forms oligomeric assemblies that are concentrated primarily on the antiparallel microtubules at the spindle midzone (Figure 17–46). Centralspindlin assembly at the midzone is stimulated by the protein kinase Aurora-B, which also localizes to the spindle midzone in anaphase (see Figure 17–45). Aurora-B localization to the central spindle depends on dephosphorylation of Cdk substrates, providing one mechanism that delays cytokinesis until anaphase.

Centralspindlin interacts with the RhoA GEF, Ect2, to activate RhoA at the equatorial cell cortex, halfway between the spindle poles (Figure 17-47). In some cell types, small subpopulations of centralspindlin and Ect2 can be seen to migrate from the spindle midzone to the cell cortex, where Ect2 then interacts with RhoA to trigger furrow formation (see Figure 17-45). The focusing of centralspindlin and Ect2 at the equator depends in part on the ability of astral microtubules to somehow inhibit centralspindlin localization outside the equatorial region.

In some cell types, the site of ring assembly is chosen before mitosis. In budding yeasts, for example, a ring of proteins called septins assembles in late G_1 at the future division site. The septins are thought to form a scaffold onto which other components of the contractile ring, including myosin II, assemble. In plant cells, an organized band of microtubules and actin filaments, called the preprophase prep

MBOC7_ptr_ch17_1027-1088.indd 1067 02/12/21 2:14 PM

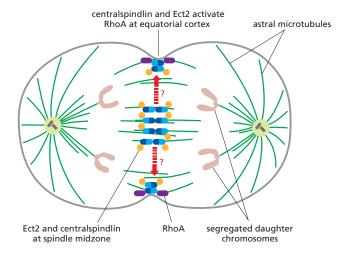

Figure 17–47 Activation of RhoA at the site of cleavage furrow formation. Centralspindlin multimers (blue) associate with the RhoA GEF, Ect2 (orange), at the spindle midzone. By uncertain mechanisms (dashed lines), some of these proteins move to the cortex at the equator of the cell, where they activate RhoA (purple) to trigger furrow formation. To focus the signal at the equator, the plus ends of astral microtubules use unknown mechanisms to inhibit the centralspindlin–Ect2 complex at other regions of the cortex.

The Phragmoplast Guides Cytokinesis in Higher Plants

In most animal cells, the inward movement of the cleavage furrow depends on an increase in the surface area of the plasma membrane. New membrane is added primarily at the cleavage furrow and is generally provided by small membrane vesicles that are transported on microtubules from the Golgi apparatus to the furrow.

Membrane deposition is particularly important for cytokinesis in higher-plant cells. These cells are enclosed by a semirigid *cell wall*. Rather than a contractile ring dividing the cytoplasm from the outside in, the cytoplasm of the plant cell is partitioned from the inside out by the construction of a new cell wall, called the **cell plate**, between the two daughter nuclei (**Figure 17–48**; **Figure 17–49**). The assembly of the cell plate begins in late anaphase and is guided by a structure called the **phragmoplast**, which contains microtubules derived from the mitotic

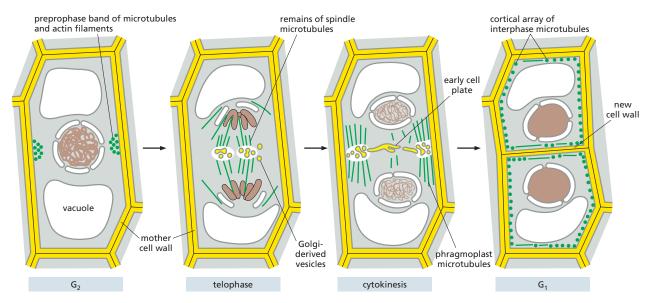

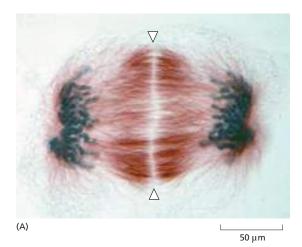

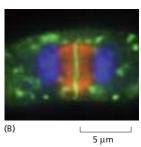

Figure 17–48 The special features of cytokinesis in a higher-plant cell. The division plane is established before M phase by a band of microtubules and actin filaments (the preprophase band) at the cell cortex. At the beginning of telophase, after the chromosomes have segregated, a new cell wall starts to assemble inside the cell at the equator of the old spindle. The microtubules of the mitotic spindle remaining at telophase form the phragmoplast. The plus ends of these microtubules no longer overlap but end at the cell equator. Golgi-derived vesicles, filled with cell-wall material, are transported along these microtubules and fuse to form the new cell wall, which grows outward to reach the plasma membrane and original cell wall. The plasma membrane and the membrane surrounding the new cell wall fuse, separating the two daughter cells.

MBOC7_ptr_ch17_1027-1088.indd 1068 02/12/21 2:14 PM

CYTOKINESIS 1069

spindle. Motor proteins transport small vesicles along these microtubules from the Golgi apparatus to the cell center. These vesicles, filled with polysaccharide and glycoproteins required for the synthesis of the new cell wall, fuse to form a disc-like, membrane-enclosed structure called the *early cell plate*. The plate expands outward by further vesicle fusion until it reaches the plasma membrane and the original cell wall and divides the cell in two. Later, cellulose microfibrils are laid down within the matrix of the cell plate to complete the construction of the new cell wall.

Membrane-enclosed Organelles Must Be Distributed to Daughter Cells During Cytokinesis

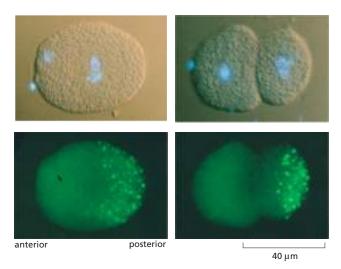

The process of mitosis ensures that each daughter cell receives a full complement of chromosomes. When a eukaryotic cell divides, however, each daughter cell must also inherit all of the other essential cell components, including the membrane-enclosed organelles. As discussed in Chapter 12, organelles such as mitochondria and chloroplasts cannot be assembled *de novo* from their individual components; they can arise only by the growth and division of the preexisting organelles. Similarly, cells cannot make a new endoplasmic reticulum (ER) unless some part of it is already present.

How, then, do the various membrane-enclosed organelles segregate when a cell divides? Organelles such as mitochondria and chloroplasts are usually present in large enough numbers to be safely inherited if, on average, their numbers roughly double once each cycle. The ER in interphase cells is continuous with the nuclear membrane and is organized by the microtubule cytoskeleton. Upon entry into M phase, the reorganization of the microtubules and breakdown of the nuclear envelope releases the ER. In most cells, the ER remains largely intact and is cut in two during cytokinesis. The Golgi apparatus is reorganized and fragmented during mitosis. Golgi fragments associate with the spindle poles and are thereby distributed to opposite ends of the spindle, ensuring that each daughter cell inherits the materials needed to reconstruct the Golgi in telophase.

Some Cells Reposition Their Spindle to Divide Asymmetrically

Most animal cells divide symmetrically: the contractile ring forms around the equator of the parent cell, producing two daughter cells of equal size and with the same components. This symmetry results from the placement of the mitotic spindle, which in most cases tends to center itself in the cytoplasm. Astral microtubules and motor proteins that either push or pull on these microtubules contribute to the centering process.

Figure 17-49 Cytokinesis in plant cells during telophase. (A) In this light micrograph, the early cell plate (between the two arrowheads) has formed in a plane perpendicular to the plane of the page. The microtubules of the spindle are stained with gold-labeled antibodies against tubulin, and the DNA in the two sets of daughter chromosomes is stained with a dark blue dye. Note that there are no astral microtubules, because there are no centrosomes in higher-plant cells. (B) In this fluorescence micrograph of a plant cell, DNA is stained blue and microtubules are red. A protein called Syntaxin (green) lies along the cell plate at the cell equator, where it is responsible for stimulating the fusion of Golgi vesicles delivering cell-wall materials. (A, courtesy of Andrew Bajer; B, from C.-M.K. Ho et al., Plant Cell 23:2909-2923, 2011. Republished with permission of American Society of Plant Biologists.)

There are many instances in development, however, when cells divide asymmetrically to produce two cells that differ in size, in the cytoplasmic contents they inherit, or in both. Usually, the two different daughter cells are destined to develop along different pathways. To create daughter cells with different fates in this way, the mother cell must first segregate certain components (called *cell-fate determinants*) to one side of the cell and then position the plane of division so that the appropriate daughter cell inherits these components (Figure 17–50). To position the plane of division asymmetrically, the spindle has to be moved in a controlled manner within the dividing cell. It seems likely that changes in local regions of the cell cortex direct such spindle movements and that motor proteins localized there pull one of the spindle poles, via its astral microtubules, to the appropriate region. Genetic analyses in *Caenorhabditis elegans* and *Drosophila* have identified some of the proteins required for such asymmetric divisions, and some of these proteins seem to have a similar role in vertebrates.

Mitosis Can Occur Without Cytokinesis

Although nuclear division is usually followed by cytoplasmic division, there are exceptions. Some cells undergo multiple rounds of nuclear division without intervening cytoplasmic division. In the early *Drosophila* embryo, for example, the first 13 rounds of nuclear division occur without cytoplasmic division, resulting in the formation of a single large cell containing several thousand nuclei that are arranged in a monolayer near the surface. A cell in which multiple nuclei share the same cytoplasm is called a **syncytium**. This arrangement greatly speeds up early development, as the cells do not have to take the time to go through all the steps of cytokinesis for each division. After these rapid nuclear divisions, membranes are created around each nucleus in one round of coordinated cytokinesis called *cellularization*. The plasma membrane extends inward and, with the help of an actin–myosin ring, pinches off to enclose each nucleus (Figure 17–51).

Nuclear division without cytokinesis also occurs in some types of mammalian cells. Megakaryocytes, which produce blood platelets, and some hepatocytes and muscle cells, for example, become multinucleated in this way.

Summary

After mitosis completes the formation of a pair of daughter nuclei, cytokinesis finishes the cell cycle by dividing the cell itself. Cytokinesis depends on a ring of actin and myosin filaments that contracts in late mitosis at a site midway between the segregated chromosomes. In animal cells, the positioning of the

Figure 17-50 An asymmetric cell division segregating cytoplasmic components to only one daughter cell. These light micrographs illustrate the controlled asymmetric segregation of specific cytoplasmic components to one daughter cell during the first division of a fertilized egg of the nematode C. elegans. The fertilized egg is shown in the left micrographs and the two daughter cells in the right micrographs. The cells above have been stained with a blue. DNA-binding, fluorescent dye to show the nucleus (and polar bodies); they are viewed by both differential-interference-contrast microscopy and fluorescence microscopy. The cells below are the same cells stained with an antibody against P-granules and viewed by fluorescence microscopy. These small granules are made of RNA and proteins and determine which cells become germ cells. They are distributed randomly throughout the cytoplasm of the unfertilized egg (not shown) but become segregated to the posterior pole of the fertilized egg. The cleavage plane is oriented to ensure that only the posterior daughter cell receives the P-granules when the egg divides. The same segregation process is repeated in several subsequent cell divisions, so that the P-granules end up only in cells that give rise to eggs and sperm. (Courtesy of Susan Strome.)

MEIOSIS 1071

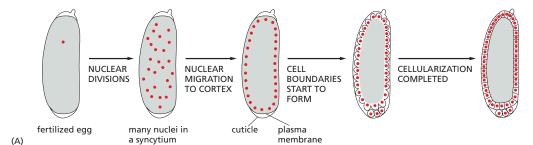

Figure 17–51 Mitosis without cytokinesis in the early *Drosophila* embryo. (A) The first 13 nuclear divisions occur synchronously and without cytoplasmic division to create a large syncytium. Most of the nuclei migrate to the cortex, and the plasma membrane extends inward and pinches off to surround each nucleus to form individual cells in a process called cellularization. (B) Fluorescence micrograph of multiple mitotic spindles in a *Drosophila* embryo before cellularization. The microtubules are stained *green* and the centrosomes *red*. Note that all the nuclei go through the cycle synchronously; here, they are all in metaphase, with the unlabeled chromosomes seen as a dark band at the spindle equator. (B, courtesy of Kristina Yu and William Sullivan.)

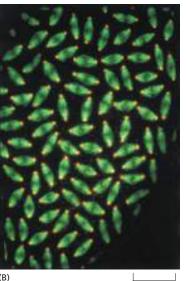

contractile ring is determined by proteins associated with the midzone microtubules of the anaphase spindle. Dephosphorylation of Cdk targets, which results from Cdk inactivation in anaphase, triggers cytokinesis at the correct time after anaphase.

MEIOSIS

Most eukaryotic organisms reproduce sexually: the genomes of two parents mix to generate offspring that are genetically distinct from either parent. The cells of these organisms are generally *diploid*; that is, they contain two slightly different copies, or *homologs*, of each chromosome, one from each parent. Sexual reproduction depends on a specialized nuclear division process called *meiosis*, which produces *haploid* cells carrying only a single copy of each chromosome. In many organisms, the haploid cells differentiate into specialized reproductive cells called *gametes*—eggs and sperm in most species. In these species, the reproductive cycle ends when a sperm and egg fuse to form a diploid *zygote*, which has the potential to form a new individual. In this section, we consider the basic mechanisms and regulation of meiosis, with an emphasis on how they compare with those of mitosis.

Meiosis Includes Two Rounds of Chromosome Segregation

Meiosis reduces the chromosome number by half using many of the same molecular machines and control systems that operate in mitosis. As in the mitotic cell cycle, the cell begins the meiotic program by duplicating its chromosomes in meiotic S phase, resulting in pairs of sister chromatids that are tightly linked along their entire lengths by cohesin complexes. Unlike mitosis, however, two successive rounds of chromosome segregation then occur (Figure 17-52). The first of these divisions (meiosis I) solves the problem, unique to meiosis, of segregating the homologs. The duplicated paternal and maternal homologs pair up alongside each other and become physically linked by the process of genetic recombination. These pairs of homologs, each containing a pair of sister chromatids, then line up on the first meiotic spindle. In the first meiotic anaphase, duplicated homologs rather than sister chromatids are pulled apart and segregated into the two daughter nuclei. Only in the second division (meiosis II), which occurs without further DNA replication, are the sister chromatids pulled apart and segregated (as in mitosis) to produce haploid daughter nuclei. In this way, each diploid nucleus that enters meiosis produces four haploid nuclei, each of which contains either the maternal or paternal copy of each chromosome, but not both (Movie 17.7).

10 μm

Figure 17–52 Comparison of meiosis and mitosis. For clarity, only one pair of homologous chromosomes (homologs) is shown. (A) Meiosis is a form of nuclear division in which a single round of chromosome duplication (meiotic S phase) is followed by two rounds of chromosome segregation. The duplicated homologs, each consisting of tightly bound sister chromatids, pair up and are segregated into different daughter nuclei in meiosis I; the sister chromatids are segregated in meiosis II. As indicated by the formation of chromosomes that are partly red and partly blue, homolog pairing in meiosis leads to genetic recombination (crossing-over) during meiosis I. Each diploid cell that enters meiosis therefore produces four genetically different haploid nuclei, which are distributed by cytokinesis into haploid cells that differentiate into gametes. (B) In mitosis, by contrast, homologs do not pair up, and the sister chromatids are segregated during the single division. Thus, each diploid cell that divides by mitosis produces two genetically identical diploid daughter nuclei, which are distributed by cytokinesis into a pair of daughter cells.

MBOC7_ptr_ch17_1027-1088.indd 1072 02/12/21 2:14 PM

MEIOSIS 1073

Duplicated Homologs Pair During Meiotic Prophase

During mitosis in most organisms, homologous chromosomes behave independently of each other. During meiosis I, however, it is crucial that homologs recognize each other and associate physically in order for the maternal and paternal homologs to be bi-oriented on the first meiotic spindle. Special mechanisms mediate these interactions.

The gradual juxtaposition of homologs occurs during a prolonged period called meiotic prophase (or prophase I), which can take hours in yeasts, days in mice, and weeks in higher plants. Like their mitotic counterparts, duplicated meiotic prophase chromosomes first appear as long threadlike structures, in which the sister chromatids are so tightly glued together that they appear as one. It is during early prophase I that the homologs begin to associate along their length in a process called pairing, which, in some organisms at least, begins with interactions between complementary DNA sequences (called pairing sites) in the two homologs. As prophase progresses, the homologs become more closely juxtaposed, forming a four-chromatid structure called a bivalent (Figure 17–53A). In most species, homolog pairs are then locked together by homologous recombination: DNA double-strand breaks are formed at several locations in each sister chromatid, resulting in large numbers of DNA recombination events between the homologs (as described in Chapter 5). Some of these events lead to reciprocal DNA exchanges called crossovers, where the DNA of a chromatid crosses over to become continuous with the DNA of a homologous chromatid (Figure 17-53B; also see Figure 5-53).

Homolog Pairing Culminates in the Formation of a Synaptonemal Complex

The paired homologs are brought into close juxtaposition, with their structural axes (*axial cores*) about 400 nm apart, by a mechanism that depends in most species on the double-strand DNA breaks that occur in sister chromatids. What pulls the axes together? One possibility is that the large protein machine, called a *recombination complex*, which assembles on a double-strand break in a chromatid, binds the matching DNA sequence in the nearby homolog and helps reel in this partner. This so-called *presynaptic alignment* of the homologs is followed by *synapsis*, in which the axial core of a homolog becomes tightly linked to the axial core of its partner by a closely packed array of *transverse filaments* to create a **synaptonemal complex**, which bridges the gap, now only 100 nm, between the homologs (**Figure 17–54**). Although crossing-over begins

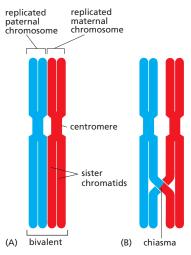

Figure 17-53 Homolog pairing and crossing-over. (A) The structure formed by two closely aligned duplicated homologs is called a bivalent. As in mitosis, the sister chromatids in each homolog are tightly connected along their entire lengths and at their centromeres. At this stage, the homologs are usually joined by a protein complex called the synaptonemal complex (not shown; see Figure 17-54). (B) A later-stage bivalent in which a single crossover has occurred between nonsister chromatids. It is only when the synaptonemal complex disassembles and the paired homologs separate a little at the end of prophase I, as shown, that the crossover is seen microscopically as a thin connection between the homologs called a chiasma.

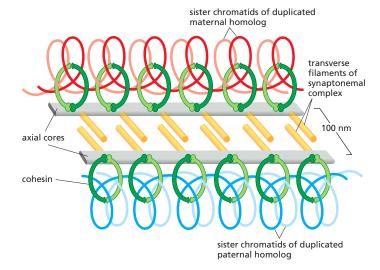

Figure 17–54 Simplified schematic drawing of a synaptonemal complex. Each homolog is organized around a protein axial core, and the synaptonemal complex forms when these homolog axes are linked by rod-shaped transverse filaments. The axial core of each homolog also interacts with the cohesin complexes that hold the sister chromatids together (see Figure 9–28). (Modified from K. Nasmyth, *Annu. Rev. Genet.* 35:673–745, 2001.)

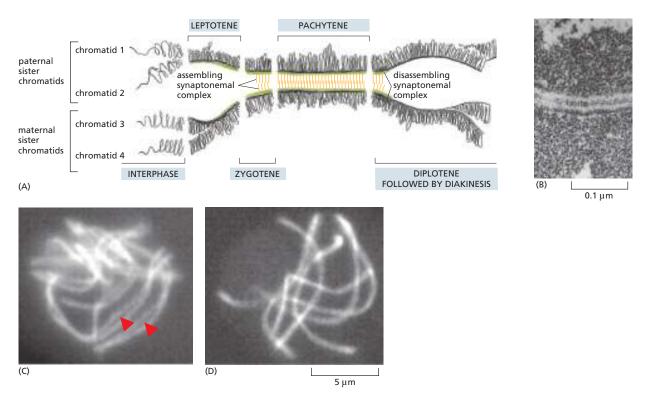

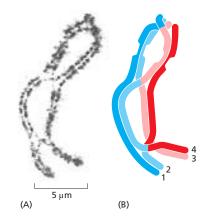

Figure 17–55 Homolog synapsis and desynapsis during the different stages of prophase I. (A) A single bivalent is shown schematically. At leptotene, the two sister chromatids coalesce, and their chromatid loops extend out from a common axial core. Assembly of the synaptonemal complex begins in early zygotene and is complete in pachytene. The complex disassembles in diplotene. (B) An electron micrograph of a synaptonemal complex from a meiotic cell at pachytene in a lily flower. (C and D) Immunofluorescence micrographs of prophase I cells of the fungus Sordaria. Partially synapsed bivalents at zygotene are shown in C and fully synapsed bivalents are shown in D. Red arrowheads in C point to regions where synapsis is still incomplete. (B, courtesy of Brian Wells; C and D, from A. Storlazzi et al., Genes Dev. 17:2675–2687, 2003. With permission from Cold Spring Harbor Laboratory Press.)

before the synaptonemal complex assembles, the final steps occur while the DNA is held in the complex.

The morphological changes that occur during homolog pairing are the basis for dividing meiotic prophase into five sequential stages—leptotene, zygotene, pachytene, diplotene, and diakinesis (Figure 17–55). Prophase starts with *leptotene*, when homologs condense and pair and genetic recombination begins. At *zygotene*, the synaptonemal complex begins to assemble at sites where the homologs are closely associated and recombination events are occurring. At *pachytene*, the assembly process is complete, and the homologs are synapsed along their entire lengths (see Figure 9–28). The pachytene stage can persist for days or longer, until desynapsis begins at *diplotene* with the disassembly of the synaptonemal complex and the concomitant condensation and shortening of the chromosomes. It is only at this stage, after the complex has disassembled, that the individual crossover events between nonsister chromatids can be seen as inter-homolog connections called **chiasmata** (singular, **chiasma**), which now play a crucial part in holding the compact homologs together (Figure 17–56). The homologs are now ready to begin the process of segregation.

Figure 17–56 A bivalent with three chiasmata resulting from three crossover events. (A) Light micrograph of a grasshopper bivalent. (B) Schematic of the three crossovers shown in A. Each sister chromatid is numbered. Note how the combination of the chiasmata and the tight attachment of the sister chromatid arms to each other (mediated by cohesin complexes) holds the two homologs together after the synaptonemal complex has disassembled; if either the chiasmata or the sister-chromatid cohesion failed to form, the homologs would come apart at this stage and not be segregated properly in meiosis I. (A, courtesy of Bernard John.)

MEIOSIS 1075

Homolog Segregation Depends on Several Unique Features of Meiosis I

A fundamental difference between meiosis I and mitosis (and meiosis II) is that in meiosis I, homologs rather than sister chromatids separate and then segregate (see Figure 17–52). This difference depends on three features of meiosis I that distinguish it from mitosis (Figure 17–57).

First, both sister kinetochores in a homolog must attach stably to the same spindle pole. This type of attachment is normally avoided during mitosis (see Figure 17–35). In meiosis I, however, the two sister kinetochores are fused into a single microtubule-binding unit that attaches to just one pole (see Figure 17–57A). The fusion of sister kinetochores is achieved by a complex of proteins that is localized at the kinetochores in meiosis I, but we do not know in any detail how these proteins work. They are removed from kinetochores after meiosis I, so that in meiosis II the sister-chromatid pairs can be bi-oriented on the spindle as they are in mitosis.

Second, crossovers generate a strong physical linkage between homologs, allowing their bi-orientation at the equator of the spindle—much like cohesion between sister chromatids is important for their bi-orientation in mitosis (and meiosis II). Crossovers hold homolog pairs together only because the

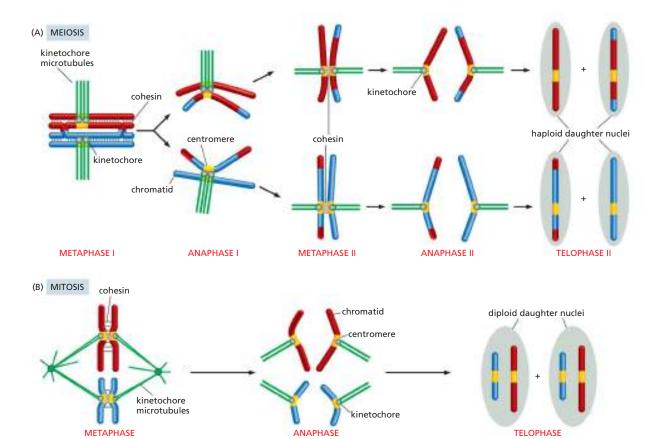

Figure 17–57 Comparison of chromosome behavior in meiosis I, meiosis II, and mitosis. Chromosomes behave similarly in mitosis and meiosis II, but they behave very differently in meiosis I. (A) In meiosis I, the two sister kinetochores are located side-by-side on each homolog and attach to microtubules from the same spindle pole. The proteolytic cleavage of cohesin along the sister-chromatid arms unglues the arms and resolves the crossovers, allowing the duplicated homologs to separate at anaphase I, while the residual cohesin at the centromeres keeps the sisters together. Cleavage of centromeric cohesin allows the sister chromatids to separate at anaphase II. (B) In mitosis, by contrast, the two sister kinetochores attach to microtubules from different spindle poles, and the two sister chromatids come apart at the start of anaphase and segregate into separate daughter nuclei.

arms of the sister chromatids are connected by sister-chromatid cohesion (see Figure 17–57A).

Third, cohesin is removed in anaphase I only from chromosome arms and not from the regions near the centromeres, where the kinetochores are located. The loss of arm cohesion triggers homolog separation at the onset of anaphase I. This process depends on APC/C activation, which leads to securin destruction, separase activation, and cohesin cleavage along the arms (see Figure 17–39).

Cohesins near the centromeres are protected from separase in meiosis I by a kinetochore-associated protein called *shugoshin* (from the Japanese word for "guardian spirit"). Shugoshin acts by recruiting a protein phosphatase that removes phosphates from centromeric cohesins. Cohesin phosphorylation is normally required for separase to cleave cohesin; thus, removal of this phosphorylation near the centromere prevents cohesin cleavage. Sister-chromatid pairs therefore remain linked through meiosis I, allowing their correct bi-orientation on the spindle in meiosis II. Shugoshin is inactivated after meiosis I. At the onset of anaphase II, APC/C activation triggers centromeric cohesin cleavage and sister-chromatid separation—much as it does in mitosis. After anaphase II, nuclear envelopes form around the chromosomes to produce four haploid nuclei, after which cytokinesis and other differentiation processes lead to the production of haploid gametes.

Crossing-Over Is Highly Regulated

Crossing-over has two distinct functions in meiosis: it helps hold homologs together so that they are properly segregated to the two daughter nuclei produced by meiosis I, and it contributes to the genetic diversification of the gametes that are eventually produced. As might be expected, therefore, crossing-over is highly regulated: the number and location of double-strand breaks along each chromosome are controlled, as is the likelihood that a break will be converted into a crossover. On average, the result of this regulation is that each pair of human homologs is linked by about two or three crossovers (Figure 17–58).

Although the double-strand breaks that occur in meiosis I can be located almost anywhere along the chromosome, they are not distributed uniformly: they cluster at "hot spots," where the DNA is accessible, and occur only rarely in "cold spots," such as the heterochromatin regions around centromeres and telomeres.

At least two kinds of regulation influence the location and number of crossovers that form, neither of which is well understood. Both operate before the synaptonemal complex assembles. One ensures that at least one crossover forms between the members of each homolog pair, as is necessary for normal homolog

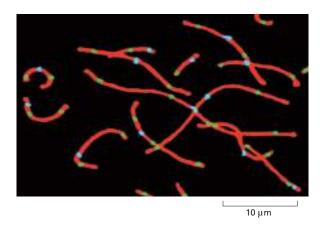

Figure 17–58 Crossovers between homologs in the human testis. In these immunofluorescence micrographs, antibodies were used to stain the synaptonemal complexes (red), the centromeres (blue), and the sites of crossing-over (green). Note that all of the bivalents have at least one crossover and none have more than four. (Modified from A. Lynn et al., Science 296:2222–2225, 2002. With permission from AAAS.)

segregation in meiosis I. In the other, called *crossover interference*, the presence of one crossover event inhibits another from forming close by, perhaps by locally depleting proteins required for converting a double-strand DNA break into a stable crossover.

Meiosis Frequently Goes Wrong

The sorting of chromosomes that takes place during meiosis is a remarkable feat of intracellular bookkeeping. In humans, each meiosis requires that the starting cell keep track of 92 chromatids (46 chromosomes, each of which has duplicated), distributing one complete set of each type of autosome to each of the four haploid progeny. Not surprisingly, mistakes can occur in allocating the chromosomes during this elaborate process. Mistakes are especially common in human female meiosis, which arrests for years after diplotene: meiosis I is completed only at *ovulation*, and meiosis II only after the egg is fertilized. Indeed, such chromosome segregation errors during egg development are the most common cause of spontaneous abortion (miscarriage) and intellectual disability in humans.

When homologs fail to separate properly—a phenomenon called **nondisjunction**—the result is that some of the resulting haploid gametes lack a particular chromosome, while others have more than one copy of it. Upon fertilization, these gametes form abnormal embryos, most of which die. Some survive, however. *Down syndrome* in humans, for example, which is the leading cause of intellectual disability, is caused by an extra copy of chromosome 21, usually resulting from nondisjunction during meiosis I in the female ovary. Segregation errors during meiosis I increase greatly with advancing maternal age.

Summary

Haploid gametes are produced by meiosis, in which a diploid nucleus undergoes two successive cell divisions after one round of DNA replication. Meiosis is dominated by a prolonged prophase. At the start of prophase, the chromosomes have replicated and consist of two tightly joined sister chromatids. Homologous chromosomes then pair up and become progressively more closely juxtaposed as prophase proceeds. The tightly aligned homologs undergo genetic recombination, forming crossovers that help hold each pair of homologs together during metaphase I. Meiosis-specific, kinetochore-associated proteins help ensure that both sister chromatids in a homolog attach to the same spindle pole; other kinetochore-associated proteins ensure that the homologs remain connected at their centromeres during anaphase I, so that homologs rather than sister chromatids are segregated in meiosis I. After meiosis I, meiosis II follows rapidly, without DNA replication, in a process that resembles mitosis, in that sister chromatids are pulled apart at anaphase.

CONTROL OF CELL DIVISION AND CELL GROWTH

A fertilized mouse egg and a fertilized human egg are similar in size, yet they produce animals of very different sizes. What factors in the control of cell behavior in humans and mice are responsible for these size differences? The same fundamental question can be asked for each organ and tissue in an animal's body. What factors determine the length of an elephant's trunk or the size of its brain or its liver? These questions are largely unanswered, but it is nevertheless possible to say what the ingredients of an answer must be.

The size of an organ or organism depends on its total cell mass, which depends on both the total number of cells and their size. Cell number, in turn, depends on the rates of cell division and cell death. Organ and body size are therefore determined by three fundamental processes: cell growth, cell division, and cell survival. Each is tightly regulated—both by intracellular programs and by extracellular signal molecules that control these programs.

MBOC7_ptr_ch17_1027-1088.indd 1077 02/12/21 2:14 PM

The extracellular signal molecules that regulate cell growth, division, and survival are generally soluble secreted proteins, proteins bound to the surface of cells, or components of the extracellular matrix. They can be divided operationally into three major classes:

- Mitogens, which stimulate cell division, primarily by triggering a wave of G₁/S-Cdk activity that relieves intracellular negative controls that otherwise block progress through the cell cycle.
- Growth factors, which stimulate cell growth (an increase in cell mass) by promoting the synthesis of proteins and other macromolecules and by inhibiting their degradation.
- 3. *Survival factors*, which promote cell survival by suppressing the form of programmed cell death known as *apoptosis*.

Many extracellular signal molecules promote all of these processes, while others promote one or two of them. Indeed, the term "growth factor" is often used inappropriately to describe a factor that has any of these activities. Even worse, the term "cell growth" is often used to mean an increase in cell number, or *cell proliferation*.

In addition to these three classes of stimulating signals, there are extracellular signal molecules that suppress cell proliferation, cell growth, or both. There are also extracellular signal molecules that activate apoptosis.

In this section, we focus primarily on how mitogens and other factors, such as DNA damage, control the rate of cell division. We then turn to the important but poorly understood problem of how a proliferating cell coordinates its growth with cell division so as to maintain its appropriate size. We discuss the control of cell survival and cell death by apoptosis in Chapter 18.

Mitogens Stimulate Cell Division

Unicellular organisms tend to grow and divide as fast as they can, and their rate of proliferation depends largely on the availability of nutrients in the environment. The cells of a multicellular organism, however, divide only when the organism needs more cells. Thus, for an animal cell to proliferate, it must receive stimulatory extracellular signals, in the form of **mitogens**, from other cells, usually its neighbors. Mitogens overcome intracellular braking mechanisms that block progress through the cell cycle.

More than 50 animal proteins are known to act as mitogens. Most of these proteins have a broad specificity. *Platelet-derived growth factor (PDGF)*, for example, can stimulate many types of cells to divide, including fibroblasts, smooth muscle cells, and neuroglial cells. Similarly, *epidermal growth factor (EGF)* acts not only on epidermal cells but also on many other cell types, including both epithelial and nonepithelial cells. Some mitogens, however, have a narrow specificity: *erythropoietin*, for example, only induces the proliferation of red blood cell precursors. Many mitogens, including PDGF, also have actions other than the stimulation of cell division: they can stimulate cell growth, survival, differentiation, or migration, depending on the circumstances and the cell type.

In some tissues, inhibitory extracellular signal proteins oppose the positive regulators and thereby inhibit organ growth. The best-understood inhibitory signal proteins are transforming growth factor- β (TGF β) and its relatives. TGF β inhibits the proliferation of several cell types, mainly by blocking cell-cycle progression in G_1 .

Cells Can Enter a Specialized Nondividing State

In the absence of a mitogenic signal to proliferate, Cdk inhibition in G_1 is maintained by the multiple mechanisms discussed earlier, and progression into a new cell cycle is blocked. In some cases, cells partly disassemble their cell-cycle control system and withdraw from the cycle to a specialized nondividing state called G_0 .

Most cells in our body are in G_0 , but the molecular basis and reversibility of this state vary in different cell types. Most of our neurons and skeletal muscle

MBOC7_ptr_ch17_1027-1088.indd 1078 02/12/21 2:14 PM

cells, for example, are in a *terminally differentiated* G_0 state, in which their cell-cycle control system is completely dismantled: the expression of the genes encoding various Cdks and cyclins is permanently turned off, and cell division rarely occurs. Some cell types withdraw from the cell cycle only transiently and retain the ability to reassemble the cell-cycle control system quickly and reenter the cycle. Most liver cells, for example, are in G_0 , but they can be stimulated to divide if the liver is damaged. Still other types of cells, including fibroblasts and some lymphocytes, withdraw from and reenter the cell cycle repeatedly throughout their lifetime.

Almost all the variation in cell-cycle length in the adult body occurs during the time the cell spends in G_1 or G_0 . By contrast, the time a cell takes to progress from the beginning of S phase through mitosis is usually brief (typically 12–24 hours in mammals) and relatively constant, regardless of the interval from one division to the next.

Mitogens Stimulate G₁-Cdk and G₁/S-Cdk Activities

For the vast majority of animal cells, mitogens control the rate of cell division by acting in the G_1 phase of the cell cycle. As discussed earlier, multiple mechanisms act during G_1 to suppress Cdk activity. Mitogens release these brakes on Cdk activity, thereby allowing entry into a new cell cycle.

As we discuss in Chapter 15, mitogens interact with cell-surface receptors to trigger multiple intracellular signaling pathways. One major pathway acts through the monomeric GTPase ${\bf Ras}$, which leads to the activation of a *mitogenactivated protein kinase* (${\it MAP kinase}$) cascade (see Figure 15–50). This leads to an increase in the production of transcription regulatory proteins, including ${\bf Myc}$. Myc is thought to promote cell-cycle entry by several mechanisms, one of which is to increase the expression of genes encoding ${\bf G_1}$ -cyclins (D cyclins), thereby increasing ${\bf G_1}$ -Cdk (cyclin D-Cdk4) activity. Myc also has a major role in stimulating the transcription of genes that increase cell growth.

The key function of G_1 -Cdk complexes in animal cells is to activate a group of gene regulatory factors called the **E2F proteins**, which bind to specific DNA sequences in the promoters of a wide variety of genes that encode proteins required for S-phase entry, including G_1 /S-cyclins, S-cyclins, and proteins involved in DNA synthesis and chromosome duplication. In the absence of mitogenic stimulation, E2F-dependent gene expression is inhibited by an interaction between E2F and members of the **retinoblastoma protein** (**Rb**) family. When cells are stimulated to divide by mitogens, active G_1 -Cdk accumulates and phosphorylates Rb family members, reducing their binding to E2F. The liberated E2F proteins then activate expression of their target genes (**Figure 17–59**).

This transcriptional control system, like so many other control systems that regulate the cell cycle, includes feedback loops that ensure that entry into the cell cycle is complete and irreversible. The liberated E2F proteins, for example, increase the transcription of their own genes. In addition, E2F-dependent transcription of G_1/S -cyclin (cyclin E) and S-cyclin (cyclin A) genes leads to increased G_1/S -Cdk and S-Cdk activities, which in turn increase Rb protein phosphorylation and promote further E2F release (see Figure 17–59).

The central member of the Rb family, the Rb protein itself, was identified originally through studies of an inherited form of eye cancer in children, known as retinoblastoma (discussed in Chapter 20). The loss of both copies of the Rb gene leads to excessive proliferation of some cells in the developing retina, suggesting that the Rb protein is particularly important for restraining cell division in this tissue. The complete loss of Rb does not immediately cause increased proliferation of retinal or other types of cells, in part because Cdh1 and CKIs also help inhibit progression through G_1 and in part because other cell types contain Rb-related proteins that provide backup support in the absence of Rb. It is also likely that other proteins, unrelated to Rb, help to regulate the activity of E2F.

Additional layers of control promote an overwhelming increase in S-Cdk activity at the beginning of S phase. We mentioned earlier that the APC/C

MBOC7_ptr_ch17_1027-1088.indd 1079 02/12/21 2:14 PM

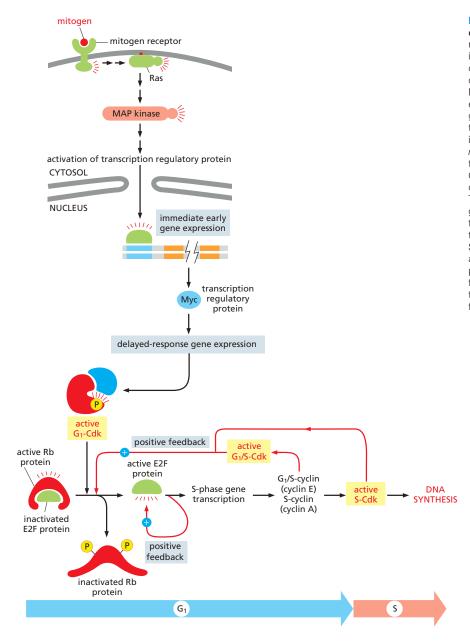

Figure 17-59 Mitogen stimulation of cellcycle entry. As discussed in Chapter 15, mitogens bind to cell-surface receptors to initiate intracellular signaling pathways. One of the major pathways involves activation of the small GTPase Ras, which activates a MAP kinase cascade, leading to increased expression of numerous immediate early genes, including the gene encoding the transcription regulatory protein Myc. Myc increases the expression of many delayedresponse genes, including some that lead to increased G₁-Cdk activity (cyclin D-Cdk4), which triggers the phosphorylation of members of the Rb family of proteins. This inactivates the Rb proteins, freeing the gene regulatory protein E2F to activate the transcription of G₁/S genes, including the genes for a G₁/S-cyclin (cyclin E) and S-cyclin (cyclin A). The resulting G₁/S-Cdk and S-Cdk activities further enhance Rb protein phosphorylation, forming a positive feedback loop. E2F proteins also stimulate the transcription of their own genes, forming another positive feedback loop.

activator Cdh1 suppresses cyclin levels after mitosis. In animal cells, however, $G_1\text{-}$ and $G_1/S\text{-}$ cyclins are resistant to APC/C–Cdh1 and can therefore act unopposed by the APC/C to promote Rb protein phosphorylation and E2F-dependent gene expression. S-cyclin, by contrast, is not resistant, and its level is initially restrained by APC/C–Cdh1 activity. However, $G_1/S\text{-}$ Cdk also phosphorylates and inactivates APC/C–Cdh1, thereby allowing the accumulation of S-cyclin, further promoting S-Cdk activation. $G_1/S\text{-}$ Cdk also inactivates CKI proteins that suppress S-Cdk activity. The overall effect of all these interactions is the rapid and complete activation of the S-Cdk complexes required for S-phase initiation.

DNA Damage Blocks Cell Division

Progression through the cell cycle, and thus the rate of cell proliferation, is controlled not only by extracellular mitogens but also by other extracellular and intracellular signals. One of the most important influences is DNA damage,

MBOC7_ptr_ch17_1027-1088.indd 1080 02/12/21 2:14 PM

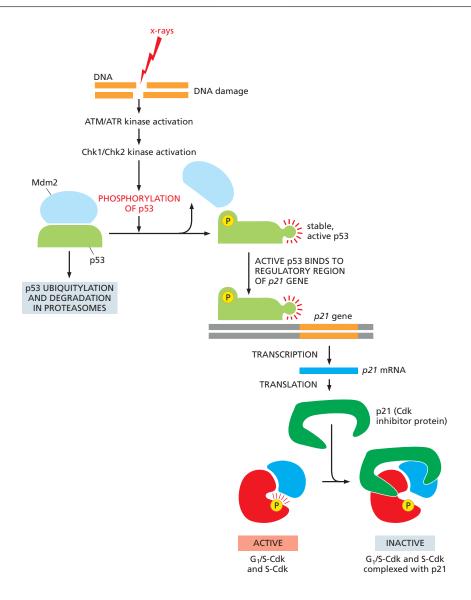

Figure 17-60 How DNA damage arrests the cell cycle in G1. When DNA is damaged, various protein kinases are recruited to the site of damage and initiate a signaling pathway that causes cell-cycle arrest. The first kinase at the damage site is either ATM or ATR, depending on the type of damage. Additional protein kinases, called Chk1 and Chk2, are then recruited and activated, resulting in the phosphorylation of the transcription regulatory protein p53. Mdm2 normally binds to p53 and promotes its ubiquitylation and destruction in proteasomes. Phosphorylation of p53 blocks its binding to Mdm2; as a result, p53 accumulates to high levels and stimulates transcription of numerous genes, including the gene that encodes the CKI protein p21. The p21 binds and inactivates G₁/S-Cdk and S-Cdk complexes, arresting the cell in G₁. In some cases, DNA damage also induces either the phosphorylation of Mdm2 or a decrease in Mdm2 production, which causes a further increase in p53 (not shown).

which can occur as a result of spontaneous chemical reactions in DNA, errors in DNA replication, or exposure to radiation or certain chemicals (discussed in Chapter 5). It is essential that damaged chromosomes are repaired before attempting to duplicate or segregate them. The cell-cycle control system can readily detect DNA damage and arrest the cycle at either of two transitions—one at Start, which prevents entry into the cell cycle and into S phase, and one at the G_2/M transition, which prevents entry into mitosis (see Figure 17–20).

DNA damage initiates a signaling pathway by activating one of a pair of related protein kinases called **ATM** and **ATR**, which associate with the site of damage and phosphorylate various target proteins, including two other protein kinases called Chk1 and Chk2. These various kinases phosphorylate other target proteins that lead to cell-cycle arrest. A major target is the gene regulatory protein **p53**, which stimulates transcription of the gene encoding p21, a CKI protein; p21 binds to G_1/S -Cdk and S-Cdk complexes and inhibits their activities, thereby helping to block entry into the cell cycle (**Figure 17–60** and **Movie 17.8**).

DNA damage activates p53 by an indirect mechanism. In undamaged cells, p53 is highly unstable and is present at very low concentrations. This is largely because it interacts with another protein, *Mdm2*, which acts as a ubiquitin ligase that targets p53 for destruction by proteasomes. Phosphorylation of p53 after

MBOC7_ptr_ch17_1027-1088.indd 1081 02/12/21 2:14 PM

DNA damage reduces its binding to Mdm2. This decreases p53 degradation, which results in a marked increase in p53 concentration in the cell. In addition, the decreased binding to Mdm2 enhances the ability of p53 to stimulate gene transcription (see Figure 17–60).

The protein kinases Chk1 and Chk2 also block cell-cycle progression by phosphorylating members of the Cdc25 family of protein phosphatases, thereby inhibiting their function. As described earlier, these phosphatases are particularly important in the activation of M-Cdk at the beginning of mitosis (see Figure 17–16). Chk1 and Chk2 phosphorylate Cdc25 at inhibitory sites that are distinct from the phosphorylation sites that stimulate Cdc25 activity. The inhibition of Cdc25 activity by DNA damage helps block entry into mitosis (see Figure 17–20).

The DNA damage response can also be activated by problems that arise when a replication fork fails during DNA replication. When nucleotides are depleted, for example, replication forks stall during the elongation phase of DNA synthesis. To prevent the cell from attempting to segregate partially replicated chromosomes, the same mechanisms that respond to DNA damage detect the stalled replication forks and block entry into mitosis until the problems are resolved.

A low level of DNA damage occurs in the normal life of any cell, and this damage accumulates in the cell's progeny if the DNA damage response is not functioning. Over the long term, the accumulation of genetic damage in cells lacking the DNA damage response leads to an increased frequency of cancerpromoting mutations. Indeed, mutations in the *p53* gene occur in at least half of all human cancers (discussed in Chapter 20). This loss of p53 function allows the cancer cell to accumulate mutations more readily. Similarly, a rare genetic disease known as *ataxia telangiectasia* is caused by a defect in ATM, one of the protein kinases that are activated in response to x-ray-induced DNA damage; people with this disease are very sensitive to x-rays and suffer from increased rates of cancer.

What happens if DNA damage is so severe that repair is not possible? The answer differs in different organisms. Unicellular organisms such as budding yeast arrest their cell cycle to try to repair the damage, but the cycle resumes even if the repair cannot be completed. For a single-celled organism, life with mutations is apparently better than no life at all. In multicellular organisms, however, the health of the organism takes precedence over the life of an individual cell. Cells that divide with severe DNA damage threaten the life of the organism, as genetic damage can often lead to cancer and other diseases. Thus, animal cells with severe DNA damage do not attempt to continue division, but instead commit suicide by undergoing apoptosis. Thus, unless the DNA damage is repaired, the DNA damage response can lead to either cell-cycle arrest or cell death. DNA damage-induced apoptosis often depends on the activation of p53.

Many Human Cells Have a Built-In Limitation on the Number of Times They Can Divide

Many human cells divide a limited number of times before they stop and undergo a permanent cell-cycle arrest. Fibroblasts taken from normal human tissue, for example, go through only about 25–50 population doublings when cultured in a standard mitogenic medium. Toward the end of this time, proliferation slows down and finally halts, and the cells enter a nondividing state from which they never recover. This phenomenon is called **replicative cell senescence**.

Replicative cell senescence in human fibroblasts seems to be caused by changes in the structure of the **telomeres**, the repetitive DNA sequences and associated proteins at the ends of chromosomes. As discussed in Chapter 5, when a cell divides, telomeric DNA sequences are not replicated in the same manner as the rest of the genome but instead are synthesized by the enzyme **telomerase**. Telomerase also promotes the formation of protein cap structures that protect the chromosome ends. Because human fibroblasts, and many other human somatic cells, do not produce telomerase, their telomeres become shorter with every cell division, and their protective protein caps progressively deteriorate. Eventually,

MBOC7_ptr_ch17_1027-1088.indd 1082 02/12/21 2:14 PM

the exposed chromosome ends are sensed as DNA damage, which activates a p53-dependent cell-cycle arrest (see Figure 17-60). Rodent cells, by contrast, maintain telomerase activity when they proliferate in culture and therefore do not have such a telomere-dependent mechanism for limiting proliferation. The forced expression of telomerase in normal human fibroblasts, using genetic engineering techniques, blocks this form of senescence. Unfortunately, most cancer cells have regained the ability to produce telomerase and therefore maintain telomere function as they proliferate; as a result, they do not undergo replicative cell senescence.

Cell Proliferation Is Accompanied by Cell Growth

If cells proliferated without growing, they would get progressively smaller and there would be no net increase in total cell mass. In most proliferating cell populations, therefore, cell growth accompanies cell division. In single-celled organisms such as yeasts, both cell growth and cell division require only nutrients. In animals, by contrast, both cell growth and cell proliferation depend on extracellular signal molecules, produced by other cells, which we call **growth factors** and mitogens, respectively.

Like mitogens, the extracellular growth factors that stimulate animal cell growth bind to receptors on the cell surface and activate intracellular signaling pathways. These pathways stimulate the accumulation of proteins and other macromolecules, and they do so by both increasing their rate of synthesis and decreasing their rate of degradation. They also trigger increased uptake of nutrients and production of the ATP required to fuel the increased protein synthesis. One of the most important intracellular signaling pathways activated by growth factor receptors involves the enzyme phosphoinositide 3-kinase (*PI 3-kinase*), which adds a phosphate from ATP to the 3' position of inositol phospholipids in the plasma membrane (discussed in Chapter 15). The activation of PI 3-kinase leads to the activation of a protein kinase called *mTORC1*, which lies at the heart of cell growth regulatory pathways in all eukaryotes (see Figure 15–55). mTORC1 activates many targets in the cell that stimulate metabolic processes, including protein and lipid synthesis, or reduce protein turnover (Figure 17–61).

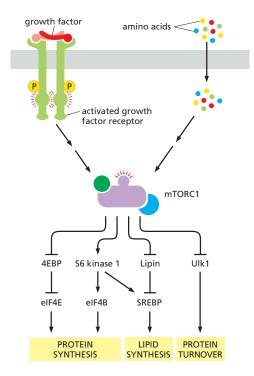

Figure 17-61 Stimulation of cell growth by extracellular growth factors and nutrients. The occupation of cell-surface receptors by growth factors leads to the activation of a complex signaling pathway that results in the activation of the multisubunit protein kinase mTORC1 (see Figure 15-55). Cytosolic amino acids also help activate mTORC1. mTORC1 phosphorylates multiple proteins, including 4EBP and the protein kinase S6 kinase 1 (S6K1), to stimulate the activity of the translation initiation factors elF4E and elF4B, thereby stimulating protein synthesis, mTORC1 also acts through S6K1, as well as another protein called Lipin, to activate a transcription regulator called SREBP, which increases the expression of genes involved in lipid synthesis. Finally, mTORC1 phosphorylates another protein kinase, Ulk1, reducing its ability to promote protein turnover.

MBOC7_ptr_ch17_1027-1088.indd 1083 02/12/21 2:14 PM

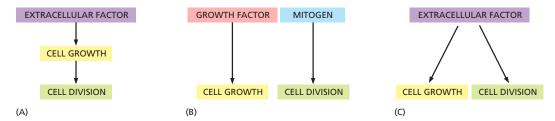

Figure 17–62 Potential mechanisms for coordinating cell growth and division. In proliferating cells, cell size is maintained by mechanisms that coordinate rates of cell division and cell growth. Numerous alternative coupling mechanisms are thought to exist, and different cell types appear to employ different combinations of these mechanisms. (A) In many cell types—particularly yeast—the rate of cell division is governed by the rate of cell growth, so that division occurs only when growth rate achieves some minimal threshold; in yeasts, it is mainly the levels of extracellular nutrients that regulate the rate of cell growth and thereby the rate of cell division. (B) In some animal cell types, growth and division can each be controlled by separate extracellular factors (growth factors and mitogens, respectively), and cell size depends on the relative levels of the two types of factors. (C) Some extracellular factors can stimulate both cell growth and cell division by simultaneously activating signaling pathways that promote growth and other pathways that promote cell-cycle progression.

Proliferating Cells Usually Coordinate Their Growth and Division

For proliferating cells to maintain a constant size, they must coordinate their growth with cell division to ensure that cell size doubles with each division: if cells grow too slowly, they will get smaller with each division, and if they grow too fast, they will get larger with each division. It is not clear how cells achieve this coordination, but it is likely to involve multiple mechanisms that vary in different organisms and even in different cell types of the same organism (Figure 17–62).

Animal cell growth and division are not always coordinated, however. In many cases, they are completely uncoupled to allow growth without division or division without growth. Muscle cells and nerve cells, for example, can grow dramatically after they have permanently withdrawn from the cell cycle. Similarly, the eggs of many animals grow to an extremely large size without dividing; after fertilization, however, this relationship is reversed, and many rounds of division occur without growth.

Compared to cell division, there has been surprisingly little study of how cell size is controlled in animals. As a result, it remains a mystery how cell size is determined and why different cell types in the same animal grow to be so different in size. One of the best-understood cases in mammals is the adult *sympathetic neuron*, which has permanently withdrawn from the cell cycle. Its size depends on the amount of *nerve growth factor* (NGF) secreted by the target cells it innervates; the greater the amount of NGF the neuron has access to, the larger it becomes. It seems likely that the genes a cell expresses set limits on the size it can be, while extracellular signal molecules and nutrients regulate the size within these limits. The challenge is to identify the relevant genes and signal molecules for each cell type.

Summary

In multicellular animals, cell size, cell division, and cell survival are carefully controlled to ensure that the organism and its organs achieve and maintain an appropriate size. Mitogens stimulate the rate of cell division by removing intracellular molecular brakes that restrain cell-cycle progression in G_1 . Growth factors

PROBLEMS 1085

promote cell growth (an increase in cell mass) by stimulating the synthesis and inhibiting the degradation of macromolecules. To maintain a constant cell size, proliferating cells employ multiple mechanisms to ensure that cell growth is coordinated with cell division.

PROBLEMS

Which statements are true? Explain why or why not.

- **17–1** As there are about 10^{13} cells in an adult human, and about 10^{10} cells die and are replaced each day, we become new people every 3 years.
- **17–2** All three of the major cell-cycle transitions—Start, G_2/M , and metaphase-to-anaphase—depend on the activity of Cdks.
- **17–3** Initiation of DNA synthesis is permitted only at origins of replication that are licensed by being loaded with Mcm complexes.
- 17–4 Chromosomes are positioned on the metaphase plate by equal and opposite forces that pull them toward the two poles of the spindle.
- **17–5** Meiosis segregates the paternal homologs into sperm and the maternal homologs into eggs.
- **17–6** If we could turn on telomerase activity in all our cells, we could prevent aging.

Discuss the following problems.

- 17–7 Some cell-cycle genes from human cells function perfectly well when expressed in yeast cells. Why do you suppose that is considered remarkable? After all, many human genes encoding enzymes for metabolic reactions also function in yeast, and no one thinks that is remarkable.
- **17–8** Hoechst 33342 is a membrane-permeant dye that fluoresces when it binds to DNA. When a population of cells is incubated briefly with the Hoechst dye and then sorted in a flow cytometer, which measures the fluorescence of each cell, the cells display various levels of fluorescence as shown in **Figure Q17–1**.

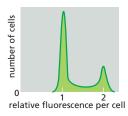

Figure Q17–1 Analysis of Hoechst 33342 fluorescence in a population of cells sorted in a flow cytometer (Problem 17–8).

- A. Which cells in Figure Q17-1 are in the G_1 , S, G_2 , and M phases of the cell cycle? Explain the basis for your answer.
- B. Sketch the sorting distributions you would expect for cells that were treated with inhibitors that block the cell cycle in the G_1 , S, or M phase. Explain your reasoning.
- 17–9 A two-component Fucci (fluorescent ubiquitylation-based cell-cycle indicator) used in fruit flies gives different-colored cells at different points in the cell cycle, as shown in Figure Q17–2. If this result was obtained by tagging protein A with GFP (green) and protein B with RFP (red), when during the cell cycle are these proteins expressed?

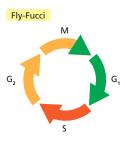

Figure Q17–2 A two-component Fucci system in fruit flies (Problem 17–9). (From Figure 5a of N. Zielke and B.A. Edgar, Wiley Interdiscip. Rev. Dev. Biol. 4:469–487, 2015. With permission from Wiley.)

- A. Protein A in G_1 , S, and G_2 ; protein B in G_1 , S, and G_2 B. Protein A in G_2 , M, and G_1 ; protein B in S, G_2 , and early M
- C. Protein A in late M and G_1 ; protein B in S
- D. Protein A in late M, G_1 , and S; protein B in G_2 and early M
- **17–10** What specific event does the cell-cycle control system stimulate at the metaphase-to-anaphase transition?
- **17–11** Which one of the following combinations of activities of a protein kinase and a protein phosphatase would give the highest activity for a target protein that is most active when phosphorylated?
- A. Kinase OFF; phosphatase OFF
- B. Kinase OFF; phosphatase ON
- C. Kinase ON; phosphatase OFF
- D. Kinase ON; phosphatase ON

17–12 The yeast cohesin subunit Scc1, which is essential for sister-chromatid cohesion, can be artificially regulated for expression at any point in the cell cycle. If expression is turned on at the beginning of S phase, all the cells divide satisfactorily and survive. By contrast, if Scc1 expression is turned on only after S phase is completed, the cells fail to divide and they die, even though Scc1 accumulates in the nucleus and interacts efficiently with chromosomes. Why do you suppose that cohesin must be present during S phase for cells to divide normally?

17–13 A living cell from the lung epithelium of a newt is shown at different stages in M phase in **Figure Q17–3**. Order these light micrographs into the correct sequence and identify the stage in M phase that each represents.

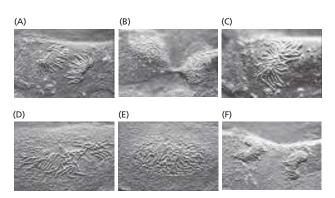

Figure Q17–3 Light micrographs of a single cell at different stages of M phase (Problem 17–13). (Courtesy of Conly L. Rieder.)

17–14 How many kinetochores are there in a human cell at mitosis?

17–15 If a cell just entering mitosis is treated with nocodazole, which destabilizes microtubules, the nuclear envelope breaks down and chromosomes condense, but no spindle forms and the cell cycle arrests in mitosis. In contrast, if such a cell is treated with cytochalasin D, which destabilizes actin filaments, mitosis proceeds normally but generates a binucleate cell that proceeds into G_1 phase. Explain the basis for the different outcomes of these treatments with cytoskeleton inhibitors. What do these results tell you about cell-cycle checkpoints in M phase?

17–16 Early on in the study of recombination during meiosis, geneticists concluded that there was about one crossover per chromosome arm. Using fluorescent tags that stain the synaptonemal complex red, the centromeres blue, and the crossovers green, it is now possible to observe

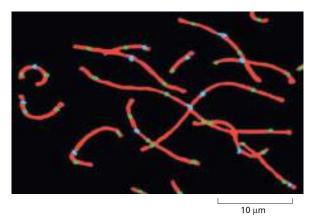

Figure Q17–4 Crossovers between homologs in human cells (Problem 17–16). (Modified from A. Lynn et al., *Science* 296:2222–2225, 2002. With permission from AAAS.)

directly the distribution of crossovers in chromosomes. For the 13 complete bivalents shown in **Figure Q17-4**, how many have more than one crossover in the arm of a chromosome?

17–17 Down syndrome (trisomy 21) and Edwards syndrome (trisomy 18) are the most common autosomal trisomies seen in human infants. Does this fact mean that these chromosomes are the most difficult to segregate properly during meiosis?

17–18 The human genome consists of 23 pairs of chromosomes (22 pairs of autosomes and one pair of sex chromosomes). During meiosis, the maternal and paternal sets of homologs pair, and then are separated into gametes, so that each contains 23 chromosomes. If you assume that the chromosomes in the paired homologs are randomly assorted to daughter cells, how many potential combinations of paternal and maternal homologs can be generated during meiosis? (For the purposes of this calculation, assume that no recombination occurs.)

17–19 High doses of caffeine interfere with the DNA damage response in mammalian cells. Why then do you suppose the Surgeon General has not yet issued an appropriate warning to heavy coffee and cola drinkers? A typical cup of coffee (150 mL) contains 100 mg of caffeine (196 g/mole). Assuming that the caffeine is not metabolized or excreted (but that all the liquid is), approximately how many cups of coffee would you have to drink to reach the dose (10 mM) required to interfere with the DNA damage response? (A typical adult contains about 40 liters of water.)

CHAPTER

18

Cell Death

The development and maintenance of multicellular organisms depend not only on cell growth and cell division but also on cell death. During animal development, for example, carefully orchestrated patterns of cell growth, division, and death help determine the size and shape of limbs and organs. The maintenance of tissue size in adult animals often requires that cells die at the same rate as they are produced—a process called cell turnover. Such "normal" cell death also occurs in plants during development and in the senescence of flowers and leaves, and it can also occur in unicellular organisms, including yeasts and bacteria. Most of these normal cell deaths are suicides, in which a sequence of molecular events destroys the cells from within, but the molecular mechanisms can differ widely. In this chapter, we focus on a molecularly distinct form of cell suicide called apoptosis (from the Greek word meaning "falling off," as leaves from a tree), even though it occurs only in animal cells. Apoptosis is thought to occur in all animals, and it is by far the most common way for our cells to die. It has also been the most intensely studied form of cell death.

A cell dying by apoptosis undergoes characteristic morphological and biochemical changes, in part, to package itself to be eaten and digested quickly by a nearby cell. Figure 18-1 shows a normal rat cell (panel A) and rat cells of the same type undergoing two different forms of cell death (panels B-D). In apoptosis, the cell shrinks and condenses, the cytoskeleton collapses, the nuclear envelope disassembles, and the nuclear chromatin condenses and fragments (Figure 18–1B). The apoptotic cell surface often forms multiple large protrusions called blebs (Movie 18.1), and, if the cell is large, it breaks up into membraneenclosed fragments called apoptotic bodies. Importantly, the surface of the cell and its fragments become chemically altered, so that a neighboring cell, often a macrophage in vertebrates, rapidly engulfs the cell and fragments before they can spill their contents (Figure 18-1C). In this way, the cell dies neatly, and the cell and its fragments are rapidly cleared away, without causing a damaging inflammatory response. Because apoptotic cells are eaten and digested so quickly, there are often few dead cells to be seen, even in a tissue where large numbers of cells have died by apoptosis.

Damaged or infected cells can also die by apoptosis, ensuring that they are eliminated before they can threaten the health of the animal. There are, however, many non-apoptotic ways for severely damaged or stressed animal cells to die. These are usually lumped together under the umbrella term *cell necrosis*. A common, largely passive form of cell necrosis occurs when cells lyse in response to an acute tissue insult, such as trauma or a blocked blood supply: the cells swell and burst (Figure 18–1D), spilling their contents over their neighbors and eliciting an inflammatory response. In other forms of cell necrosis, the cell takes an active part in the death process, and they are given special names such as necroptosis or pyroptosis, depending on the nature of the inducing stress and the molecular mechanisms involved.

In this chapter, we discuss the major functions of apoptosis in vertebrates, its molecular mechanism and regulation, and how excessive or insufficient apoptosis can contribute to human disease.

MBOC7_ptr_ch18_1089-1104.indd 1089 02/12/21 12:26 PM

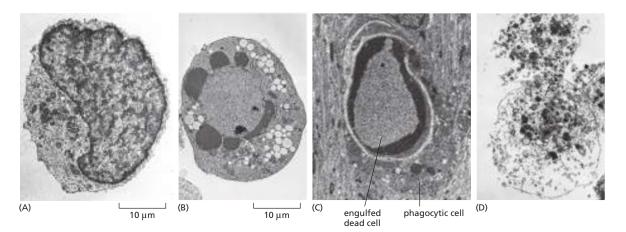

Figure 18–1 Two distinct forms of cell death. These electron micrographs show developing rat oligodendrocyte precursor cells in different states: (A) a normal cell in culture; (B) a cell in culture that has died by apoptosis because it was deprived of extracellular survival signals (discussed later); (C) a cell in a normal developing optic nerve that has died by apoptosis and has been engulfed by a neighboring phagocytic cell; (D) a cell in culture that died by necrosis. Note that the apoptotic cells in B and C have an intact plasma membrane, but the chromatin has become condensed and distorted and concentrated at the margin of the nucleus, whereas the necrotic cell in D seems to have exploded. The large vacuoles visible in the cytoplasm of the cell in B are a variable feature of apoptosis. (Courtesy of Julia Burne and Martin Raff.)

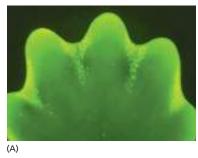

Apoptosis Eliminates Unwanted Cells

The amount of apoptotic cell death that occurs in many developing and adult vertebrate tissues is astonishing: at least a million cells die this way each second in a healthy adult human (and are replaced by cell division). It seems remarkably wasteful for so many cells to die, especially as the vast majority are perfectly healthy at the time they kill themselves. What is the benefit of such massive cell death?

In some cases, especially in animal development, the function of cell death is clear. Apoptosis helps sculpt our hands and feet during embryonic development: these appendages start out as spade-like structures, and the individual digits separate only as the cells between them die, as illustrated for a mouse paw in Figure 18-2. In other cases, cells die by apoptosis when the structure they form is no longer needed. When a tadpole changes into a frog at metamorphosis, for example, the cells in the tail die by apoptosis, and the tail, which is not needed in the frog, disappears. Apoptosis also functions as a qualitycontrol process in development, eliminating cells that are abnormal, misplaced, nonfunctional, or potentially dangerous to the animal. Striking examples occur in the vertebrate adaptive immune system, where apoptosis eliminates developing T and B lymphocytes that either fail to produce potentially useful antigen-specific receptors or produce self-reactive receptors that make the cells potentially dangerous (discussed in Chapter 24); it also eliminates most of the lymphocytes activated to proliferate by an infection, after they have helped destroy the responsible microbes.

In adult tissues that are neither growing nor shrinking, cell death and cell division must be tightly regulated to ensure they are in balance. If part of the liver is removed in an adult rat, for example, liver cell proliferation increases to make up the loss. Conversely, if a rat is treated with the drug phenobarbital—which stimulates liver cell growth and division (and thereby liver enlargement)—and then the phenobarbital treatment is stopped, apoptosis in the liver greatly increases until the liver cell number has returned to normal, usually within a week or so. Thus, liver cell number is kept constant through the regulation of both the cell death rate and the cell birthrate. The control mechanisms responsible for such remarkable regulation are largely unknown.

Animal cells can recognize damage in their various organelles and, if the damage is great enough, they can kill themselves by undergoing apoptosis. An important example is DNA damage, which can produce cancer-promoting

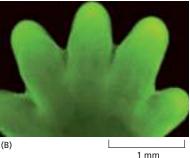

Figure 18–2 Sculpting the digits in the developing mouse paw by apoptosis.

(A) The paw in this mouse fetus has been stained with the dye acridine orange, which enters apoptotic cells and thereby brightly labels them in the normal developing paw. The apoptotic cells appear as bright green dots concentrated between the developing digits. (B) The interdigital cell death has eliminated much of the tissue between the developing digits, as seen one day later, when there are very few apoptotic cells. (From W. Wood et al., Development 127:5245–5252, 2000. With permission from the Company of Biologists.)

CELL DEATH 1091

mutations if not repaired. Cells have various ways of detecting DNA damage (see Figure 17-60) and can die by apoptosis if they cannot repair it.

Apoptosis Depends on an Intracellular Proteolytic Cascade Mediated by Caspases

A family of specialized intracellular proteases triggers apoptosis by cleaving numerous, but specific, intracellular proteins at specific amino acid sequences, thereby bringing about the dramatic changes that occur during apoptosis. Because these proteases have a cysteine at their active site and cleave their target proteins at specific aspartic acids, they are called **caspases** (c for cysteine and asp for aspartic acid). Not all caspases are involved in apoptosis: indeed, the first human caspase identified, caspase-1, mainly helps stimulate inflammatory responses by cleaving the precursors of two pro-inflammatory, extracellular signal molecules (cytokines, discussed in Chapter 24). The caspases involved in apoptosis preexist in the cytosol of nearly all our cells as inactive precursors (often called procaspases), which are activated during apoptosis. There are two major classes of these apoptotic caspases: *initiator* caspases and *executioner* caspases.

Initiator caspases, as their name implies, begin the apoptotic program. In mammals, they are mainly *caspase-8* and *caspase-9*. They are made as inactive soluble monomers and are activated only when the monomers dimerize. The dimerization occurs when an apoptotic signal triggers the assembly of a specific *adaptor-protein* complex, which then recruits multiple copies of identical initiator caspase monomers to form larger *activation complexes*, within which the monomers dimerize and become activated. Each monomer in the activated caspase dimer then cleaves its partner at specific sites to form the mature, activated, initiator caspase dimer (**Figure 18–3**).

The major function of initiator caspases is to activate the **executioner caspases**, which orchestrate the apoptosis program. There are three executioner caspases in vertebrates—*caspase-3*, *caspase-6*, and *caspase-7*. Unlike initiator caspases, executioner caspases normally exist as inactive soluble dimers, which are activated by cleavage, almost always mediated by an initiator caspase (**Figure 18-4**). Each initiator caspase can activate many copies of one or more executioner caspases, resulting in an amplifying *caspase cascade*. Once activated, executioner caspases catalyze the widespread protein cleavage events that are responsible for killing the cell in a characteristic way and preparing it for rapid engulfment and digestion

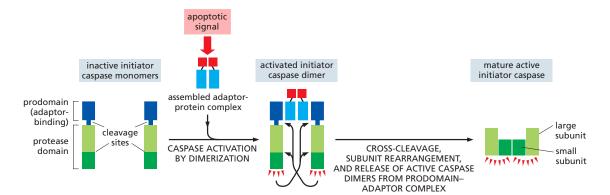

Figure 18–3 Activation of an initiator caspase at the start of apoptosis. An initiator caspase contains a protease domain in its large carboxyl-terminal region and a smaller, adaptor-protein-binding prodomain in its amino-terminal region. The caspase is made as an inactive monomer, which is activated by dimerization. The dimerization and activation only occurs when apoptotic signals trigger the assembly of specific adaptor-protein complexes (shown here as a hypothetical simplest form—a homodimer). Each type of adaptor complex then recruits multiple copies of one type of initiator caspase monomer, allowing them to dimerize and thereby become active. In the case shown, once activated, each monomer in the activated caspase dimer cross-cleaves its partner at specific sites; the cleavage in the protease domain enables the large and small caspase subunits to rearrange, and cleavage between the large protease domain and the prodomain releases the mature, active caspase dimer from the prodomain—adaptor complex.

MBOC7_ptr_ch18_1089-1104.indd 1091 02/12/21 12:26 PM

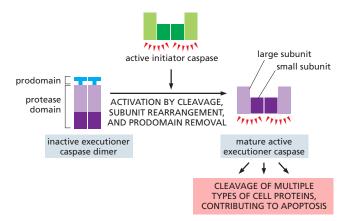

Figure 18-4 Executioner caspase activation during apoptosis. Executioner caspases have very short prodomains, which lack sites for interacting with other proteins. They are initially formed as inactive dimers, which are activated by cleavage at a site in each protease domain, almost always by an initiator caspase. The cleavages allow the large and small subunits to rearrange to form two active protease sites, each of which then cleaves off the prodomain of its partner monomer to produce the mature, active executioner caspase, as shown. The mature activated caspase then cleaves a variety of cell target proteins, leading to the controlled apoptotic death of the cell.

by neighboring cells. The caspase-initiated proteolytic cascade is not only self-amplifying and destructive but also irreversible, so that once a cell starts out along the path to apoptotic death, it cannot turn back.

Executioner caspases cleave hundreds of different cell proteins during apoptosis, but the roles of these target proteins in apoptosis are known in only a minority of cases, several of which we mention here. The cleavage of nuclear lamins by caspase-6, for example, causes the irreversible breakdown of the nuclear lamina (discussed in Chapter 12). The cleavage by caspase-3 of an inhibitor protein that normally holds a particular DNA-degrading endonuclease in an inactive form frees the endonuclease to cut up the DNA in the cell nucleus during apoptosis (Figure 18–5). The cleavage of certain proteins that regulate the actin cytoskeleton results in the actin polymerization in the cell cortex that is responsible for the surface blebbing in apoptosis, mentioned earlier (and see Movie 18.1). The cleavage of other actin regulators and some cell-cell adhesion proteins that attach cells to their neighbors helps an apoptotic cell round up and detach from its neighbors, making it easier for a neighboring cell to engulf it. As we discuss later, the cleavage of two phospholipid transfer proteins in the plasma membrane results in the exposure of phosphatidylserine on the surface of apoptotic cells, where it serves as an "eat me" signal to neighboring phagocytic cells. Importantly, preventing any one of these individual protein-cleavage steps does not stop apoptotic cell death, although it changes its characteristics as expected in each case.

How is an initiator caspase first activated in response to an apoptotic signal? Our cells use two main activation pathways: one is signaled from outside the cell and is called the *extrinsic pathway*, and the other is signaled from mitochondria

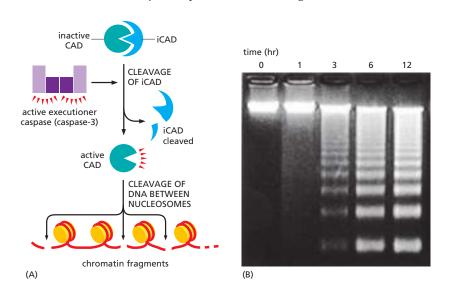

Figure 18-5 DNA fragmentation during apoptosis. (A) In healthy cells, a caspaseactivated DNase (CAD) is held in an inactive state by an inhibitor protein. iCAD. Activation of an executioner caspase, caspase-3, during apoptosis leads to cleavage of iCAD, releasing the active DNase to cut the chromosomal DNA between nucleosomes. (B) Because the DNA cleavage occurs only at accessible sites in linker regions between nucleosomes, the DNA is cut into fragments of variable size, equivalent to the DNA associated with either one or multiple nucleosomes (as shown in A), producing a ladder pattern upon DNA gel electrophoresis. The pattern shown was obtained by inducing apoptosis in mouse thymus lymphocytes with dexamethasone, extracting DNA at the times indicated at the top of the gel, separating the fragments by size by electrophoresis in an agarose gel, and staining the DNA in the gel with ethidium bromide. (B, from D. McIlroy et al., Genes Dev. 14:549-558, 2000. With permission from Cold Spring Harbor Laboratory Press.)

MBOC7_ptr_ch18_1089-1104.indd 1092 02/12/21 12:26 PM

CELL DEATH 1093

inside the cell and is called the *intrinsic*, or *mitochondrial*, *pathway*. Each uses its own initiator caspase and adaptor proteins, as we now discuss.

Activation of Cell-Surface Death Receptors Initiates the Extrinsic Pathway of Apoptosis

Extracellular signal proteins binding to cell-surface **death receptors** trigger the **extrinsic pathway** of apoptosis. Death receptors are transmembrane proteins containing an extracellular ligand-binding domain, a single transmembrane domain, and an intracellular *death domain* that is required for the receptors to activate the apoptotic program. The receptors are homotrimers and belong to the *tumor necrosis factor (TNF) receptor* family, which has eight members, including a receptor for TNF itself and the *Fas* death receptor. The ligands that activate the death receptors are also homotrimers, belonging to the *TNF family* of signal proteins.

A relatively well-understood example of how death receptors trigger the extrinsic pathway of apoptosis is the activation of the **Fas receptor** on the surface of a target cell by **Fas ligand** on the surface of a killer (cytotoxic) lymphocyte (discussed in Chapter 24). Fas signaling has a role in regulating the numbers of T and B lymphocytes, as indicated by the finding that inactivation of Fas signaling results in an abnormal increase in these cells. As shown in **Figure 18–6**, the binding of

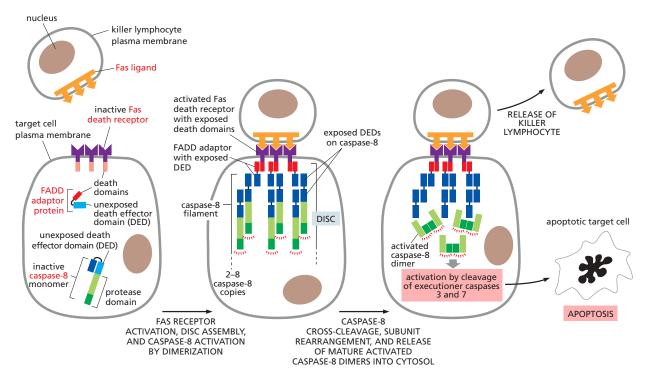

Figure 18–6 The extrinsic pathway of apoptosis activated through Fas death receptors. Trimeric Fas ligands on the surface of a killer lymphocyte bind to trimeric Fas death receptors on the surface of a target cell, inducing the target cell to kill itself by undergoing apoptosis by the extrinsic pathway. Although not shown, at least two trimeric Fas ligands have to bind to and cluster at least two trimeric Fas receptors to activate the pathway; for clarity, only a single copy of the ligand and receptor is shown. The ligand-induced receptor clustering (not shown) exposes a death domain on the receptor tails, as indicated here by the change in the color of the domain from light red to dark red upon exposure. Each exposed death domain binds to a similar exposed death domain on the cytosolic adaptor protein FADD (for Fas-associated death domain). The bound FADD protein then exposes a death effector domain (DED; dark blue), enabling FADD to recruit an inactive, monomeric initiator caspase (mainly caspase-8) by binding to an exposed DED (dark blue) on the prodomain of the caspase. Each caspase-8 monomer has two DEDs, and, when one binds to an exposed DED, the other becomes exposed (as indicated by the change in the DED color from light blue to dark blue) and can recruit another caspase-8 monomer; this results in a chain reaction in which the caspase-8 monomers oligomerize into a three-dimensional helical filament (not shown), with each FADD protein attached to up to eight caspase-8 molecules. The end result is the assembly of a large death-inducing signaling complex (DISC) composed of multiple copies of Fas, FADD, and caspase-8. Within the DISC, neighboring caspase-8 monomers interact to form activated dimers, which can now cross-cleave their partner monomers (not shown, but see Figure 18–3), cleaving off the prodomain and forming the mature activated dimers, which are released into the cytosol, where they can cleave and activate executioner caspases to induce apoptosis. In human cells, the caspase-10 initiator caspas

MBOC7_ptr_ch18_1089-1104.indd 1093 02/12/21 12:26 PM

trimeric Fas ligands to the trimeric Fas receptors clusters the receptors, exposing death domains on the receptor tails, which then bind and cluster a small intracellular adaptor protein called *FADD*. The clustered FADD proteins, in turn, recruit multiple copies of an inactive, monomeric initiator caspase (mainly caspase-8), which oligomerize, completing the formation of a large **death-inducing signaling complex (DISC)** on the cytoplasmic face of the target-cell plasma membrane. The oligomerization of caspase-8 allows the dimerization and activation of the caspase, which then cleaves itself to form mature, active caspase-8 dimers that can cleave and activate downstream executioner caspases to induce apoptosis.

The sensitivity of different cell types to Fas-induced apoptosis varies. Many cells produce inhibitory proteins that act to restrain the extrinsic apoptotic pathway. Some cells, for example, produce a protein called *FLIP*, which resembles caspase-8 but lacks protease activity because it is missing the key cysteine required in the active site. FLIP dimerizes with caspase-8 in the DISC and prevents it from activating executioner caspases to initiate apoptosis. In this way, FLIP sets an inhibitory threshold that the extrinsic pathway, through activated caspase-8, must overcome to trigger apoptosis. As we discuss later, for the extrinsic pathway to kill some cell types, it has to overcome another caspase inhibitor, which it does by recruiting the intrinsic apoptotic pathway—the pathway we now discuss.

The Intrinsic Pathway of Apoptosis Depends on Proteins Released from Mitochondria

Cells can also activate their apoptosis program from inside the cell, often in response to developmental signals or to injury such as DNA damage. In vertebrate cells, these apoptotic responses are mediated by the **intrinsic pathway** of apoptosis, which is also called the **mitochondrial pathway**, as it depends on the release into the cytosol of mitochondrial proteins that normally reside in the intermembrane space of these organelles (see Figure 12–47). The most important of these released proteins is **cytochrome** *c*, which is a water-soluble component of the mitochondrial electron-transport chain and therefore has a central role in ATP production by oxidative phosphorylation in mitochondria (see Figure 14–18). When released into the cytosol (Figure 18–7), however, it takes on an entirely new function: it can induce apoptosis, independent of its electron-transport activity.

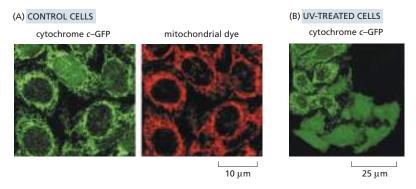

Figure 18–7 Release of cytochrome *c* from mitochondria into the cytosol during the intrinsic pathway of apoptosis. These fluorescence micrographs show human cancer cells in culture. The cells were transfected with a gene encoding a fusion protein consisting of cytochrome *c* linked to green fluorescent protein (cytochrome *c*–GFP), and they were also treated with a red dye that accumulates in mitochondria. (A) Unstimulated control cells: the overlapping distribution of the *green* and *red* confirms that the cytochrome *c*–GFP is located in mitochondria. (B) Cells were irradiated with ultraviolet (UV) light to induce the intrinsic pathway of apoptosis and were photographed 5 hours later. The seven cells in the bottom right of this micrograph have released their cytochrome *c* from mitochondria into the cytosol, whereas the other cells in the micrograph have not yet done so. CELL DEATH 1095

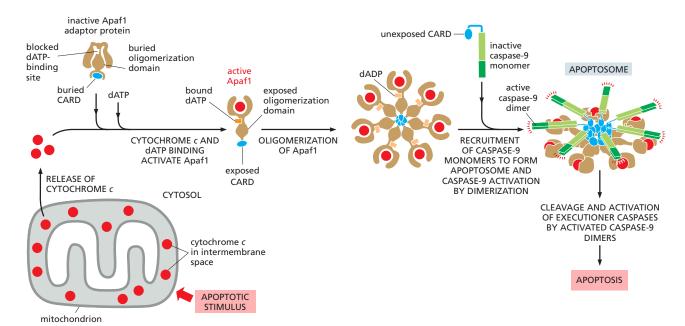

Figure 18–8 The intrinsic pathway of apoptosis. Intracellular apoptotic stimuli cause mitochondria to release cytochrome c. The binding of cytochrome c to the cytosolic adaptor protein Apaf1 induces a conformational change in Apaf1, which activates it, exposing a binding site for deoxy-ATP (dATP), an oligomerization domain, and a caspase recruitment domain (CARD). The exposed oligomerization domain mediates the assembly of Apaf1 into a wheel-like heptamer. Each CARD in the heptamer then recruits an inactive caspase-9 monomer through its own CARD, forming a large apoptosome, with the interacting CARDs clustered above the central hub of the apoptosome. The dATP is hydrolyzed to dADP during the assembly process. Within the apoptosome, the caspase-9 monomers are activated by dimerization. Activated caspase-9 dimers then cleave and activate downstream executioner caspases, leading to apoptosis. Note that the CARD domain is related in structure and function to the death effector domain (DED) of caspase-8 (see Figure 18–6).

(It remains an important mystery how, during evolution, mitochondria and cytochrome c came to acquire their surprising role in apoptosis.)

Once released, into the cytosol, cytochrome c binds to an adaptor protein called **Apaf1** (apoptotic protease activating factor 1), causing the adaptor to bind deoxy-ATP and oligomerize into a large, wheel-like heptamer. The heptamer then recruits inactive initiator caspase-9 monomers into the complex, forming an even larger structure called an **apoptosome** (**Figure 18–8**). Caspase-9 is activated by dimerization within the apoptosome, just as the other major initiator caspase, caspase-8, is activated by dimerization within the DISC (see Figure 18–6). Once activated, caspase-9 cleaves and activates the downstream executioner caspases that mediate apoptosis.

The intrinsic pathway is responsible for the great majority of apoptotic cell deaths in vertebrates. For upstream signals to activate the intrinsic pathway, they have to alter the outer mitochondrial membrane so that the soluble proteins in the intermembrane space such as cytochrome c can diffuse into the cytosol. This crucial outer membrane permeabilization step is controlled by interactions between members of the Bcl2 family of proteins, as we now discuss.

Bcl2 Proteins Are the Critical Controllers of the Intrinsic Pathway of Apoptosis

The intrinsic pathway is tightly regulated to ensure that cells kill themselves by apoptosis only when it is appropriate. This regulation is largely the function of the **Bcl2 family** of proteins, which are named after the first family member described (\underline{B} cell lymphoma- $\underline{2}$), as explained later. In mammalian cells, complex interactions between these proteins control the permeabilization of the outer mitochondrial membrane and thereby govern the release into the cytosol of cytochrome c and

MBOC7_ptr_ch18_1089-1104.indd 1095 02/12/21 12:26 PM

Figure 18–9 Schematic drawing of the BH domains in the three classes of Bcl2 family proteins. Note that the BH3 domain is the only one of the four BH domains shared by all Bcl2 family members; it mediates the direct interactions between pro-apoptotic and anti-apoptotic family members (see Figure 18–10C and D).

other soluble proteins in the intermembrane space, a process called **mitochondrial outer membrane permeabilization (MOMP)**. Like the caspase family, the Bcl2 family of proteins is found in all animals and has been remarkably conserved; a human Bcl2 protein, for example, can suppress apoptosis when expressed in the worm *Caenorhabditis elegans*.

There are three structural and functional classes of mammalian Bcl2 family proteins: (1) *Anti-apoptotic Bcl2 family proteins*, including Bcl2 itself, inhibit apoptosis by preventing MOMP. (2) *Pro-apoptotic Bcl2 family effectors* can directly induce MOMP by creating openings in the outer mitochondrial membrane. (3) A second class of pro-apoptotic Bcl2 family proteins, called *BH3-only proteins* (for reasons explained shortly), promotes apoptosis by regulating the other two classes. The balance between the activities of these three classes largely determines whether MOMP occurs or not and, therefore, whether a mammalian cell lives or dies by the intrinsic pathway of apoptosis.

As illustrated in Figure 18–9, the anti-apoptotic Bcl2 family proteins, including Bcl2 itself and *Bcl extra-large* (*BclxL*), share four distinctive *Bcl2 homology* (*BH*) domains (BH1–4). The two main pro-apoptotic Bcl2 family effectors, *Bak* and *Bax*, are structurally similar to Bcl2 but lack the BH4 domain. The members of the second class of pro-apoptotic Bcl2 family proteins share sequence homology with Bcl2 in only the BH3 domain and are therefore called *BH3-only proteins*; they are by far the largest class of Bcl2 proteins.

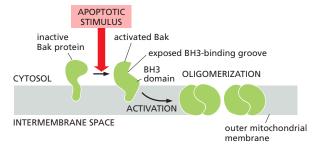

When an apoptotic stimulus triggers the intrinsic pathway, the **pro-apoptotic Bcl2 family effectors**, **Bak** and **Bax**, become activated and trigger MOMP by aggregating into oligomers of various sizes in the mitochondrial outer membrane, producing openings in the membrane by an uncertain mechanism, allowing cytochrome *c* and other intermembrane proteins to escape into the cytosol (**Figure 18–10A and B**). At least one of these pro-apoptotic effectors is required for the intrinsic pathway of apoptosis to operate in mammalian cells: mutant mouse cells that lack both proteins do not undergo MOMP or engage the intrinsic apoptotic pathway. Whereas Bak is bound to the mitochondrial outer membrane even in the absence of an apoptotic signal (see Figure 18–10A and B), Bax is mainly located in the cytosol until an apoptotic signal activates it, causing it to relocate to the outer membrane, where it oligomerizes. As we discuss below, the activation of Bak and Bax usually depends on activated BH3-only proteins.

The anti-apoptotic Bcl2 family proteins such as Bcl2 and BclxL are also located on the cytosolic surface of the outer mitochondrial membrane, where they help prevent inappropriate MOMP. They do so by binding to the BH3 domain of active pro-apoptotic effectors Bak and Bax, thereby preventing their oligomerization (Figure 18–10C). There are at least five mammalian anti-apoptotic Bcl2 family proteins, and every mammalian cell requires at least one to avoid apoptosis and therefore to survive. Moreover, a number of these anti-apoptotic proteins must be inhibited for the intrinsic pathway to induce apoptosis, and BH3-only proteins mediate this inhibition.

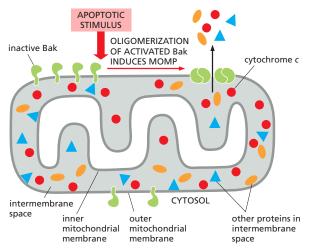

The **BH3-only proteins**, the largest subclass of Bcl2 family proteins, promote MOMP and thereby apoptosis when they are either produced or activated in cells in response to an apoptotic stimulus. They do so in at least two ways. (1) Some BH3-only proteins, including Bad (see Figure 18–9), inhibit certain

CELL DEATH 1097

(C) PREVENTION OF MOMP BY BclxL

(D) INDUCTION OF MOMP BY A BH3-ONLY PROTEIN (SUCH AS Bad)

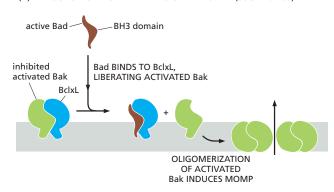

Figure 18–10 How pro-apoptotic Bcl2 family effectors induce MOMP and how anti-apoptotic Bcl2 family proteins block it. (A) Most of the pro-apoptotic effector Bak is already attached to the outer mitochondrial membrane before the protein is activated. When activated by an apoptotic stimulus, the protein undergoes a conformational change that both exposes a BH3 domain and creates a BH3-binding groove, allowing Bak–Bak oligomerization in the outer membrane. (B) The Bak oligomers induce MOMP by creating openings in the outer membrane that allow cytochrome c and other soluble proteins in the intermembrane space to diffuse into the cytosol; although the details of how Bak (and Bax) oligomers produce the openings are uncertain, it is thought that they form large ring structures that disrupt the integrity of the outer membrane. Once released into the cytosol, cytochrome c stimulates the assembly of apoptosomes (see Figure 18–8). (C) The anti-apoptotic Bcl2 family protein BclxL, like Bak, is normally bound to the outer mitochondrial membrane, where it can interact via its BH3-binding groove to the exposed BH3 domain on activated Bak, thereby blocking Bak–Bak oligomerization, MOMP, and apoptosis. (D) One way BH3-only proteins such as Bad are thought to indirectly induce MOMP and apoptosis is by inhibiting certain anti-apoptotic Bcl2 family proteins such as BclxL.

anti-apoptotic Bcl2 family proteins by binding via their BH3 domain to the BH3-binding groove on the anti-apoptotic protein. This binding blocks the anti-apoptotic activity of the Bcl2 family protein, thereby allowing Bax and/or Bak to oligomerize in the outer mitochondrial membrane to trigger MOMP (Figure 18–10D). (2) Some BH3-only proteins, including Bim and Bid (see Figure 18–9), can directly bind to and activate Bak and Bax, stimulating them to oligomerize and trigger MOMP.

In these ways, BH3-only proteins provide the crucial link between apoptotic stimuli and the intrinsic pathway of apoptosis, with different stimuli activating or inducing the production of different BH3-only proteins. When a cell suffers DNA damage that it cannot repair, for example, the tumor suppressor protein p53 (discussed in Chapters 17 and 20) accumulates in the nucleus and activates the transcription of genes that encode the BH3-only proteins *Puma* and *Noxa* (see Figure 18–9), which then trigger MOMP and apoptosis, thereby eliminating a potentially dangerous cell that could become cancerous. As we will see, some extracellular survival signals promote a cell's survival by preventing it from

MBOC7_ptr_ch18_1089-1104.indd 1097 02/12/21 12:26 PM

undergoing apoptosis by inhibiting the synthesis or activity of certain BH3-only proteins (see Figure 18–13B).

As mentioned earlier, in some cells the extrinsic apoptotic pathway has to recruit the intrinsic pathway to help kill the target cell; the BH3-only protein *Bid* is the link between the two pathways. Bid is normally inactive in these cells, but, when death receptors activate the extrinsic pathway (see Figure 18–6), the initiator caspase, caspase-8, cleaves Bid, creating an active form of the protein that translocates to the outer mitochondrial membrane to activate Bax and/or Bak, causing them to oligomerize and trigger MOMP. MOMP is required for activated death receptors to kill these cells because it releases proteins from the mitochondrial intermembrane space that neutralize an inhibitory protein present in the cytosol of these cells that normally blocks apoptosis, as we explain next.

An Inhibitor of Apoptosis (an IAP) and Two Anti-IAP Proteins Help Control Caspase Activation in the Cytosol of Some Mammalian Cells

Because activation of an apoptotic caspase cascade leads to certain cell death, cells employ multiple mechanisms to help ensure that these proteases are activated only when appropriate. The inhibition of caspase-8 by the FLIP protein in the extrinsic apoptotic pathway is one example discussed earlier (see p. 1095). Another line of defense against inappropriate caspase activation is provided by caspase inhibitor proteins called **inhibitors of apoptosis (IAPs)**. These proteins were first identified in certain insect viruses (baculoviruses), which encode IAP proteins to prevent a host cell that is infected by the virus from activating caspases and killing itself by apoptosis, which would curtail the virus's replication. Most animal cells also make IAP proteins, although most of these proteins do not regulate caspases and apoptosis.

Mammalian cells seem to have only one IAP that can directly inhibit caspase activity. It is called **XIAP** (because it is encoded on the X chromosome), and it resides in the cytosol of many of our cells. It binds to and inhibits caspase-9, an initiator caspase, and the executioner caspases, caspase-3 and caspase-7, thereby setting an inhibitory threshold that these caspases must overcome to trigger apoptosis. In these cells, XIAP also helps regulate the levels of the three caspase proteins: it has a ubiquitin-ligase domain that polyubiquitylates the caspases that XIAP binds to, marking them for destruction in proteasomes (see Figure 3–67).

When the intrinsic pathway of apoptosis is activated, among the proteins released from the mitochondrial intermembrane space by MOMP are two **anti-IAP proteins** called *Smac* and *Omi*. In cells with XIAP in their cytosol, these anti-IAP proteins bind to XIAP and prevent it from inhibiting caspases, thereby promoting caspase activation and apoptosis (**Figure 18-11**). This is why the extrinsic apoptotic pathway needs to recruit the intrinsic pathway (involving MOMP and caspases 9, 3, and 7) to induce apoptosis in some cells, as mentioned earlier; these are cells that express XIAP in their cytosol.

Extracellular Survival Factors Inhibit Apoptosis in Various Ways

As discussed in Chapters 15 and 21, extracellular signals regulate most activities of animal cells, including apoptosis. They are part of the normal "social" controls that ensure individual cells behave for the good of the organism as a whole—in this case, by surviving when the cells are needed and killing themselves when they are not. Some extracellular signal molecules stimulate apoptosis, whereas others inhibit it. We have discussed signal proteins such as Fas ligand that activate death receptors to trigger the extrinsic pathway of apoptosis. Other extracellular signal molecules that stimulate apoptosis are especially important during vertebrate development: a surge of thyroid hormone in the bloodstream, for example, signals cells in the tadpole tail to undergo apoptosis at metamorphosis. In mice, locally produced signal proteins stimulate cells between developing fingers and

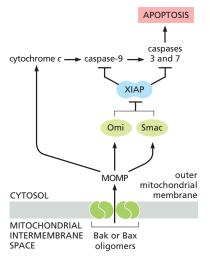

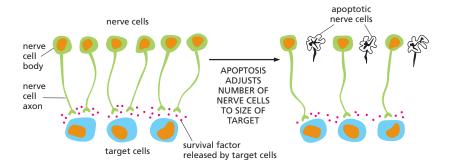

Figure 18–11 How MOMP overcomes XIAP inhibition. In some mammalian cells, the presence of XIAP in the cytosol inhibits initiator caspase-9 and executioner caspases 3 and 7; the XIAP binds to the active site of the three enzymes, blocking their activities. However, as well as releasing cytochrome c, MOMP releases two anti-IAP proteins, Smac and Omi, which inhibit the anti-caspase activity of XIAP, thereby allowing the activation of these caspases in the cytosol during the intrinsic pathway of apoptosis (see Figure 18–8).

02/12/21 12:26 PM

CELL DEATH 1099

toes to kill themselves, thereby sculpting these digits (see Figure 18–2). Here, however, we focus on extracellular signal molecules that promote cell survival by inhibiting apoptosis and are collectively called **survival factors**.

Most animal cells require such signals from other cells to avoid undergoing apoptosis, usually by the intrinsic pathway. This surprising arrangement apparently helps ensure that cells survive only when and where they are needed. Some nerve cells, for example, are produced in excess in the developing nervous system and then compete for limited amounts of survival factors that are secreted by the target cells they normally connect to. Nerve cells that receive enough survival signals live, while the others die by apoptosis. In this way, the number of surviving neurons is automatically adjusted so that it is appropriate for the number of target cells they connect with (Figure 18–12). A similar competition for limited amounts of survival factors produced locally or systemically might help control cell numbers in other tissues, both during development and in adulthood.

Survival factors usually bind to cell-surface receptors, which activate intracellular signaling pathways (discussed in Chapter 15) that suppress the apoptotic program, usually by regulating the expression or activity of members of the Bcl2 family of proteins. Some survival factors, for example, stimulate the synthesis of anti-apoptotic Bcl2 family proteins such as Bcl2 itself or BclxL (Figure 18–13A). Some others act by inhibiting the function of pro-apoptotic BH3-only proteins such as Bad (Figure 18–13B). Some developing neurons, like those illustrated in Figure 18–12, use a counterintuitive alternative strategy, in which survival-factor receptors stimulate apoptosis when they are unoccupied and stop doing so when survival factors bind. The end result in all these cases is the same: cell survival depends on survival-factor binding to cell-surface receptors.

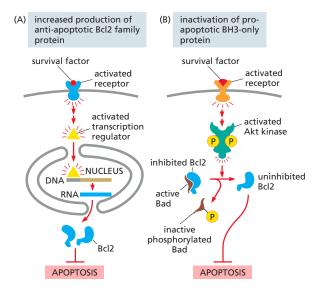

Figure 18-12 How survival factors and apoptosis can help adjust the number of developing nerve cells to the size of the target tissue the nerve cells innervate. In this example, more nerve cells are produced than can be supported by the limited amount of survival factors produced by the cells in a target tissue. As a result, some nerve cells receive an insufficient amount of survival factor to avoid apoptosis. This strategy of overproduction followed by culling during development helps ensure that all the appropriate target cells are contacted by appropriate nerve cells and that surplus nerve cells are automatically eliminated.

Figure 18-13 Two of the various ways that extracellular survival factors can inhibit apoptosis. (A) Some survival factors suppress apoptosis by stimulating the transcription of genes that encode anti-apoptotic Bcl2 family proteins such as Bcl2 (as shown here) or BclxL. (B) Many others activate the serine/threonine protein kinase Akt, which, among many other targets, phosphorylates and inactivates the pro-apoptotic BH3-only protein Bad (see Figure 18-9). When not phosphorylated, Bad promotes apoptosis by binding to and inhibiting an anti-apoptotic Bcl2 family protein such as Bcl2 itself. Once phosphorylated, Bad dissociates, freeing Bcl2 to suppress apoptosis (see Figure 18-10C and Figure 15-54). Akt can also suppress apoptosis by phosphorylating and inactivating transcription regulatory proteins that stimulate the transcription of genes encoding proteins that promote apoptosis, such as the BH3-only protein Bim (not shown). There are also many other ways that survival factors can inhibit apoptosis that are not illustrated here.

MBOC7_ptr_ch18_1089-1104.indd 1099 02/12/21 12:26 PM

Healthy Neighbors Phagocytose and Digest Apoptotic Cells

Apoptotic cell death is a tidy process. The apoptotic cell and its fragments do not break open and release their contents. Instead, they usually remain intact until they are rapidly phagocytosed and digested by neighboring cells (usually macrophages in humans), leaving no trace. In this way, apoptosis avoids triggering a destructive inflammatory response. The engulfment process depends on chemical changes on the surface of the apoptotic cell, which displays various "eat me" signals that are recognized by the phagocytic cells.

The most important of these signals is the negatively charged phospholipid phosphatidylserine. In healthy cells, phosphatidylserine is normally located exclusively in the inner leaflet of the lipid bilayer of the plasma membrane (see Figure 10-15); it is kept there by a specific phospholipid flippase that uses ATP hydrolysis to flip phosphatidylserine (PS) and phosphatidylethanolamine (PE) from the outer to the inner leaflet. In cells undergoing apoptosis, however, PS accumulates on the cell surface by two mechanisms. First, executioner caspases cleave the phospholipid flippase, thereby inactivating it, preventing PS and PE from being transferred from the outer to the inner leaflet. Second, executioner caspases cleave and thereby activate a phospholipid scramblase that transfers plasma membrane phospholipids nonspecifically between the inner and outer lipid leaflets, thereby scrambling them between the two leaflets. These two mechanisms responsible for the exposure of PS on the surface of apoptotic cells are illustrated in Figure 18-14 and Movie 18.2. The appearance of PS on the cell surface also occurs in some forms of necrotic cell death, even in the absence of caspase activation; disruption of the plasma membrane is sufficient to do it.

The PS on apoptotic and necrotic cells is recognized by a variety of soluble "bridging" proteins that interact with both the exposed PS and specific receptors on the surface of a neighboring phagocytic cell, triggering the cytoskeletal and other changes that initiate the engulfment process.

Macrophages are professional phagocytes and will phagocytose dead cells, microbes, cell debris, latex beads, and almost any other particles, but they do not phagocytose healthy cells within the organism's own body—even those healthy cells that transiently expose phosphatidylserine on their surface when activated, such as platelets and some Tlymphocytes. One reason is that almost all of our cells display signal proteins on their surface that bind to inhibitory receptors on the surface of macrophages, stimulating the receptors to block phagocytosis. Thus, in addition to expressing cell-surface "eat me" signals such as phosphatidylserine that stimulate phagocytosis, apoptotic cells must also remove or inactivate the "don't eat me" signals that block phagocytosis.

Either Excessive or Insufficient Apoptosis Can Contribute to Disease

There are many human disorders in which too many cells undergo apoptosis and thereby contribute to pathological tissue loss. Among the most common and dramatic examples are heart attacks and strokes caused by an acute interruption of the blood supply to the heart or brain, respectively. In these conditions, many cells initially die by necrosis. If the blocked blood vessel is unblocked, either through an arterial catheter or with clot-disrupting drugs, some of the surviving cells in the oxygen-deprived tissue die by apoptosis, contributing to the tissue loss. It is hoped that, in the future, drugs that can block the apoptotic cell deaths, as well as drugs that can block some forms of necrotic cell death, will be able to decrease the tissue loss and its debilitating consequences.

There are other disorders in which too few cells die by apoptosis. For example, as mentioned earlier, mutations in mice and humans that inactivate the genes that encode either the Fas death receptor or its ligand prevent the normal deaths of some types of lymphocytes, resulting in the abnormal accumulation of these cells in the spleen and lymph glands. In many cases, this leads to autoimmune disorders, because some self-reactive lymphocytes fail to be eliminated and react

CELL DEATH 1101

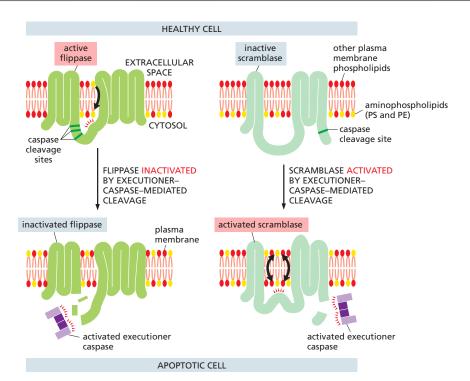

Figure 18–14 The two caspase-dependent mechanisms responsible for the accumulation of phosphatidylserine on the surface of apoptotic cells. In healthy cells (top half of figure), an ATP-dependent aminophospholipid flippase (ATP11C) actively flips phosphatidylserine (PS) and phosphatidylethanolamine (PE) from the outer to the inner leaflet of the plasma membrane lipid bilayer, keeping these lipids mainly confined to the inner leaflet. During apoptosis (bottom half of figure), activated executioner caspases (caspase-3, caspase-7, or both) cleave and thereby inactivate the ATP11C flippase, preventing its lipid translocation activity; at the same time, the activated executioner caspases cleave and thereby activate a phospholipid scramblase (Xkr8) in the plasma membrane that nonspecifically flips phospholipids between the two lipid leaflets of the membrane, scrambling them between the leaflets. (Although not shown, the ATP11C flippase is tightly associated with a smaller transmembrane protein, CDC50, which is required to chaperone the flippase to the plasma membrane and possibly to assist in the lipid translocation process.)

With the flippase permanently inactivated and the scramblase permanently activated, PS and PE become rapidly and irreversibly exposed on the apoptotic cell surface, where the PS serves as an "eat me" signal to neighboring phagocytic cells. Both of these caspase-dependent mechanisms are required to create this rapid and effective "eat me" signal: if only the flippase were inactivated, it could take a very long time for PS to accumulate in effective amounts on the apoptotic cell surface, because phospholipids rarely flip spontaneously between the two leaflets of a lipid bilayer without an enzyme (such as the scramblase) catalyzing it (see Figure 10–10B). Similarly, if only the scramblase were activated, the active flippase would rapidly return any scrambled PS from the external leaflet to the internal one, thereby removing the PS from the cell surface. Figure 12–39 illustrates the actions of phospholipid scramblases in lipid bilayer synthesis in the ER membrane and of phospholipid scramblases in generating lipid bilayer asymmetry in some other intraceullar membranes. (Modified from S. Nagata et al., Cell Death Differ. 23:952–961, 2016.)

against the individual's own tissues. The increase in lymphocytes can also lead to lymphocyte cancers called lymphomas.

Indeed, decreased apoptosis makes an important contribution to many types of cancer, because the normal inhibitory controls on apoptosis are often defective in cancer cells. The *Bcl2* gene, for example, was first identified in a common form of human lymphoma, in which a chromosome translocation causes excessive production of the anti-apoptotic Bcl2 protein (as mentioned earlier, Bcl2 gets its name from this *B cell lymphoma*). The increased amount of Bcl2 protein in the lymphocytes that carry the translocation promotes the development of cancer by inhibiting apoptosis, thereby abnormally prolonging the cells' survival and increasing their number; the increase in Bcl2 also decreases the cells' sensitivity to anticancer drugs, which often work by causing cancer cells to undergo apoptosis (discussed in Chapter 20).

MBOC7_ptr_ch18_1089-1104.indd 1101 02/12/21 12:26 PM

Similarly, the gene encoding the tumor suppressor protein p53 is mutated in about 50% of human cancers so that it no longer promotes apoptosis or cell-cycle arrest in response to DNA damage (as discussed in Chapters 17 and 20). The lack of p53 function, therefore, enables the cancer cells to survive and proliferate even when their DNA is damaged; in this way, the cells progressively accumulate more mutations, some of which make the cancer more malignant. As many anticancer drugs induce apoptosis (and cell-cycle arrest) by p53-dependent mechanisms, the loss of p53 function also makes cancer cells less sensitive to these drugs.

If decreased apoptosis contributes to a cancer, then we should be able to treat the cancer with drugs that promote apoptosis. This approach has recently led to the development of small chemicals that block the function of anti-apoptotic Bcl2 family proteins such as Bcl2 and BclxL, by binding with high affinity to the BH3-binding groove of these proteins, in much the same way that pro-apoptotic BH3-only proteins do (see Figure 18–10D). These BH3-mimetic drugs (Figure 18–15) activate the intrinsic pathway of apoptosis, increasing the amount of tumor cell death in certain cancers, especially those that depend on particular anti-apoptotic Bcl2 family proteins for their survival.

Most human cancers are carcinomas, which arise in epithelial tissues such as those in the lung, intestinal tract, breast, and prostate (discussed in Chapter 20). Such epithelial cancer cells display many abnormalities in their behavior, including a decreased ability to adhere to the extracellular matrix and to one another at specialized cell–cell junctions. In the next chapter, we discuss these vitally important structures, which are responsible for holding our cells in tissues and organs in their proper place.

Summary

Animal cells can activate various intracellular death programs and kill themselves when they are seriously damaged or stressed, no longer needed, or are a threat to the organism. In most cases, these deaths occur by apoptosis, in which the cells shrink, the nucleus and cells condense and often fragment, and neighboring phagocytic cells rapidly engulf the cells or fragments before there is any leakage of cytoplasmic contents. Apoptosis is mediated by proteolytic enzymes called caspases, which cleave specific intracellular proteins to kill the cell quickly and neatly.

Apoptotic caspases are present as inactive precursors in almost all nucleated animal cells. The activation of initiator caspases occurs when an apoptotic stimulus activates adaptor proteins, which bring inactive initiator caspase monomers into proximity within large activation complexes, in which the monomers are activated by dimerization. The activated initiator caspase dimers cleave themselves and then activate downstream executioner caspase dimers by cleaving them; the activated executioner caspases then cleave hundreds of target proteins in the cell. The amplifying, irreversible caspase cascade is responsible for all the events of apoptosis, including those that collectively kill the cell and prepare it for being phagocytosed and rapidly digested by a neighboring cell.

Cells use two distinct pathways to activate initiator caspases to trigger apoptosis: the extrinsic pathway is activated by extracellular ligands binding to cell-surface death receptors; the intrinsic pathway is activated from within the cell by developmental signals or stress signals. Each pathway uses its own initiator caspases, adaptor proteins, and activation complexes. In the extrinsic pathway, the death receptors recruit caspase-8 via adaptor proteins to form the activation complex called the DISC. In the intrinsic pathway, intracellular signals induce mitochondrial outer membrane permeabilization (MOMP), which releases soluble proteins from the mitochondrial intermembrane space into the cytosol; released cytochrome c activates the adaptor protein Apaf1, which recruits caspase-9 monomers to form a large activation complex called an apoptosome. Anti-apoptotic and proapoptotic intracellular Bcl2 family proteins interact with one another to tightly control MOMP to ensure that the intrinsic pathway of apoptosis is normally only activated when the death of the cell benefits the animal.

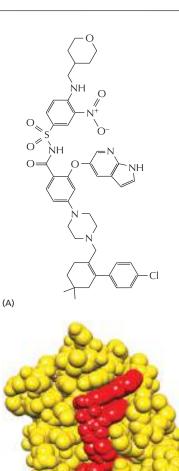

Figure 18-15 A BH3-mimetic drug that specifically inhibits the Bcl2 antiapoptotic Bcl2 family protein. As shown in Figure 18-10D, one way BH3-only proteins can promote apoptosis is by binding to the long BH3-binding groove in anti-apoptotic Bcl2 family proteins such as Bcl2 itself, thereby preventing the protein from blocking apoptosis. (A) The chemical structure of venetoclax, which was designed and synthesized to bind tightly and specifically in the BH3-binding groove of Bcl2. (B) Crystal structure of venetoclax (red) bound to the human Bcl2 protein (vellow). By inhibiting the activity of Bcl2, the drug promotes apoptosis in any cell that depends on this protein for survival, as is the case for cells of human chronic lymphocytic leukemia, for which this drug is in clinical use. (PDB code: 600K.)

PROBLEMS 1103

PROBLEMS

Which statements are true? Explain why or why not.

18–1 In normal adult tissues, cell death usually balances cell division.

18–2 Mammalian cells that do not have cytochrome *c* should be resistant to apoptosis induced by DNA damage.

Discuss the following problems.

18–3 Fas ligand is a homotrimeric plasma membrane protein on killer lymphocytes that binds to a homotrimeric death receptor, Fas, on the surface of target cells, including some lymphocytes (**Figure Q18–1**). The clustering of trimeric Fas by the binding of clusters of Fas ligand alters the conformation of Fas so that it binds an adaptor protein, which then recruits and activates caspase-8, triggering a caspase cascade that leads to apoptotic cell death.

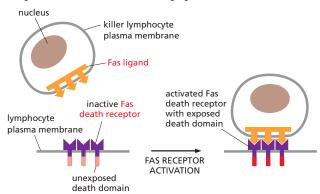

Figure Q18–1 The binding of trimeric Fas ligand to Fas (Problem 18–3). Although not shown, at least two trimeric Fas ligands have to bind to and cluster at least two trimeric Fas receptors to activate the pathway; for clarity, only a single copy of the ligand and receptor is shown.

In humans, the autoimmune lymphoproliferative syndrome (ALPS) is associated with dominant mutations in Fas that include point mutations and C-terminal truncations. In individuals that are heterozygous for such mutations, some lymphocytes do not die at their normal rate and accumulate in abnormally large numbers, causing a variety of clinical problems. In contrast to these patients, individuals heterozygous for mutations that eliminate Fas expression entirely do not have these clinical problems.

Assuming that the normal and dominant forms of Fas are expressed to the same level and assemble randomly into trimers, what fraction of Fas–Fas ligand complexes on a lymphocyte from a heterozygous ALPS patient would be expected to be composed entirely of normal Fas subunits? Does your calculation suggest an explanation for why individuals heterozygous for expressed Fas mutants have clinical problems, whereas heterozygous individuals with unexpressed Fas mutants have no clinical problems?

18–4 In contrast to their similar brain abnormalities, newborn mice deficient in Apaf1 or caspase-9 have distinctive abnormalities in their paws. Apaf1-deficient mice

fail to eliminate the webs between their developing digits, whereas caspase-9-deficient mice have normally formed digits (Figure Q18-2). If Apaf1 and caspase-9 function in the same apoptotic pathway, how is it possible for these deficient mice to differ in web-cell apoptosis?

Figure Q18–2 Appearance of paws in *Apaf1*^{-/-} and *Casp9*^{-/-} newborn mice relative to normal newborn mice (Problem 18–4). (From H. Yoshida et al., *Cell* 94:739–750, 1998. With permission from Elsevier.)

18–5 When human cancer cells are exposed to ultraviolet (UV) light at 90 mJ/cm², most of the cells undergo apoptosis within 24 hours. Release of cytochrome *c* from mitochondria can be detected as early as 6 hours after exposure of a population of such cells to UV light, and it continues to increase for more than 10 hours thereafter. Does this mean that individual cells slowly release their cytochrome *c* over this time period? Or, alternatively, do individual cells release their cytochrome *c* rapidly but with different cells being triggered at variable times?

To answer this fundamental question, you have fused the gene for green fluorescent protein (GFP) to the gene for cytochrome c, so that you can observe the behavior of individual cells by confocal fluorescence microscopy. In cells that are expressing the cytochrome c-GFP fusion protein, fluorescence shows the punctate pattern typical of mitochondrial proteins. You then irradiate these cells with UV light and observe individual cells for changes in the punctate pattern. Two such cells (outlined in white) are shown in Figure Q18–3A and B. Release of

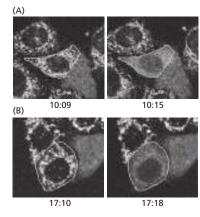

Figure Q18–3 Analysis of cytochrome c–GFP release from mitochondria of individual cells by time-lapse video fluorescence microscopy (Problem 18–5). (A) Cells observed for 6 minutes, 10 hours after UV irradiation. (B) Cells observed for 8 minutes, 17 hours after UV irradiation. One cell in A and one in B, each outlined in white, have released their cytochrome c–GFP during the time frame of the observation, which is shown as hours:minutes below each panel. (From J.C. Goldstein et al., Nat. Cell Biol. 2:156–162, published 2000 by Nature Publishing Group. Reproduced with permission from SNCSC.)

cytochrome *c*-GFP is detected as a change from a punctate to a diffuse pattern of fluorescence characteristic of a cytosolic protein. Times after UV exposure are indicated as hours:minutes below the individual panels.

Which model for cytochrome c release do these observations support? Explain your reasoning.

- **18–6** Imagine that you could microinject cytochrome *c* into the cytosol of wild-type mammalian cells, or into the cytosol of cells that were defective for the process of mitochondrial outer membrane permeabilization (MOMP). Would you expect the injected wild-type cells or the injected MOMP-defective cells to undergo apoptosis? Explain your reasoning.
- **18–7** Which one of the following statements about Bcl2 family members is correct?
- A. Bak is pro-apoptotic and Bax is anti-apoptotic.
- B. Bax is pro-apoptotic and BclxL is anti-apoptotic.
- C. Bcl2 is pro-apoptotic and Bak is anti-apoptotic.
- D. BclxL is pro-apoptotic and Bcl2 is anti-apoptotic.

18–8 One important role of Fas and Fas ligand is to mediate the elimination of tumor cells by killer lymphocytes. In a study of 35 primary lung and colon tumors, half the tumors were found to have amplified and overexpressed a gene for a secreted protein that binds to Fas ligand. How do you suppose that overexpression of this protein might contribute to the survival of these tumor cells? Explain your reasoning.

CELLS IN THEIR SOCIAL CONTEXT

Cell Junctions and the Extracellular Matrix

CHAPTER

19

Of all the social interactions between cells in a multicellular organism, the most fundamental are those that hold the cells together. Cells may be linked by direct interactions or they may be held together within the *extracellular matrix*, a complex network of proteins and polysaccharide chains that the cells secrete. By one means or another, cells must cohere if they are to form an organized multicellular structure that can withstand and respond to the various external forces that try to pull it apart.

Mechanisms of cell cohesion govern the architecture of tissues and organs—their shape, strength, and the arrangement of different cell types. The making and breaking of the attachments between cells and the modeling of the extracellular matrix govern the way cells move within the organism, guiding them as the body grows, develops, and repairs itself. Attachments to other cells and to the extracellular matrix control the orientation and behavior of the cell's cytoskeleton, thereby allowing cells to sense and respond to changes in the mechanical features of their environment. Thus, the apparatus of cell junctions and the extracellular matrix is critical for every aspect of the organization, function, and dynamics of multicellular structures. Defects in this apparatus underlie an enormous variety of diseases.

The key features of cell junctions and the extracellular matrix are best illustrated by considering two broad categories of tissues that are found in all animals (Figure 19–1). Connective tissues, such as bone or tendon, are formed from an extracellular matrix produced by cells that are distributed sparsely in the matrix. It is the matrix—rather than the cells—that bears most of the mechanical stress to which the tissue is subjected. *Cell-matrix junctions* link connective tissue cells to the matrix, allowing the cells to move through the matrix and monitor changes in its mechanical properties.

In **epithelial tissues**, such as the lining of the gut or the epidermal covering of the skin, cells are tightly bound together into sheets called **epithelia**. The extracellular matrix is less pronounced, consisting mainly of a thin mat called the *basal lamina* (or *basement membrane*) underlying the sheet. Within the epithelium, cells are attached to each other directly by *cell-cell junctions*, where cytoskeletal filaments are anchored, transmitting stresses across the interiors of the cells, from

adhesion site to adhesion site. The cytoskeletons of epithelial cells are also linked to the basal lamina through cell–matrix junctions.

Figure 19-2 provides a closer view of epithelial cells to illustrate the major types of cell-cell and cell-matrix junctions that we will discuss in this chapter. The diagram shows the typical arrangement of junctions in a *simple columnar* epithelium such as the lining of the small intestine of a vertebrate. Here, a single layer of tall cells stands on a basal lamina, with the cells' uppermost surface, or **apical** surface, free and exposed to the extracellular medium. On their sides, or *lateral* surfaces, the cells make junctions with one another. Two types of cell-cell junctions link the cytoskeletons of adjacent cells: **adherens junctions** are connected to actin filaments, and **desmosomes** are linked to intermediate filaments. Because these junctions anchor the cells strongly to each other and thus help the

Figure 19–1 How animal cells are bound together in two major tissue types. In connective tissue, the extracellular matrix is the main stress-bearing component. In epithelial tissue, the cytoskeleton of the cell is the main stress-bearing component: the cytoskeletons of cells are linked from cell to cell by adhesive junctions and transmit mechanical stresses across the interiors of the cells. Cell-matrix attachments bond epithelial tissue to the connective tissue beneath it.

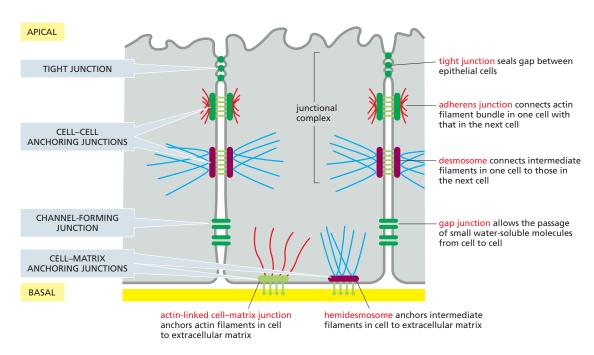

Figure 19–2 A summary of the various cell junctions found in a vertebrate epithelial cell. In the apical region of the cell, the relative positions of the junctions are the same in nearly all vertebrate epithelia. The tight junction occupies the most apical position, followed by the adherens junction (adhesion belt) and then by a special parallel row of desmosomes; together, these three junctions form a structure called a junctional complex. Gap junctions and additional desmosomes are less regularly organized. Two types of cell—matrix anchoring junctions tether the basal surface of the cell to the basal lamina. The drawing is based on epithelial cells of the small intestine.

MBOC7_ptr_ch19_1105-1162.indd 1106 02/12/21 12:25 PM

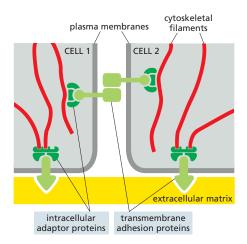

Figure 19–3 Transmembrane adhesion proteins link the cytoskeleton to extracellular structures. The external linkage may be either to other cells (cell–cell junctions, mediated typically by cadherins) or to extracellular matrix (cell–matrix junctions, mediated typically by integrins). The internal linkage to the cytoskeleton is generally indirect, via intracellular adaptor proteins, to be discussed later.

tissue withstand mechanical stress, they are sometimes called **anchoring junctions**. At the **basal** surface of the cells, two additional types of anchoring junctions link the cytoskeleton of the epithelial cell to the basal lamina: *actin-linked cell-matrix junctions* anchor actin filaments to the matrix, while *hemidesmosomes* anchor intermediate filaments to it.

Two other types of cell-cell junctions are shown in Figure 19–2. *Tight junctions* hold the cells closely together near the apical surface, sealing the gap between the cells and thereby preventing molecules from leaking across the epithelium. Near the basal end of the cells are channel-forming junctions, called *gap junctions*, that create passageways linking the cytoplasms of adjacent cells.

Each of the four major anchoring junction types depends on **transmembrane adhesion proteins** that span the plasma membrane, with one end linking to the cytoskeleton inside the cell and the other end linking to other structures outside it (**Figure 19–3**). These cytoskeleton-linked transmembrane proteins fall neatly into two superfamilies, corresponding to the two basic kinds of external attachment. Proteins of the **cadherin** superfamily chiefly mediate attachment of cell to cell (**Movie 19.1**). Proteins of the **integrin** superfamily chiefly mediate attachment of cells to matrix. There is specialization within each family: some cadherins link to actin and form adherens junctions, while others link to intermediate filaments and form desmosomes; likewise, some integrins link to actin and form actin-linked cell–matrix junctions, while others link to intermediate filaments and form hemidesmosomes (**Table 19–1**).

TABLE 19–1 Anchoring Junctions				
Junction	Transmembrane adhesion protein	Extracellular ligand	Intracellular cytoskeletal attachment	Intracellular adaptor proteins

There are some exceptions to these rules. Some integrins, for example, mediate cell-cell rather than cell-matrix attachment. Moreover, there are other types of cell adhesion molecules that can provide transient cell-cell attachments more flimsy than anchoring junctions but sufficient to stick cells together in special circumstances.

We begin the chapter with a discussion of the major forms of cell-cell junctions. We then consider in turn the extracellular matrix of animals, the structure and function of integrin-mediated cell-matrix junctions, and, finally, the plant cell wall, a special form of extracellular matrix.

CELL-CELL JUNCTIONS

Cell-cell junctions come in many forms and can be regulated by a variety of mechanisms. The best understood and most common are the two types of cellcell anchoring junctions, which employ cadherins to link the cytoskeleton of one cell with that of its neighbor. Their primary function is to resist the external forces that pull cells apart. The epithelial cells of your skin, for example, must remain tightly linked when they are stretched, pinched, or poked. Cell-cell anchoring junctions must also be dynamic and adaptable, so that they can be altered or rearranged when tissues are remodeled or repaired or when there are changes in the forces acting on them.

In this section, we focus primarily on the cadherin-based anchoring junctions. We then briefly describe tight junctions and gap junctions. Finally, we consider the more transient cell-cell adhesion mechanisms employed by some cells in the bloodstream.

Cadherins Form a Diverse Family of Adhesion Molecules

Cadherins are present in all multicellular animals. They are also present in the choanoflagellates, which are closely related to animals but can exist either as free-living unicellular organisms or as multicellular colonies. Other eukaryotes, including fungi and plants, lack cadherins, and they are also absent from bacteria and archaea. Cadherins therefore seem to be part of the essence of what it is to be an animal.

The cadherins take their name from their dependence on Ca²⁺ ions: removing Ca²⁺ from the extracellular medium causes adhesions mediated by cadherins to come apart. The first three cadherins to be discovered were named according to the main tissues in which they were found: *E-cadherin* is present on many types of epithelial cells; N-cadherin on nerve, muscle, and lens cells; and P-cadherin on cells in the placenta and epidermis. All are also found in other tissues. These and other classical cadherins are closely related in sequence throughout their extracellular and intracellular domains.

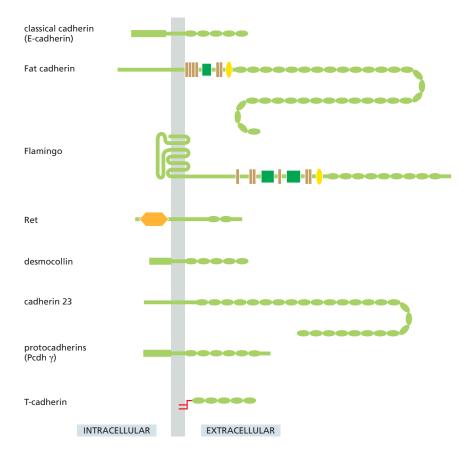

There are also a large number of nonclassical cadherins that are more distantly related in sequence, with more than 50 expressed in the brain alone. The nonclassical cadherins include proteins with known adhesive function, such as the diverse protocadherins found in the brain, and the desmocollins and desmogleins that form desmosomes (see Table 19-1). Together, the classical and nonclassical cadherin proteins constitute the cadherin superfamily (Figure 19-4), with more than 180 members in humans.

Cadherins Mediate Homophilic Adhesion

Anchoring junctions between cells are usually symmetrical: if the linkage is to actin in the cell on one side of the junction, it will be to actin in the cell on the other side. In fact, the binding between cadherins is generally homophilic (liketo-like; Figure 19-5): cadherin molecules of a specific subtype on one cell bind to cadherin molecules of the same or closely related subtype on adjacent cells.

The spacing between the cell membranes at an anchoring junction is precisely defined and depends on the structure of the participating cadherin molecules. All

MBOC7_ptr_ch19_1105-1162.indd 1108 02/12/21 12:25 PM CELL-CELL JUNCTIONS 1109

among cadherin superfamily members. These proteins all have extracellular portions containing multiple copies of the extracellular cadherin domain (green ovals). In the classical cadherins of vertebrates there are 5 of these domains, and in desmogleins and desmocollins there are 4 or 5, but some nonclassical cadherins have more than 30. The intracellular portions are more varied, reflecting interactions with a wide variety of

Figure 19-4 The cadherin superfamily.

The diagram shows some of the diversity

is not present, and the protein is attached to the plasma membrane by a glycosylphosphatidylinositol (GPI) anchor. The differently colored motifs in Fat, Flamingo, and Ret represent conserved domains that are also found in other protein families.

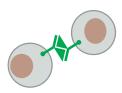

intracellular ligands, including signaling molecules and adaptor proteins that connect the cadherin to the cytoskeleton. In some cases, such as

T-cadherin, a transmembrane domain

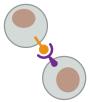

the members of the superfamily, by definition, have an extracellular portion consisting of several copies of the *extracellular cadherin (EC) domain*. Homophilic binding occurs at the N-terminal tips of the cadherin molecules—the cadherin domains that lie farthest from the membrane. These terminal domains each form a knob and a nearby pocket, and the cadherin molecules protruding from opposite cell membranes bind by insertion of the knob of one domain into the pocket of the other (Figure 19–6A).

Each cadherin domain forms a more-or-less rigid unit, joined to the next cadherin domain by a hinge. Ca^{2+} ions bind to sites near each hinge and prevent it from flexing, so that the whole string of cadherin domains behaves as a rigid and slightly curved rod. When Ca^{2+} is removed, the hinges can flex, and the structure becomes floppy (**Figure 19–6B**). At the same time, the conformation at the N-terminus is thought to change slightly, weakening the binding affinity for the matching cadherin molecule on the opposite cell.

Unlike receptors for soluble signaling molecules, which bind their specific ligand with high affinity, cadherins (and most other cell-cell adhesion proteins) typically bind to their partners with relatively low affinity. Strong attachments result from the formation of many such weak bonds in parallel. When binding to oppositely oriented partners on another cell, cadherin molecules are often clustered side-to-side with many other cadherin molecules on the same cell (Figure 19–6C). The strength of this junction is far greater than that of any individual intermolecular bond, and yet regulatory mechanisms can easily disassemble the junction by separating the molecules sequentially, just as two pieces of fabric can be joined strongly by Velcro and yet easily peeled apart from the sides. A similar "Velcro principle" also operates at cell-cell and cell-matrix adhesions formed by other types of transmembrane adhesion proteins.

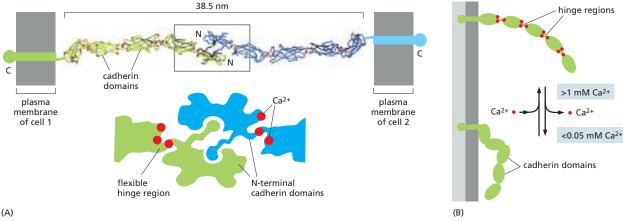

HOMOPHILIC BINDING

HETEROPHILIC BINDING

Figure 19–5 Homophilic versus heterophilic binding. Cadherins in general bind homophilically; some other cell adhesion molecules, discussed later, bind heterophilically.

MBOC7_ptr_ch19_1105-1162.indd 1109 02/12/21 12:25 PM

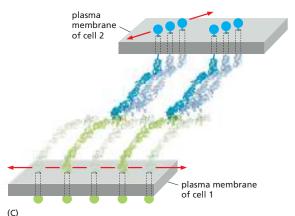

Figure 19-6 Cadherin structure and function. (A) The extracellular region of a classical cadherin contains five copies of the extracellular cadherin domain (see Figure 19-4) separated by flexible hinge regions. At a typical extracellular Ca2+ concentration (>1 mM), Ca2+ ions (red dots) bind in the neighborhood of each hinge, preventing it from flexing. To generate cellcell adhesion, the cadherin domain at the N-terminal tip of one cadherin molecule binds the cadherin domain at the N-terminal tip of a cadherin molecule on another cell. The structure was determined by x-ray diffraction of the crystallized C-cadherin extracellular region. The two cadherins shown here, although identical, are colored differently for clarity. (B) If the extracellular Ca2+ concentration is decreased artificially in an experiment, Ca²⁺ binding decreases. As a result, increased flexibility in the hinge regions results in a floppier molecule that is no longer oriented correctly to interact with a cadherin on another cell—and adhesion fails. (C) At a typical cell-cell junction, an organized array of cadherin molecules functions like Velcro to hold cells together. Cadherins on the same cell are thought to be coupled by side-to-side interactions between their N-terminal head regions, resulting in a linear array like the alternating green and light green cadherins on the lower cell shown here. These arrays are thought to interact with perpendicular arrays on an adjacent cell (blue cadherin molecules, top cell). Multiple perpendicular arrays on both cells interact to form a tight-knit mat of cadherin proteins. (A, based on T.J. Boggon et al., Science 296:1308-1313, 2002; C, based on O.J. Harrison et al., Structure 19:244-256, 2011.)

Cadherin-dependent Cell-Cell Adhesion Guides the Organization of Developing Tissues

Cadherins form specific homophilic attachments, explaining why there are so many different family members. Cadherins are not like glue, making cell surfaces generally sticky. Rather, they mediate highly selective recognition, enabling cells of a similar type to stick together and to stay segregated from other types of cells.

Selectivity in the way that animal cells consort with one another was first demonstrated in the 1950s, long before the discovery of cadherins, in experiments in which amphibian embryos were dissociated into single cells. These cells were then mixed up and allowed to reassociate. Remarkably, the dissociated cells often reassembled into structures resembling those of the original embryo (Figure 19–7).

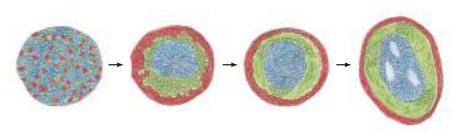

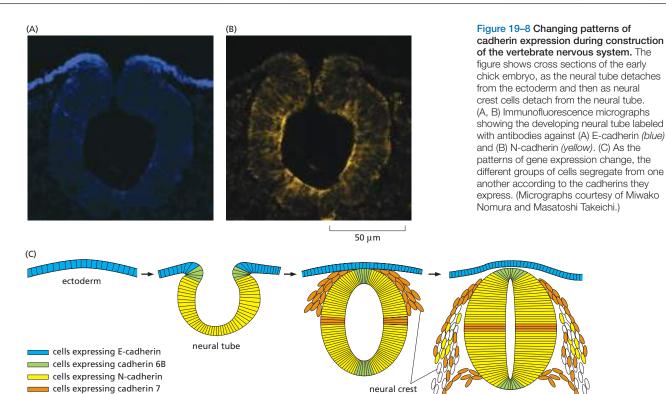

Figure 19–7 Sorting out. Cells from different layers of an early amphibian embryo will sort out according to their origins. In the classical experiment shown here, mesoderm cells (green), neural plate cells (blue), and epidermal cells (red) have been disaggregated and then reaggregated in a random mixture. They sort out into an arrangement reminiscent of a normal embryo, with a "neural tube" internally, epidermis externally, and mesoderm in between. (Modified from P.L. Townes and J. Holtfreter, J. Exp. Zool. 128:53–120, 1955. With permission from John Wiley & Sons.)

MBOC7_ptr_ch19_1105-1162.indd 1110 02/12/21 12:26 PM

CELL-CELL JUNCTIONS 1111

cells

These experiments, together with numerous more recent experiments, reveal that selective cell-cell recognition systems make cells of the same differentiated tissue preferentially adhere to one another.

Cadherins play a crucial part in these cell-sorting processes. The appearance and disappearance of specific cadherins correlate with steps in embryonic development where cells regroup and change their contacts to create new tissue structures. In the vertebrate embryo, for example, changes in cadherin expression are seen when the neural tube forms and pinches off from the overlying ectoderm: neural tube cells lose E-cadherin and acquire other cadherins, including N-cadherin, while the cells in the overlying ectoderm continue to express E-cadherin (Figure 19–8A and B). Then, when the neural crest cells migrate away from the neural tube, these cadherins become scarcely detectable, and another cadherin (cadherin 7) appears that helps hold the migrating cells together as loosely associated cell groups (Figure 19–8C). Finally, when some of the neural crest cells aggregate to form a ganglion, they switch on expression of N-cadherin again. If N-cadherin is artificially overexpressed in the emerging neural crest cells, the cells fail to escape from the neural tube.

Studies with cultured cells further support the importance of homophilic cadherin binding in tissue segregation. In a line of cultured fibroblasts called *L cells*, for example, cadherins are not expressed and the cells do not adhere to one another. When these cells are transfected with DNA encoding E-cadherin, E-cadherins on one cell bind to E-cadherins on another, resulting in cell-cell adhesion. If L cells expressing different cadherins are mixed together, they sort out and aggregate separately, indicating that different cadherins preferentially bind to their own type (Figure 19–9A), mimicking what happens when cells derived from tissues that express different cadherins are mixed together. A similar segregation of cells occurs if L cells expressing different amounts of the same cadherin are mixed together (Figure 19–9B). It therefore seems likely that both qualitative and quantitative differences in the expression of cadherins have a role in organizing tissues.

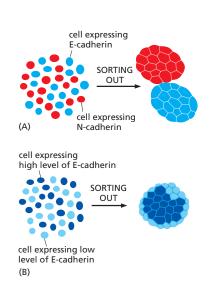

Figure 19–9 Cadherin-dependent cell sorting. Cells in culture can sort themselves out according to the type and level of cadherins they express. This can be visualized by labeling different populations of cells with dyes of different colors. (A) Cells expressing N-cadherin sort out from cells expressing E-cadherin. (B) Cells expressing high levels of E-cadherin sort out from cells expressing low levels of E-cadherin. The cells expressing high levels adhere more strongly and congregate internally.

MBOC7_ptr_ch19_1105-1162.indd 1111 02/12/21 12:26 PM

Assembly of Strong Cell–Cell Adhesions Requires Changes in the Actin Cytoskeleton

In their mature form, adherens junctions are enormous protein complexes containing hundreds to thousands of cadherin molecules, packed into dense, regular arrays that are linked on the extracellular side by lateral interactions between cadherin domains (see Figure 19–6C). The assembly of these junctions over a large surface area is not simply a matter of adding more cadherins to an initial attachment site, but also requires changes in the underlying actin cytoskeleton. Most important, strong adhesion requires a decrease in *cortical tension* at the site of the adhesion.

Cortical tension in a cell is much like the surface tension of a water droplet. In water, binding between water molecules at the air–water interface pulls the surface inward, resulting in a spherical shape that resists disruption by other surfaces that do not interact with the water molecules (Figure 19–10A). Similarly, an unattached cell in suspension assumes a spherical shape because of cortical tension, which results from the contractile activity generated by bundles of actin and non-muscle myosin II at the cell cortex, just beneath the plasma membrane (Figure 19–10B). This cortical tension is so strong that when two cells initially interact through binding of cadherins on their surfaces, cortical tension prevents the spreading of the adhesion surface—and the cells interact at a single point.

Assembly of a large adhesion surface therefore depends on local reduction of cortical tension, which is achieved by inhibition of cortical actin-myosin fiber formation. These changes depend in part on two small GTPases called Rac and Rho. As we discussed in Chapter 16 (see Figure 16–75), signals generated by these GTPases govern local actin filament behavior: Rho generally promotes the formation of actin-myosin stress fibers at the cell cortex, while Rac inhibits the formation of these fibers and instead promotes branched actin networks. When two epithelial precursor cells first interact at a small cluster of cadherin linkages, the cadherins generate intracellular signals that promote local activation of Rac and inhibition of Rho. The result is disassembly of actin-myosin fibers and loss of local cortical tension—which then allows further cadherin recruitment to

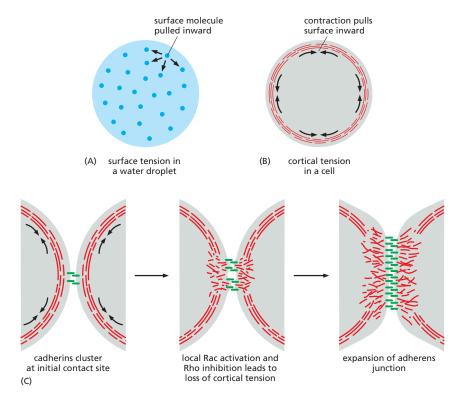

Figure 19-10 Local changes in cortical tension help promote the initial formation of an adherens junction. (A) Surface tension of a water droplet results from binding among water molecules at the air-water interface, pulling the surface inward. (B) In an unattached cell, the contraction of actin-myosin bundles at the cell cortex (red) creates cortical tension, drawing the surface inward. (C) When two epithelial cell precursors first interact, small cadherin clusters (green) assemble at the contact site. Cortical tension prevents this initial interaction site from spreading. The cadherins generate local signals to inhibit the GTPase Rho and activate the GTPase Rac, leading to localized disassembly of actin-myosin fibers, loss of cortical tension, and formation of branched actin networks and cell protrusions—all of which allow the recruitment of more cadherins and the spreading of the cell-cell junction over a greater surface area. In the long term (not shown), the large adherens junction inhibits Rac and stimulates Rho, thereby promoting formation of local actin-myosin fibers that interact with the cadherins (see

Figure 19-11).

MBOC7_ptr_ch19_1105-1162.indd 1112 02/12/21 12:26 PM

CELL-CELL JUNCTIONS 1113

spread the adhesion to a larger surface area (Figure 19–10C). Rac activation has the added benefit of stimulating local actin protrusions from the cell, which also contributes to expansion of the junction. The implications of this mechanism are clear: the development of strong adhesions depends not only on the cell adhesion molecules themselves but also on the associated regulatory systems that govern actin behavior.

Eventually, after large numbers of cadherin molecules are aligned at a nascent adherens junction, Rac is inhibited and Rho is activated, which promotes the assembly of linear, contractile actin filament bundles that link the adherens junction to the actin cytoskeleton. These new linkages pull the junction inward, generating tension that stimulates further actin recruitment and expansion of the junction, as we describe in the next sections.

Catenins Link Classical Cadherins to the Actin Cytoskeleton

The extracellular domains of cadherins mediate homophilic binding at adherens junctions. The intracellular domains of typical cadherins, including all classical and some nonclassical ones, interact with filaments of the cytoskeleton: actin at adherens junctions and intermediate filaments at desmosomes (see Table 19–1). These cytoskeletal linkages are essential for efficient cell-cell adhesion, as cadherins that lack their cytoplasmic domains cannot stably hold cells together.

The linkage of cadherins to the cytoskeleton depends on adaptor proteins that assemble on the cytoplasmic tail of the cadherin. At adherens junctions, the cadherin tail binds two such proteins, β -catenin and a distant relative called p120-catenin; a third protein called α -catenin interacts with β -catenin and recruits other proteins to provide a dynamic linkage to actin filaments (Figure 19–11). At desmosomes, cadherins are linked to intermediate filaments through other adaptor proteins, including a β -catenin-related protein called plakoglobin, as we discuss later.

Adherens Junctions Respond to Tension from Inside and Outside the Tissue

The protein complexes that mediate junctions either between cells or between cells and the extracellular matrix are dynamic machines that have the remarkable ability to sense mechanical stresses and generate biochemical signals that lead to an appropriate response. We call this *mechanotransduction*.

As we discussed in the previous sections, adherens junctions are linked through catenins to contractile bundles of actin and myosin II. These junctions are therefore subjected to pulling forces generated by the attached actin. The pulling forces are important for junction assembly and maintenance: inhibition of myosin activity, for example, results in the disassembly of many adherens junctions. Furthermore, the contractile forces acting on a junction in one cell are balanced by contractile forces at the junction of the neighboring cell, so that no cell pulls others toward it.

Adherens junctions sense the forces acting on them and modify local actin and myosin behavior to balance the forces on both sides of the junction. Evidence for these mechanisms comes from studies of pairs of cultured mammalian cells connected by adherens junctions. If contractile activity in one cell is increased experimentally, the adherens junctions linking the two cells increase in size, and the contractile activity of the second cell increases to match that of the first—resulting in a balance of forces across the junction. These and other experiments reveal that adherens junctions are not simply passive sites of protein–protein binding but are tension sensors that regulate their behavior in response to changing mechanical conditions.

Mechanotransduction at cell–cell junctions is thought to depend, at least in part, on proteins in the cadherin complex that alter their shape when stretched by tension. The protein α -catenin, for example, is stretched from a folded to an extended conformation when contractile activity increases at the junction. The

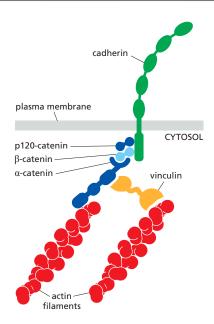

Figure 19–11 The linkage of classical cadherins to actin filaments. The cadherins are coupled indirectly to actin filaments through an adaptor protein complex containing p120-catenin, β -catenin, and α -catenin. Other proteins, including vinculin, associate with α -catenin and help provide the linkage to actin. β -Catenin has a second, and very important, function in intracellular signaling, as we discuss in Chapter 15 (see Figure 15–61). For clarity, this diagram does not show the cadherin of the adjacent cell in the junction.

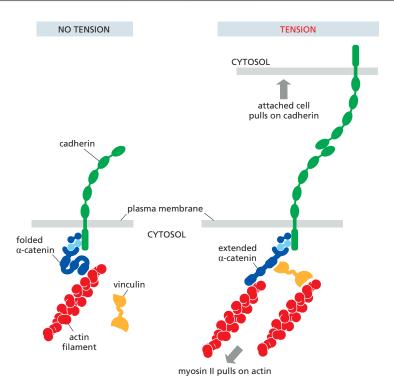

Figure 19–12 Mechanotransduction in an adherens junction. Cell–cell junctions are able to sense increased tension and respond by strengthening their actin linkages. When actin filaments are pulled from within the cell by non-muscle myosin II, the resulting force unfolds a domain in α -catenin, thereby exposing an otherwise hidden binding site for the adaptor protein vinculin. Vinculin then promotes additional actin recruitment, strengthening the linkages between the junction and the cytoskeleton.

unfolding exposes a cryptic binding site for another protein, vinculin, which promotes the recruitment of more actin to the junction (Figure 19–12). It is likely that these changes also lead to local regulation of the small GTPases that control actin and myosin behavior. By mechanisms such as this, pulling on a junction alters local actin behavior to make the junction stronger. Furthermore, as noted above, pulling on a junction in one cell will increase the contractile force generated in the attached cell.

Because all the cells in an epithelium are mechanically linked through their cell-cell junctions and cytoskeletons, mechanotransduction can also work over long distances. In the developing wing of *Drosophila*, for example, contraction of cells in the hinge of the wing results in mechanical stresses that spread throughout the wing, triggering changes in cell movement and orientation that are important for wing formation. It is likely that tension sensors throughout the tissue detect shifts in mechanical stress and trigger a molecular response. Because tension spreads quickly through all connected cells in a tissue, it provides an unusually rapid and effective signal for modifying cell behavior throughout the tissue.

Tissue Remodeling Depends on the Coordination of Actin-mediated Contraction with Cell–Cell Adhesion

Adherens junctions are an essential part of the machinery for modeling the shapes of multicellular structures in the animal body. By indirectly linking the actin filaments in one cell to those in its neighbors, they enable the cells in the tissue to use their actin cytoskeletons in a coordinated way.

Adherens junctions occur in various forms. In many nonepithelial tissues, they appear as small punctate or linear attachments that connect the cortical actin filaments beneath the plasma membranes of two interacting cells. In heart muscle, they anchor the actin bundles of the contractile apparatus and act in parallel with desmosomes to link the contractile cells end-to-end. But the prototypical examples of adherens junctions occur in epithelia, where they often form a continuous adhesion belt (or zonula adherens) that encircles each of the cells

MBOC7_ptr_ch19_1105-1162.indd 1114 02/12/21 12:26 PM

CELL-CELL JUNCTIONS 1115

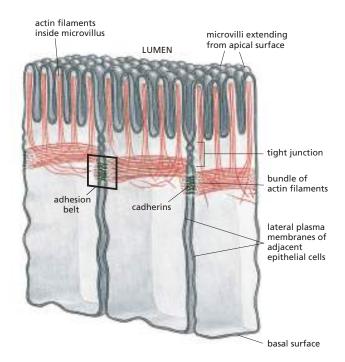

Figure 19-13 Adherens junctions between epithelial cells in the small intestine. These cells are specialized for absorption of nutrients; at their apical surfaces, facing the lumen of the gut, they have many microvilli (protrusions that increase the absorptive surface area). The adherens junction takes the form of an adhesion belt, encircling each of the interacting cells. Its most obvious feature is a contractile bundle of actin filaments running along the cytoplasmic surface of the junctional plasma membrane. The actin filament bundles are tethered by adaptor proteins to cadherins, which bind to cadherins on the adjacent cell. In this way, the actin filament bundles in adjacent cells are tied together. For clarity, this drawing does not show most of the other cell-cell and cell-matrix junctions of epithelial cells (see Figure 19-2).

just beneath the apical surface of the epithelium (Figure 19–13). Within each cell, a contractile bundle of actin filaments and myosin II lies adjacent to the adhesion belt, oriented parallel to the plasma membrane and tethered to it by the cadherins and their associated intracellular adaptor proteins. The actin–myosin bundles are thus linked, via the cadherins, into an extensive transcellular network. Coordinated contraction of this network provides the motile force for a fundamental process in animal morphogenesis—the folding of epithelial-cell sheets into tubes, spheres, and related structures (Figure 19–14).

In some forms of tissue remodeling, actin-myosin contractility is coordinated with major changes in local cell-cell adhesion patterns. An example can be found in cellular rearrangements that occur early in the development of the fruit fly *Drosophila melanogaster*. Soon after gastrulation, the outer epithelium of the

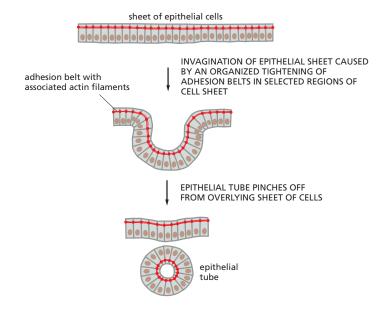

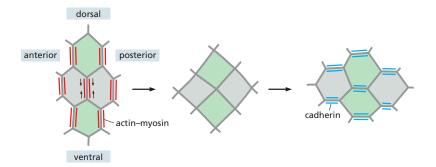

Figure 19–14 The folding of an epithelial sheet to form an epithelial tube. The oriented contraction of the bundles of actin and myosin filaments running along adhesion belts causes the epithelial cells to narrow at their apical surfaces, thereby helping the epithelial sheet to roll up into a tube. An example is the formation of the neural tube in early vertebrate development (see Figure 19–8).

MBOC7_ptr_ch19_1105-1162.indd 1115 02/12/21 12:26 PM

embryo is elongated by a process called *germ-band extension*, in which the cells converge inward along the dorsal-ventral axis and extend along the anterior-posterior axis. Actin-dependent contraction along dorsal-ventral cell boundaries is accompanied by a loss of specific adherens junctions to allow cells to insert themselves between other cells (a process called *intercalation*), resulting in a longer and narrower epithelium (Figure 19–15). We do not fully understand the mechanisms underlying the disassembly of adherens junctions along dorsal-ventral cell boundaries, but one possibility is that actin-based contractile forces pull sufficiently hard on the edges of cell-cell adhesions to peel them apart, particularly if contraction is coupled to additional regulatory mechanisms that weaken the adhesion. There is evidence, for example, that remodeling of these and other adhesions during development depends on removal of cadherins from the cell surface by clathrin-mediated endocytosis.

Desmosomes Give Epithelia Mechanical Strength

Desmosomes are structurally similar to adherens junctions but contain specialized cadherins that link to intermediate filaments instead of actin filaments. Their main function is to provide mechanical strength. Desmosomes are important in vertebrates but are not found, for example, in *Drosophila*. They are present in most mature vertebrate epithelia and are particularly plentiful in tissues that are subject to high levels of mechanical stress, such as heart muscle and the epidermis, the epithelium that forms the outer layer of the skin.

Figure 19–16A shows the general structure of a desmosome, and **Figure 19–16B** shows some of the proteins that form it. Desmosomes typically appear as buttonlike spots of adhesion, riveting the cells together (**Figure 19–16C**). Inside the cell, the bundles of rope-like intermediate filaments that are anchored to the desmosomes form a structural framework of great tensile strength (**Figure 19–16D**), with linkage to similar bundles in adjacent cells, creating a network that extends throughout the tissue (**Figure 19–17**). The particular type of intermediate filaments attached to the desmosomes depends on the cell type: they are *keratin filaments* in most epithelial cells, for example, and *desmin filaments* in heart muscle cells.

The importance of desmosomes is demonstrated by some forms of the potentially fatal skin disease *pemphigus*. Affected individuals make antibodies against one of their own desmosomal cadherin proteins. These antibodies bind to and disrupt the desmosomes that hold their epidermal cells (keratinocytes) together. This results in a severe blistering of the skin, with leakage of body fluids into the loosened epithelium.

Tight Junctions Form a Seal Between Cells and a Fence Between Plasma Membrane Domains

Sheets of epithelial cells enclose and partition the animal body, lining all its surfaces and cavities, and creating internal compartments where specialized processes occur. The epithelial sheet seems to be one of the inventions that lie at the origin of animal evolution, diversifying in a huge variety of ways but retaining an organization that is based on a set of conserved molecular mechanisms.

Figure 19-15 Remodeling of cell-cell adhesions in embryonic Drosophila epithelium. Depicted at left is a group of cells in the outer epithelium of a Drosophila embryo. During germ-band extension, cells converge toward each other (middle) on the dorsal-ventral axis and then extend (right) along the anterior-posterior axis. The result is intercalation: cells that were originally far apart along the dorsal-ventral axis (green) are inserted between the cells (gray) that separated them. These rearrangements depend on the spatial regulation of actin-myosin contractile bundles, which are localized primarily at the vertical cell boundaries (red. left). Contraction of these bundles is accompanied by removal of E-cadherin (not shown) at the same cell boundaries, resulting in shrinkage and loss of adhesion along the vertical axis (middle). New cadherin-based adhesions (blue, right) then form and expand along horizontal boundaries, resulting in extension of the cells in the anterior-posterior dimension.

CELL_CELL JUNCTIONS 1117

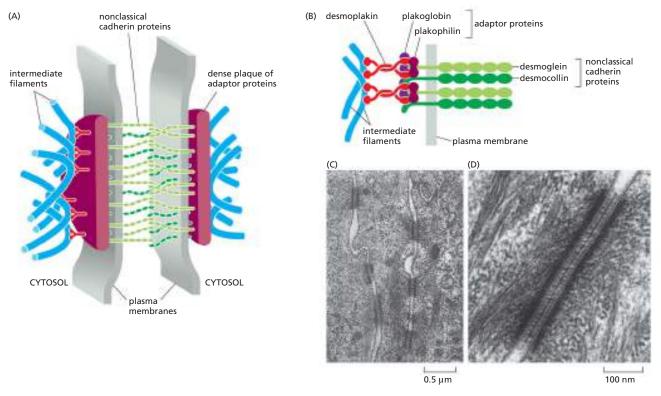

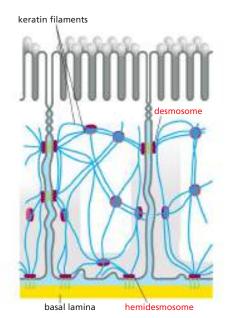

Figure 19–16 Desmosomes. (A) The structural components of a desmosome. On the cytoplasmic surface of each interacting plasma membrane is a dense plaque composed of a mixture of intracellular adaptor proteins. A bundle of intermediate filaments is attached to the surface of each plaque. Transmembrane nonclassical cadherins bind to the plaques and interact through their extracellular domains to hold the adjacent membranes together. (B) Some of the molecular components of a desmosome. Desmoglein and desmocollin are nonclassical cadherins. Their cytoplasmic tails bind *plakoglobin* (γ-catenin) and *plakophilin* (a distant relative of p120-catenin), which in turn bind to *desmoplakin*. Desmoplakin binds to the sides of intermediate filaments, thereby tying the desmosome to these filaments. (C) An electron micrograph of desmosome junctions between three epidermal cells in the skin of a baby mouse. (D) Part of the same tissue at higher magnification, showing a single desmosome, with intermediate filaments attached to it. (C and D, from W. He et al., *Science* 302:109–113, 2003. With permission from AAAS.)

Essentially all epithelia are anchored to other tissue on one side (the basal side) and free of such attachment on their opposite side (the apical side). A basal lamina lies at the interface with the underlying tissue, mediating the attachment, while the apical surface of the epithelium is generally bathed in extracellular fluid. Thus, as discussed in Chapter 16, all epithelia are structurally **polarized**, and so are their individual cells: the basal end of a cell, adherent to the basal lamina below, differs from the apical end, exposed to the medium above.

Correspondingly, all epithelia have at least one function in common: they serve as selective permeability barriers, separating the fluid that permeates the tissue on their basal side from fluid with a different chemical composition on their apical side. This barrier function requires that the adjacent cells be sealed together by **tight junctions**, so that molecules cannot leak freely across the cell sheet.

The epithelium of the small intestine provides a good illustration of tight-junction structure and function (see Figure 19–2). This epithelium has a *simple columnar* structure; that is, it consists of a single layer of tall (columnar) cells. These are of several differentiated types, but the majority are absorptive cells, specialized for uptake of nutrients from the internal cavity, or *lumen*, of the gut.

Figure 19–17 Desmosomes, hemidesmosomes, and the intermediate filament network. The keratin intermediate filament networks of adjacent cells—in this example, epithelial cells of the small intestine—are indirectly connected to one another through desmosomes, and to the basal lamina through hemidesmosomes.

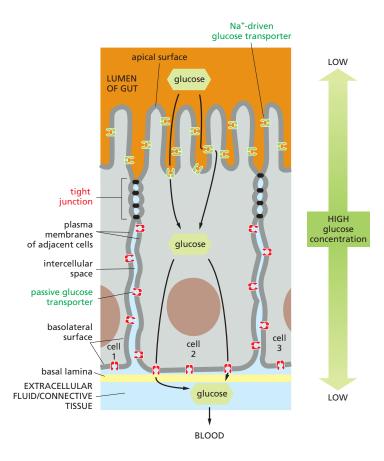

Figure 19-18 The role of tight junctions in transcellular transport. For clarity, only the tight junctions are shown. Transport proteins are confined to different regions of the plasma membrane in epithelial cells of the small intestine. This segregation results in the one-way transfer of nutrients across the epithelium from the gut lumen to the blood. In the example shown, glucose is actively transported into the cell by Na+-driven glucose transporters at its apical surface, and it leaves the cell through passive glucose transporters in its basolateral membrane. Tight junctions are thought to confine the transport proteins to their appropriate membrane domains by acting as diffusion barriers, or "fences," within the lipid bilayer of the plasma membrane; these junctions also block the backflow of glucose from the basal side of the epithelium into the gut lumen (see Movie 11.2).

The absorptive cells have to transport selected nutrients across the epithelium from the lumen into the extracellular fluid on the other side. From there, these nutrients diffuse into small blood vessels to provide nourishment to the organism. This transcellular transport depends on two sets of transport proteins in the plasma membrane of the absorptive cell. One set is confined to the apical surface of the cell (facing the lumen) and actively transports selected molecules into the cell from the gut. The other set is confined to the basolateral (basal and lateral) surfaces of the cell, and it allows the same molecules to leave the cell by passive transport into the extracellular fluid on the other side of the epithelium. For this transport activity to be effective, the spaces between the epithelial cells must be tightly sealed, so that the transported molecules cannot leak back into the gut lumen through these spaces (Figure 19-18). Moreover, the transport proteins must be correctly distributed in the plasma membranes: the apical transporters must be delivered to the apical membrane and must not be allowed to drift to the basolateral membrane, and the basolateral transporters must be delivered to and remain in the basolateral membrane. Tight junctions, besides sealing the gaps between the cells, also function as "fences" that help prevent apical or basolateral proteins from diffusing into the wrong region.

The sealing function of tight junctions is easy to demonstrate experimentally: a low-molecular-mass tracer added to one side of an epithelium will generally not pass beyond the tight junction (Figure 19–19). This seal is not absolute, however. Although all tight junctions are impermeable to macromolecules, their permeability to ions and other small molecules varies. Tight junctions in the epithelium lining the small intestine, for example, are 10,000 times more permeable to inorganic ions, such as ${\rm Na}^+$, than the tight junctions in the epithelium lining the urinary bladder. The movement of ions and other molecules between epithelial cells is called *paracellular transport*, and tissue-specific differences in transport rates generally result from differences in the proteins that form tight junctions.

CELL-CELL JUNCTIONS 1119

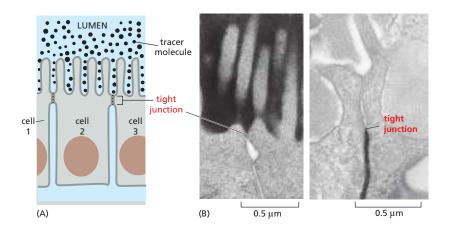

Figure 19–19 The role of tight junctions in allowing epithelia to serve as barriers to solute diffusion. (A) The drawing shows how a small extracellular tracer molecule added on one side of an epithelium is prevented from crossing the epithelium by the tight junctions that seal adjacent cells together. Adherens junctions and other cell junctions are not shown for clarity. (B) Electron micrographs of cells in an epithelium in which a small, extracellular, electron-dense tracer molecule has been added to either the apical side (on the left) or the basolateral side (on the right). The tight junction blocks passage of the tracer in both directions. (B, courtesy of Daniel Friend, by permission of E.L. Bearer.)

Tight Junctions Contain Strands of Transmembrane Adhesion Proteins

When tight junctions are visualized by freeze-fracture electron microscopy, they are seen as a branching network of *sealing strands* that completely encircles the apical end of each cell in the epithelial sheet (Figure 19–20A and B). In conventional electron micrographs, the outer leaflets of the two interacting plasma membranes are tightly apposed where sealing strands are present (Figure 19–20C). Each sealing strand is composed of a long row of transmembrane homophilic adhesion proteins embedded in each of the two interacting plasma membranes. The extracellular domains of these proteins adhere directly to one another to occlude the intercellular space (Figure 19–21).

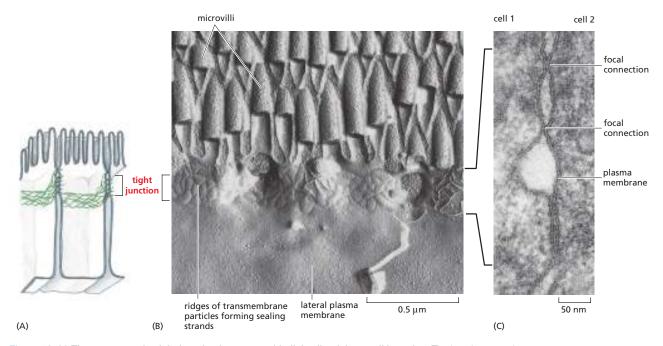

Figure 19–20 The structure of a tight junction between epithelial cells of the small intestine. The junctions are shown (A) schematically, (B) in a freeze-fracture electron micrograph, and (C) in a conventional electron micrograph. In B, the plane of the micrograph is parallel to the plane of the membrane, and the tight junction appears as a band of branching sealing strands that encircle each cell in the epithelium (see Figure 19–21A). In C, the junction is seen in cross section as a series of focal connections between the outer leaflets of the two interacting plasma membranes, each connection corresponding to a sealing strand in cross section. [B and C, from N.B. Gilula, in Cell Communication (R.P. Cox, ed.), pp. 1–29. New York: Wiley, 1974. With permission from John Wiley & Sons.]

MBOC7_ptr_ch19_1105-1162.indd 1119 02/12/21 12:26 PM

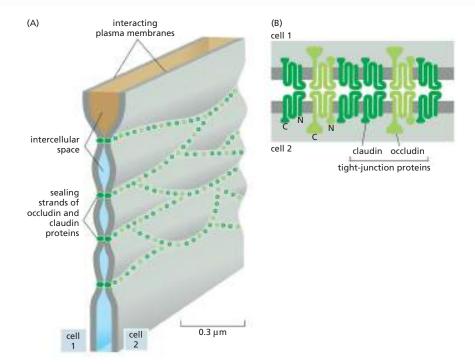

Figure 19–21 A model of a tight junction. (A) The sealing strands hold adjacent plasma membranes together. The strands are composed of transmembrane proteins that make contact across the intercellular space and create a seal. (B) The molecular composition of a sealing strand. The major extracellular components of the tight junction are members of a family of proteins with four transmembrane domains. One of these proteins, claudin, is the most important for the assembly and structure of the sealing strands, whereas the related protein occludin governs junction permeability. The two termini of these proteins are both on the cytoplasmic side of the membrane, where they interact with large scaffolding proteins that organize the sealing strands and link the tight junction to the actin cytoskeleton (not shown here, but see Figure 19-22).

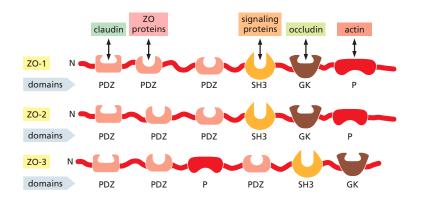

The main transmembrane proteins forming these strands are the *claudins*, which are essential for tight-junction formation and function. Mice that lack the *claudin-1* gene, for example, fail to make tight junctions between the cells in the epidermal layer of the skin; as a result, the baby mice lose water rapidly by evaporation through the skin and die within a day after birth. Conversely, if nonepithelial cells such as fibroblasts are artificially caused to express claudin genes, they will form tight-junctional connections with one another. Normal tight junctions also contain a second major transmembrane protein called *occludin*, which is not essential for the assembly or structure of the tight junction but is important for limiting junctional permeability. A third transmembrane protein, *tricellulin*, is required to seal cell membranes together and prevent transepithelial leakage at the points where three cells meet.

The claudin protein family has many members (24 in humans), and these are expressed in different combinations in different epithelia to confer particular permeability properties on the epithelial sheet. They are thought to form *paracellular pores*—selective channels allowing specific ions to cross the tight-junctional barrier, from one extracellular space to another. A specific claudin found in kidney epithelial cells, for example, is needed to let Mg^{2+} pass between the cells of the kidney tubules so that this ion can be resorbed from the urine into the blood. A mutation in the gene encoding this claudin results in excessive loss of Mg^{2+} in the urine.

Scaffold Proteins Organize Junctional Protein Complexes

Like the cadherin molecules of an adherens junction, the claudins and occludins of a tight junction interact with each other on their extracellular sides to promote junction assembly. Also as in adherens junctions, the organization of adhesion proteins in a tight junction depends on additional proteins that bind the cytoplasmic side of the adhesion proteins. The key organizational proteins at tight junctions are the *zonula occludens* (*ZO*) proteins. The three major members of the ZO family—ZO-1, ZO-2, and ZO-3—are large scaffold proteins that provide a structural support on which the tight junction is built. These intracellular molecules consist of strings of protein-binding domains, typically including several PDZ domains that can recognize and bind the C-terminal tails of specific partner proteins (Figure 19–22). One domain of these scaffold proteins can attach to

CELL-CELL JUNCTIONS 1121

a claudin protein, while others can attach to occludin or the actin cytoskeleton. Moreover, one molecule of scaffold protein can bind to another. In this way, the cell assembles a meshwork of intracellular proteins that organizes and positions the sealing strands of the tight junction.

The tight-junctional network of sealing strands usually lies just apical to adherens and desmosome junctions that bond the cells together mechanically; the whole assembly is called a *junctional complex* (see Figure 19–2). The parts of this junctional complex depend on each other for their formation. For example, anti-cadherin antibodies that block the formation of adherens junctions also inhibit the formation of tight junctions.

Gap Junctions Couple Cells Both Electrically and Metabolically

Tight junctions block the passageways through the gaps between epithelial cells, preventing extracellular molecules from leaking from one side of an epithelium to the other. Another type of junctional structure has a radically different function: it bridges gaps between adjacent cells so as to create direct channels from the cytoplasm of one to that of the other. These channels are called **gap junctions**.

Gap junctions are present in most animal tissues, including connective tissues as well as epithelia and heart muscle. Each gap junction appears in conventional electron micrographs as a patch where the membranes of two adjacent cells are separated by a uniform narrow gap of about 2–4 nm (Figure 19–23). The gap is

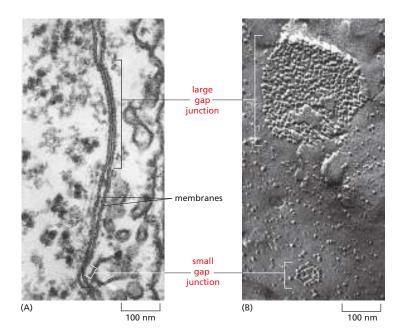

Figure 19-22 Scaffold proteins at the tight junction. The scaffold proteins ZO-1, ZO-2, and ZO-3 are concentrated beneath the plasma membrane at tight junctions. Each of the proteins contains multiple protein-binding domains, including three PDZ domains, an SH3 domain, a GK domain, and a proline-rich domain (P), linked together like beads on a flexible string. These domains enable the proteins to interact with each other and with numerous other partners, as indicated here by arrows, to generate a tightly woven protein network that organizes the sealing strands of the tight junction and links them to the actin cytoskeleton. Scaffold proteins with similar structure help organize other junctional complexes, including those at neural synapses.

Figure 19–23 Gap junctions as seen in the electron microscope. (A) Thinsection and (B) freeze-fracture electron micrographs of a large and a small gap-junction plaque between fibroblasts in culture. In B, each gap junction is seen as a cluster of homogeneous intramembrane particles. Each intramembrane particle corresponds to a connexon (see Figure 19–25). [From N.B. Gilula, in Cell Communication (R.P. Cox, ed.), pp. 1–29. New York: Wiley, 1974. With permission from John Wiley and Sons.]

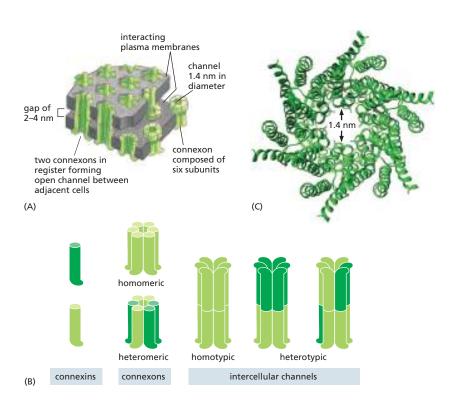

MBOC7_ptr_ch19_1105-1162.indd 1121 02/12/21 12:26 PM

spanned by channel-forming proteins, of which there are two distinct families, called the *connexins* and the *innexins*. Connexins are the predominant gapjunction proteins in vertebrates, with 21 isoforms in humans. Innexins are found in the gap junctions of invertebrates.

Gap junctions have a pore size of about 1.4 nm, which allows the exchange of inorganic ions and other small water-soluble molecules, but not of macromolecules such as proteins or nucleic acids (Figure 19-24). An electric current injected into one cell through a microelectrode causes an electrical disturbance in the neighboring cell, due to the flow of ions carrying electric charge through gap junctions. This electrical coupling via gap junctions serves an obvious purpose in tissues containing electrically excitable cells: action potentials can spread rapidly from cell to cell, without the delay that occurs at chemical synapses. In vertebrates, for example, electrical coupling through gap junctions synchronizes the contractions of heart muscle cells as well as those of the smooth muscle cells responsible for the peristaltic movements of the intestine. Gap junctions also occur in many tissues whose cells are not electrically excitable. In principle, the sharing of small metabolites and ions provides a mechanism for coordinating the activities of individual cells in such tissues and for smoothing out random fluctuations in small-molecule concentrations in different cells.

A Gap-Junction Connexon Is Made of Six Transmembrane Connexin Subunits

Connexins are four-pass transmembrane proteins, six of which assemble to form a *hemichannel*, or **connexon**. When the connexons in the plasma membranes of two cells in contact are aligned, they form a continuous aqueous channel that connects the two cell interiors (Figure 19-25). A gap junction consists of many such connexon pairs, forming a sort of molecular sieve. Not only does this sieve provide a communication channel between cells, but it also provides a form of cell-cell adhesion that supplements the cadherin- and claudin-mediated adhesions we discussed earlier.

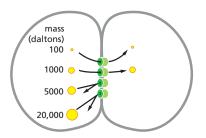

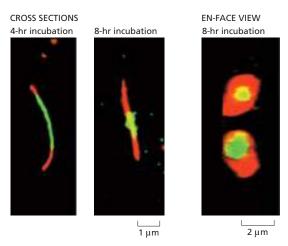

Figure 19–24 Determining the size of a gap-junction channel. When fluorescent molecules of various sizes are injected into one of two cells coupled by gap junctions, molecules with a mass of less than about 1000 daltons can pass into the other cell, but larger molecules cannot. Thus, the coupled cells share their small molecules (such as inorganic ions, sugars, amino acids, nucleotides, vitamins, and the intracellular signaling molecules cyclic AMP and inositol trisphosphate) but not their macromolecules (proteins, nucleic acids, and polysaccharides).

Figure 19-25 Gap junctions. (A) A drawing of the interacting plasma membranes of two adjacent cells connected by gap junctions. Each lipid bilayer is shown as a gray sheet. Protein assemblies called connexons (green), each of which is formed by six connexin subunits, penetrate the apposed lipid bilayers. Two connexons join across the intercellular gap to form a continuous aqueous channel connecting the two cells. (B) The organization of connexins into connexons, and connexons into intercellular channels. The connexons can be homomeric or heteromeric, and the intercellular channels can be homotypic or heterotypic. (C) The highresolution structure of a homomeric gapjunction channel, determined by x-ray crystallography of human connexin 26. In this view, we are looking down on the pore. formed from six connexin subunits. The structure illustrates the general features of the channel and suggests a pore size of about 1.4 nm, as predicted from studies of gap-junction permeability with molecules of various sizes (see Figure 19-24). (PDB code: 2ZW3.)

MBOC7_ptr_ch19_1105-1162.indd 1122 02/12/21 12:26 PM

CELL-CELL JUNCTIONS 1123

Gap junctions in different tissues can have different properties because they are formed from different combinations of connexins, creating channels that differ in permeability and regulation. Most cell types express more than one type of connexin, and two different connexin proteins can assemble into a heteromeric connexon, with its own distinct properties. Moreover, adjacent cells expressing different connexins can form intercellular channels in which the two aligned half-channels are different (see Figure 19–25B).

Like conventional ion channels (discussed in Chapter 11), individual gapjunction channels do not remain open all the time; instead, they flip between open and closed states. These changes are triggered by a variety of stimuli, including the voltage difference between the two connected cells, the membrane potential of each cell, and various chemical properties of the cytoplasm, including the pH and concentration of free Ca²⁺. Some subtypes of gap junctions can also be regulated by extracellular signals such as neurotransmitters. We are only just beginning to understand the physiological functions and structural basis of these various gating mechanisms.

Each gap-junctional plaque is a dynamic structure that can readily assemble, disassemble, or be remodeled, and it can contain a cluster of a few to many thousands of connexons (see Figure 19–23B). Studies with fluorescently labeled connexins in living cells show that new connexons are continually added around the periphery of an existing junctional plaque, while old connexons are removed from the middle of it and destroyed (Figure 19–26). This turnover is rapid: the connexin molecules have a half-life of only a few hours.

The mechanism of removal of old connexons from the middle of the plaque is not known, but the route of delivery of new connexons to its periphery seems clear: they are inserted into the plasma membrane by exocytosis, like other integral membrane proteins, and then diffuse in the plane of the membrane until they bump into the periphery of a connexon plaque and become trapped. This has a corollary: the plasma membrane away from the gap junction should contain connexons—hemichannels—that have not yet paired with their counterparts on another cell. It is thought that these unpaired hemichannels are normally held in a closed conformation, preventing the cell from losing its small molecules by leakage through them. But there is also evidence that in some circumstances they can open and serve as channels for the release of small signal molecules.

In Plants, Plasmodesmata Perform Many of the Same Functions as Gap Junctions

The tissues of a plant are organized on different principles from those of an animal. Plant cells are imprisoned within tough *cell walls* composed of an extracellular matrix rich in cellulose and other polysaccharides, as we discuss later.

Figure 19-26 Connexin turnover at a gap junction. Cells were transfected with a slightly modified connexin gene, coding for a connexin with a short amino acid tag containing four cysteines in the sequence Cys-Cys-X-X-Cys-Cys (where X denotes an arbitrary amino acid). This tetracysteine tag can bind strongly to certain small fluorescent dye molecules, which can be added to the culture medium and will readily enter cells by diffusing across the plasma membrane. In the experiment shown, a green dye was added first to label all the connexin molecules in the cells, and the cells were then washed and incubated for 4 or 8 hours. At the end of this time, a red dye was added to the medium and the cells were washed again and fixed. Connexin molecules already present at the beginning of the experiment are labeled green (and take up no red dye because their tetracysteine tags are already saturated with green dye), while connexins synthesized subsequently, during the 4- or 8-hour incubation, are labeled red. The fluorescence images show gap junctions between pairs of cells treated in this way. The central part of the gap-junction plaque is green, indicating that it consists of old connexin molecules, while the periphery is red, indicating that it consists of connexins synthesized during the previous 4 or 8 hours. The longer the time of incubation. the smaller the green central patch of old molecules, and the larger the peripheral ring of new molecules that have been recruited to replace the old ones. (From G. Gaietta et al., Science 296:503-507. 2002. With permission from AAAS.)

MBOC7_ptr_ch19_1105-1162.indd 1123 02/12/21 12:26 PM

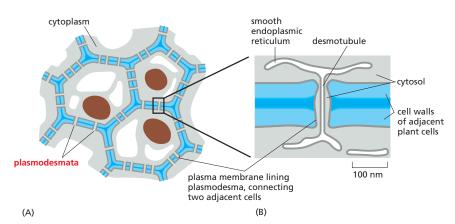

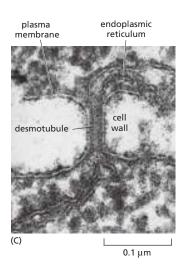

Figure 19–27 Plasmodesmata. (A) The cytoplasmic channels of plasmodesmata pierce the plant cell wall and connect cells in a plant together. (B) Each plasmodesma is lined with plasma membrane that is common to the two connected cells. It usually also contains a fine tubular structure, the desmotubule, derived from smooth endoplasmic reticulum. (C) Electron micrograph of a longitudinal section of a plasmodesma from a water fern. The plasma membrane lines the pore and is continuous from one cell to the next. Endoplasmic reticulum and its association with the central desmotubule can also be seen. (D) A similar plasmodesma seen in cross section. (C and D, from R. Overall et al., *Protoplasma* 111:134–150, 1982.)

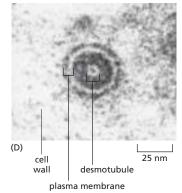

The cell walls of adjacent cells are firmly cemented to one another, which eliminates the need for anchoring junctions to hold the cells in place. But a need for direct cell-cell communication remains. Thus, plant cells have only one class of intercellular junctions, **plasmodesmata**. Like gap junctions, they directly connect the cytoplasms of adjacent cells.

In plants, the cell wall between a typical pair of adjacent cells is at least 0.1 μm thick, and so a structure very different from a gap junction is required to mediate communication across it. Plasmodesmata solve the problem. With a few specialized exceptions, every cell in a higher plant is connected to its neighbors by these structures, which form fine cytoplasmic channels through the intervening cell walls. As shown in Figure 19–27A, the plasma membrane of one cell is continuous with that of its neighbor at each plasmodesma, which connects the cytoplasms of the two cells by a roughly cylindrical channel with a diameter of 20–40 nm.

Running through the center of the channel in most plasmodesmata is a narrower cylindrical structure, the *desmotubule*, which is continuous with elements of the smooth endoplasmic reticulum (ER) in each of the connected cells (Figure 19–27B, C, and D). Between the outside of the desmotubule and the inner face of the cylindrical channel formed by plasma membrane is an annulus of cytosol through which small molecules can pass from cell to cell. As each new cell wall is assembled during the cytokinesis phase of cell division, plasmodesmata are created within it. They form around elements of smooth ER that become trapped across the developing cell plate (discussed in Chapter 17). They can also be inserted *de novo* through preexisting cell walls, where they are commonly found in dense clusters called *pit fields*. When no longer required, plasmodesmata can be removed.

In spite of the radical difference in structure between plasmodesmata and gap junctions, they seem to function in remarkably similar ways. Evidence obtained by injecting tracer molecules of different sizes suggests that plasmodesmata allow the passage of molecules with a mass of less than about 800 daltons, which is similar to the size cutoff for gap junctions. As with gap junctions, transport through plasmodesmata is regulated. Dye-injection experiments, for example, show that there can be barriers to the movement of even low-molecular-mass molecules between certain cells or groups of cells that are connected by apparently normal plasmodesmata; the mechanisms that restrict communication in these cases are not understood.

CELL_CELL JUNCTIONS 1125

Selectins Mediate Transient Cell-Cell Adhesions in the Bloodstream

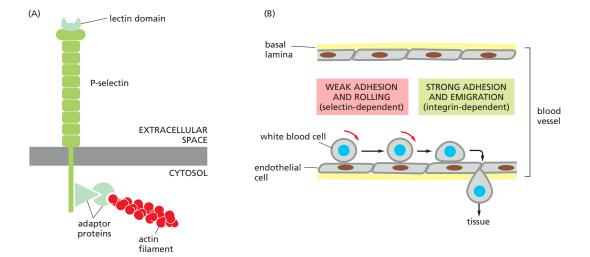

We now complete our overview of cell-cell junctions and adhesion by briefly describing some of the more specialized adhesion mechanisms used in some tissues. In addition to those we have already discussed, at least three other superfamilies of cell-cell adhesion proteins are important: the *integrins*, the *selectins*, and the adhesive *immunoglobulin* (*Ig*) *superfamily* members. We shall discuss integrins in more detail later: their main function is in cell-matrix adhesion, but a few of them mediate cell-cell adhesion in specialized circumstances. Ca²⁺ dependence provides one simple way to distinguish among these classes of adhesion proteins experimentally. Selectins, like cadherins and integrins, require Ca²⁺ for their adhesive function; Ig superfamily members do not.

Selectins are cell-surface carbohydrate-binding proteins (*lectins*) that mediate a variety of transient cell-cell adhesion interactions in the bloodstream. Their main role, in vertebrates at least, is in governing the traffic of white blood cells into lymphoid organs and inflamed tissues. White blood cells lead a nomadic life, roving between the bloodstream and the tissues, and this necessitates special adhesive behavior. The selectins control the binding of white blood cells to the endothelial cells lining blood vessels, thereby enabling the blood cells to migrate out of the bloodstream into a tissue.

Each selectin is a transmembrane protein with a conserved lectin domain that binds to a specific oligosaccharide on another cell (Figure 19-28A). There are at least three types: L-selectin on white blood cells, P-selectin on blood platelets and on endothelial cells that have been locally activated by an inflammatory response, and E-selectin on endothelial cells later in the inflammatory response. In a lymphoid organ, such as a lymph node or the spleen, the endothelial cells express oligosaccharides that are recognized by L-selectin on lymphocytes, causing the lymphocytes to loiter and become trapped. At sites of inflammation, the roles are reversed: the endothelial cells switch on expression of selectins that recognize the oligosaccharides on white blood cells and platelets, flagging the cells down to help deal with the local emergency. Selectins do not act alone, however; they collaborate with integrins, which strengthen the binding of the blood cells to the endothelium. The cell-cell adhesions mediated by both selectins and integrins are heterophilic; that is, the binding is to a molecule of a different type. Selectins bind to specific oligosaccharides on glycoproteins and glycolipids, while integrins bind to specific Ig-family proteins.

Selectins and integrins act in sequence to let white blood cells leave the blood-stream and enter tissues (Figure 19–28B). The selectins mediate a weak adhesion because the binding of the lectin domain of the selectin to its carbohydrate ligand

Figure 19-28 The structure and function of selectins. (A) Diagram of P-selectin, which attaches to the actin cytoskeleton through adaptor proteins. (B) How selectins and integrins mediate the cell-cell adhesions required for a white blood cell to migrate out of the bloodstream into a tissue. Selectins on endothelial cells bind weakly to oligosaccharides on the white blood cell, so that it becomes loosely attached and rolls along the vessel wall The white blood cell then activates a cellsurface integrin called LFA1, which binds to a protein called ICAM1 (belonging to the Ig superfamily) on the membrane of the endothelial cell. The white blood cell adheres to the vessel wall and then crawls out of the vessel (Movie 19.2).

MBOC7_ptr_ch19_1105-1162.indd 1125 02/12/21 12:26 PM

is of low affinity. This allows the white blood cell to adhere weakly and reversibly to the endothelium, rolling along the surface of the blood vessel, propelled by the flow of blood. The rolling continues until the blood cell activates its integrins. As we discuss later, these transmembrane molecules can be switched into an adhesive conformation that enables them to latch onto specific macromolecules external to the cell—in the present case, proteins on the surfaces of the endothelial cells. Once it has attached in this way, the white blood cell escapes from the bloodstream into the tissue by crawling out of the blood vessel between adjacent endothelial cells.

Members of the Immunoglobulin Superfamily Mediate Ca²⁺-independent Cell–Cell Adhesion

The chief endothelial-cell proteins that are recognized by the white blood cell integrins are called *ICAMs* (*intercellular cell adhesion molecules*) or *VCAMs* (*vascular cell adhesion molecules*). They are members of another large and ancient family of cell-surface molecules—the **immunoglobulin** (**Ig**) **superfamily**. These contain one or more extracellular Ig-like domains that are characteristic of antibody molecules. They have many functions outside the immune system that are unrelated to immune defenses.

While ICAMs and VCAMs on endothelial cells both mediate heterophilic binding to integrins, many other Ig superfamily members appear to mediate homophilic binding. An example is the *neural cell adhesion molecule* (*NCAM*), which is expressed by various cell types, including most nerve cells (**Figure 19–29**). NCAM can take different forms, generated by alternative splicing of an RNA transcript produced from a single gene. Some forms of NCAM carry an unusually large quantity of sialic acid (with chains containing hundreds of repeating sialic acid units). By virtue of their negative charge, the long polysialic acid chains can interfere with cell adhesion (because like charges repel one another); thus, these forms of NCAM can serve to inhibit adhesion rather than cause it.

Another group of Ig superfamily members, the *nectins*, collaborates with cadherins to help build and strengthen adherens junctions in many tissues. Members of the nectin family contain three Ig-like domains (see Figure 19–29) and interact with other nectins, sometimes with the same family member (homophilic) and sometimes with a different family member (heterophilic). Their short intracellular tail binds to an adaptor protein that links the nectin to the actin cytoskeleton and to cadherin at adherens junctions. Nectins help set up cell-cell interactions during embryonic development. In auditory and olfactory epithelia, for example, sensory cells are distributed as single cells in a field of larger support cells. The distribution of these cell types in the epithelium depends on specific interactions

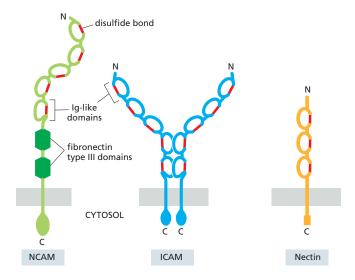

Figure 19–29 Members of the Ig superfamily of cell–cell adhesion molecules. NCAM is expressed on neurons and many other cell types, and it mediates homophilic binding. ICAM is expressed on endothelial cells and some other cell types and binds heterophilically to an integrin on white blood cells. Nectin is expressed in many cell types and is often found at adherens junctions, where it interacts with cadherins to help establish and strengthen specific cell–cell interactions during tissue formation.

MBOC7_ptr_ch19_1105-1162.indd 1126 02/12/21 12:26 PM

between nectin family members on the surfaces of the sensory and support cells. The formation of these epithelia is defective when nectin expression is experimentally reduced.

A cell of a given type generally uses an assortment of different adhesion proteins to interact with other cells, just as each cell uses an assortment of different receptors to respond to the many soluble extracellular signal molecules in its environment. Although cadherins and Ig superfamily members are frequently expressed on the same cells, the adhesions mediated by cadherins are much stronger, and they are largely responsible for holding cells together, segregating cell collectives into discrete tissues, and maintaining tissue integrity. Members of the Ig superfamily seem to contribute more to the fine-tuning of these adhesive interactions during development and regeneration, playing a part in various specialized adhesive phenomena, such as that discussed for blood cells and specialized epithelia. Thus, while mutant mice that lack N-cadherin die early in development, those that lack Ig superfamily members develop relatively normally but show moderate abnormalities in the development of certain tissues.

Summary

In epithelia, as well as in some other tissues, cells are directly attached to one another through strong cell-cell adhesions, mediated by transmembrane proteins called cadherins, which are anchored intracellularly to the cytoskeleton. Cadherins generally bind to one another homophilically: the head of one cadherin molecule binds to the head of a similar cadherin on an opposite cell. This selectivity enables mixed populations of cells of different types to sort out from one another according to the specific cadherins they express, and it helps to control cell rearrangements during development.

The "classical" cadherins at adherens junctions are linked to the actin cytoskeleton by intracellular adaptor proteins called catenins. These form an anchoring complex on the intracellular tail of the cadherin molecule and are involved not only in physical anchorage but also in the detection of and response to tension and other regulatory signals at the junction.

Tight junctions seal the gaps between cells in epithelia, creating a barrier to the diffusion of molecules across the cell sheet and also helping to separate the populations of proteins in the apical and basolateral plasma membrane domains of the epithelial cell. Claudins are the major transmembrane proteins forming tight junctions. Intracellular scaffold proteins organize the claudins and other junctional proteins into a complex protein network that is linked to the actin cytoskeleton.

The cells of many animal tissues are coupled by gap junctions, which take the form of plaques of clustered connexons, which usually allow molecules smaller than about 1000 daltons to pass directly from the inside of one cell to the inside of the next. Cells connected by gap junctions share many of their inorganic ions and other small molecules and are therefore chemically and electrically coupled.

Three additional classes of transmembrane adhesion proteins mediate more transient cell-cell adhesion: selectins, immunoglobulin (Ig) superfamily members, and integrins. Selectins are expressed on white blood cells, blood platelets, and endothelial cells; they bind heterophilically to carbohydrate groups on cell surfaces, helping to mediate the adhesive interactions between these cells. Ig superfamily proteins also play a part in these interactions, as well as in many other adhesive processes; some of them bind homophilically, some heterophilically. Integrins, though they mainly serve to attach cells to the extracellular matrix, can also mediate cell-cell adhesion by binding to specific Ig superfamily proteins.

THE EXTRACELLULAR MATRIX OF ANIMALS

Tissues are not made up solely of cells. They also contain a remarkably complex and intricate network of macromolecules constituting the *extracellular matrix*. This matrix is composed of many different proteins and polysaccharides that are

MBOC7_ptr_ch19_1105-1162.indd 1127 02/12/21 12:26 PM

Figure 19–30 Fibroblasts in connective tissue. This scanning electron micrograph shows tissue from the cornea of a rat. The extracellular matrix surrounding the fibroblasts is here composed largely of collagen fibrils. The glycoproteins, hyaluronan, and proteoglycans, which normally form a hydrated gel filling the interstices of the fibrous network, have been removed by enzyme and acid treatment. (Courtesy of T. Nishida.)

secreted locally and assembled into an organized meshwork in close association with the surfaces of the cells that produce them.

The classes of macromolecules constituting the extracellular matrix in different animal tissues are broadly similar, but variations in the relative amounts of these different classes of molecules and in the ways in which they are organized give rise to an amazing diversity of materials. The matrix can become calcified to form the rock-hard structures of bone or teeth, or it can form the transparent substance of the cornea, or it can adopt the rope-like organization that gives tendons their enormous tensile strength. It forms the jelly in a jellyfish. Covering the body of a beetle or a lobster, it forms a rigid carapace. Moreover, the extracellular matrix is more than a passive scaffold to provide physical support. It has an active and complex role in regulating the behavior of the cells that touch it, inhabit it, or crawl through its meshes, influencing their survival, development, migration, proliferation, shape, and function.

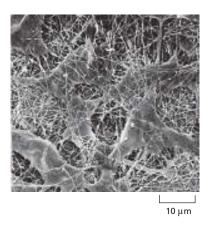

In this section, we describe the major features of the extracellular matrix in animal tissues, with an emphasis on vertebrates. We begin with an overview of the major classes of macromolecules in the matrix, after which we turn to the structure and function of the *basal lamina*, the thin layer of specialized extracellular matrix that lies beneath all epithelial cells. In the next section, we then describe the varied types of junctions that connect cells to the matrix.

The Extracellular Matrix Is Made and Oriented by the Cells Within It

The macromolecules that constitute the extracellular matrix are mainly produced locally by cells in the matrix. These cells also help to organize the matrix: the orientation of the cytoskeleton inside the cell can control the orientation of the matrix produced outside. In most connective tissues, the matrix macromolecules are secreted by cells called **fibroblasts** (**Figure 19–30**). In certain specialized types of connective tissues, such as cartilage and bone, however, they are secreted by cells of the fibroblast family that have more specific names: *chondrocytes*, for example, form cartilage, and *osteoblasts* form bone.

The extracellular matrix is constructed from three major classes of macromolecules: (1) glycosaminoglycans (GAGs), which are large and highly charged polysaccharides that are usually covalently linked to protein in the form of proteoglycans; (2) fibrous proteins, which are primarily members of the collagen family; and (3) a large class of noncollagen glycoproteins, which carry conventional asparagine-linked oligosaccharides (described in Chapter 12). All three classes of macromolecule have many members and come in a great variety of shapes and sizes (Figure 19-31). Mammals are thought to have almost 300 matrix proteins, including about 36 proteoglycans, about 40 collagens, and more than 200 glycoproteins, which usually contain multiple subdomains and self-associate to form multimers. Add to this the large number of matrix-associated proteins and enzymes that can modify matrix behavior by cross-linking, degradation, or other mechanisms, and one begins to see that the matrix is an almost infinitely variable material. Each tissue contains its own unique blend of matrix components, resulting in an extracellular matrix that is specialized for the needs of that tissue.

The proteoglycan molecules in connective tissue typically form a highly hydrated, gel-like "ground substance" in which collagens and glycoproteins are embedded. The polysaccharide gel resists compressive forces on the matrix while permitting the rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells. The collagen fibers strengthen and help organize

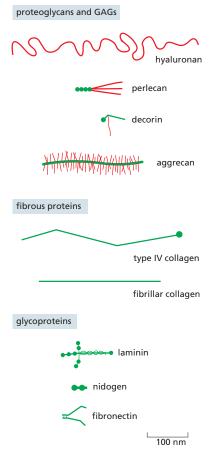

Figure 19–31 The comparative shapes and sizes of some of the major extracellular matrix macromolecules. Protein is shown in *green*, and glycosaminoglycan (GAG) in *red*.

MBOC7_ptr_ch19_1105-1162.indd 1128 02/12/21 12:26 PM

the matrix, while other fibrous proteins, such as the rubberlike *elastin*, give it resilience. Finally, the many matrix glycoproteins help cells migrate, settle, and differentiate in the appropriate locations.

Glycosaminoglycan (GAG) Chains Occupy Large Amounts of Space and Form Hydrated Gels

Glycosaminoglycans (GAGs) are unbranched polysaccharide chains composed of repeating disaccharide units. One of the two sugars in the repeating disaccharide is always an amino sugar (*N*-acetylglucosamine or *N*-acetylgalactosamine), which in most cases is sulfated. The second sugar is usually a uronic acid (glucuronic or iduronic). Because there are sulfate or carboxyl groups on most of their sugars, GAGs are highly negatively charged (Figure 19–32). Indeed, they are the most anionic molecules produced by animal cells. Four main groups of GAGs are distinguished by their sugars, the type of linkage between the sugars, and the number and location of sulfate groups: (1) *hyaluronan*, (2) *chondroitin sulfate* and *dermatan sulfate*, (3) *heparin* and *heparan sulfate*, and (4) *keratan sulfate*.

Polysaccharide chains are too stiff to fold into compact globular structures, and they are strongly hydrophilic. Thus, GAGs tend to adopt highly extended conformations that occupy a huge volume relative to their mass (Figure 19–33), and they form hydrated gels even at very low concentrations. The weight of GAGs in connective tissue is usually less than 10% of the weight of proteins, but GAG chains fill most of the extracellular space. Their high density of negative charges attracts a cloud of cations, especially Na⁺, that are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure, or turgor, that enables the matrix to withstand compressive forces (in contrast to collagen fibrils, which resist stretching forces). The cartilage matrix that lines the knee joint, for example, can support pressures of hundreds of atmospheres in this way.

Defects in the production of GAGs can affect many different body systems. In one rare human genetic disease, for example, there is a severe deficiency in the synthesis of dermatan sulfate disaccharide. The affected individuals have a short stature, a prematurely aged appearance, and generalized defects in their skin, joints, muscles, and bones.

Hyaluronan Acts as a Space Filler During Tissue Morphogenesis and Repair

Hyaluronan (also called *hyaluronic acid* or *hyaluronate*) is the simplest of the GAGs (Figure 19–34). It consists of a regular repeating sequence of up to 25,000 disaccharide units, is found in variable amounts in all tissues and fluids in adult animals, and is especially abundant in early embryos. Hyaluronan is not a typical GAG because it contains no sulfated sugars, all its disaccharide units are identical, its chain length is enormous, and it is not generally linked covalently to any core protein. Moreover, whereas other GAGs are synthesized inside the cell and released by exocytosis, hyaluronan is spun out directly from the cell surface by an enzyme complex embedded in the plasma membrane.

Figure 19–32 The repeating disaccharide sequence of a heparin glycosaminoglycan (GAG) chain.

These chains can consist of as many as 75 disaccharide units but are typically less than half that size. There is a high density of negative charges along the chain because of the presence of both carboxyl and sulfate groups; indeed, heparin is the most densely charged biological molecule known. The most common form of heparin carries three sulfate groups in each disaccharide, as shown here. In vivo, the proportion of sulfated and nonsulfated groups is highly variable. Heparin has an average of about 2.7 sulfates per disaccharide. Heparan sulfate is a closely related GAG that is generally about twice the length of heparin and less charged, with an average of about 1 sulfate per disaccharide.

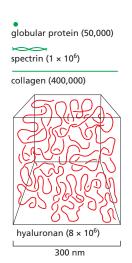

Figure 19–33 The relative dimensions and volumes occupied by various macromolecules. Several proteins and a single hydrated molecule of hyaluronan are shown, with molecular mass in daltons.

MBOC7_ptr_ch19_1105-1162.indd 1129 02/12/21 12:26 PM

Figure 19–34 The repeating disaccharide sequence in hyaluronan, a relatively simple GAG. This ubiquitous molecule in vertebrates consists of a single long chain of up to 25,000 disaccharides. Note the absence of sulfate groups.

Hyaluronan is thought to have a role in resisting compressive forces in tissues and joints. It is also important as a space filler during embryonic development, where it can be used to force a change in the shape of a structure, as a small quantity expands with water to occupy a large volume. Hyaluronan synthesized locally from the basal side of an epithelium can deform the epithelium by creating a cell-free space beneath it, into which cells subsequently migrate. In the developing heart, for example, hyaluronan synthesis helps in this way to drive formation of the valves and septa that separate the heart's chambers. Similar processes occur in several other organs. When cell migration ends, the excess hyaluronan is generally degraded by the enzyme *hyaluronidase*. Hyaluronan is also produced in large quantities during wound healing, and it is an important constituent of joint fluid, in which it serves as a lubricant.

Proteoglycans Are Composed of GAG Chains Covalently Linked to a Core Protein

Except for hyaluronan, all GAGs are covalently attached to protein as **proteogly-cans**, which are produced by most animal cells. Membrane-bound ribosomes make the polypeptide chain, or *core protein*, of a proteoglycan, which is then threaded into the lumen of the endoplasmic reticulum. The polysaccharide chains are mainly assembled on this core protein in the Golgi apparatus before delivery to the exterior of the cell by exocytosis. First, a special *linkage tetrasaccharide* is attached to a serine side chain on the core protein to serve as a primer for polysaccharide growth; then, one sugar at a time is added by specific glycosyl transferases (**Figure 19–35**). While still in the Golgi apparatus, many of the polymerized sugars are covalently modified by a sequential and coordinated series of reactions. These modifications include sulfation, which increases the negative charge, and

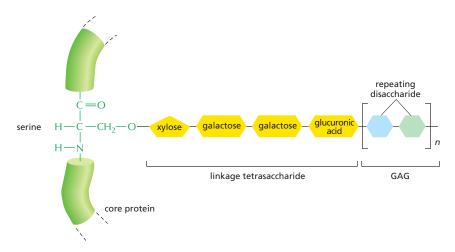

Figure 19–35 The linkage between a GAG chain and its core protein in a proteoglycan molecule. A specific linkage tetrasaccharide is first assembled on a serine side chain. The rest of the GAG chain, consisting mainly of a repeating disaccharide unit, is then synthesized, with one sugar added at a time. In chondroitin sulfate, the disaccharide is composed of D-glucuronic acid and *N*-acetyl-D-galactosamine; in heparan sulfate, it is either D-glucuronic acid or L-iduronic acid and *N*-acetyl-D-glucosamine.

MBOC7_ptr_ch19_1105-1162.indd 1130 02/12/21 12:26 PM

epimerization, which alters the configuration of the substituents around individual carbon atoms in the sugar molecule.

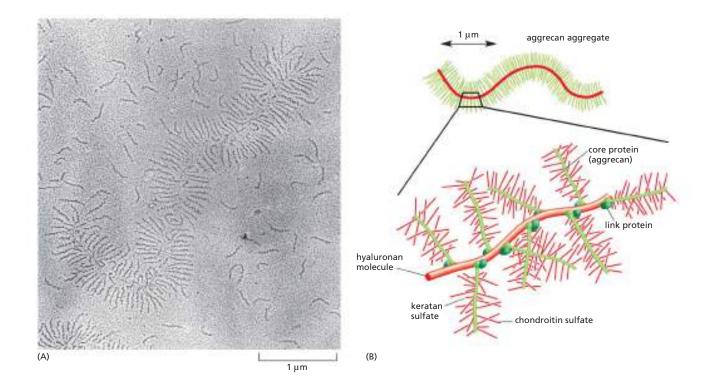

Proteoglycans are clearly distinguished from other glycoproteins by the nature, quantity, and arrangement of their sugar side chains. By definition, at least one of the sugar side chains of a proteoglycan must be a GAG. Whereas glycoproteins generally contain relatively short, branched oligosaccharide chains that contribute only a small fraction of their mass, proteoglycans can contain as much as 95% carbohydrate by mass, mostly in the form of long, unbranched GAG chains, each typically about 80 sugars long.

In principle, proteoglycans have the potential for almost limitless heterogeneity. Even a single type of core protein can carry highly variable numbers and types of attached GAG chains. Moreover, the underlying repeating sequence of disaccharides in each GAG can be modified by a complex pattern of sulfate groups. The core proteins, too, are diverse, though many of them belong to structurally related families that share specific domains involved in binding to GAGs or other proteins.

Proteoglycans can be huge. The proteoglycan aggrecan, for example, which is a major component of cartilage, has a mass of about 3×10^6 daltons with more than 100 GAG chains. Other proteoglycans are much smaller and have only 1–10 GAG chains; an example is decorin, which is secreted by fibroblasts and has a single GAG chain (see Figure 19–31). Decorin binds to collagen fibrils and regulates fibril assembly and fibril diameter; mice that cannot make decorin have fragile skin that has reduced tensile strength. The GAGs and proteoglycans of these various types can associate to form even larger polymeric complexes in the extracellular matrix. Molecules of aggrecan, for example, assemble with hyaluronan in cartilage matrix to form aggregates that are as big as a bacterium (Figure 19–36). Moreover, besides associating with one another, GAGs and proteoglycans associate with fibrous matrix proteins such as collagen and with protein meshworks such as the basal lamina, creating extremely complex composites (Figure 19–37).

Not all proteoglycans are secreted components of the extracellular matrix. Some are integral components of plasma membranes and have their core protein

Figure 19-36 An aggrecan aggregate from fetal bovine cartilage. (A) An electron micrograph of an aggrecan aggregate shadowed with platinum. Many free aggrecan molecules are also visible. (B) A drawing of the giant aggregate shown in A. It consists of about 100 aggrecan monomers (see Figure 19-31) noncovalently bound through the N-terminal domain of the core protein to a single hyaluronan molecule. A link protein binds both to the core protein of the proteoglycan and to the hyaluronan molecule, thereby stabilizing the aggregate. The molecular mass of such a complex can be 108 daltons or more, and it occupies a volume equivalent to that of a bacterium, which is about 2 μ m³. (A, courtesy of Lawrence Rosenberg.)

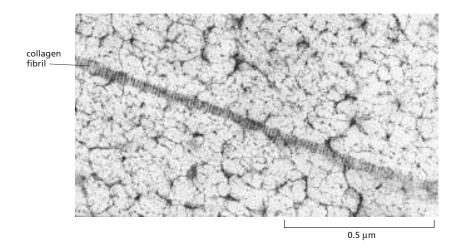

Figure 19-37 Proteoglycans in the extracellular matrix of rat cartilage. The tissue was rapidly frozen at -196°C and fixed and stained while still frozen (a process called freeze substitution) to prevent the GAG chains from collapsing. In this electron micrograph, the proteoglycan molecules are seen to form a fine filamentous network in which a single striated collagen fibril is embedded. The more darkly stained parts of the proteoglycan molecules are the core proteins; the faintly stained threads are the GAG chains. (© 1984 E.B. Hunziker and R.K. Schenk. Originally published in J. Cell Biol. https://doi.org/10.1083/jcb.98.1.277. With permission from Rockefeller University

either inserted across the lipid bilayer or attached to the lipid bilayer by a gly-cosylphosphatidylinositol (GPI) anchor. Among the best-characterized plasma membrane proteoglycans are the *syndecans*, which have a membrane-spanning core protein whose intracellular domain interacts with the actin cytoskeleton and with signaling molecules in the cell cortex. The extracellular domain is linked to multiple GAG chains (primarily heparan sulfate). Syndecans are located on the surface of many types of cells, including fibroblasts and epithelial cells. In fibroblasts, syndecans can be found in cell-matrix adhesions, where they modulate integrin function by interacting with fibronectin on the cell surface and with cytoskeletal and signaling proteins inside the cell. As we discuss later, syndecans and related proteoglycans called *glypicans* also interact with soluble peptide growth factors, influencing their effects on cell growth and proliferation.

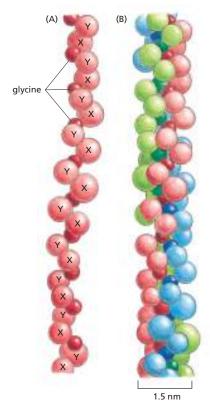

Collagens Are the Major Proteins of the Extracellular Matrix

The **collagens** are a family of fibrous proteins found in all multicellular animals. They are secreted in large quantities by connective-tissue cells and in smaller quantities by many other cell types. As a major component of skin and bone, collagens are the most abundant proteins in mammals, where they constitute 25% of the total protein mass.

The primary feature of a typical collagen molecule is its long, stiff, triple-stranded helical structure, in which three collagen polypeptide chains, called α *chains*, are wound around one another in a rope-like superhelix (Figure 19–38). Collagens are extremely rich in proline and glycine, both of which are important in the formation of the triple-stranded helix.

The human genome contains 42 distinct genes coding for different collagen α chains. Different combinations of these genes are expressed in different tissues. Although in principle thousands of types of triple-stranded collagen molecules could be assembled from various combinations of the 42 α chains, only a limited number of triple-helical combinations are possible, and roughly 40 types of collagen molecules have been found. Type I is by far the most common,

Figure 19–38 The structure of a typical collagen molecule. (A) A model of part of a single collagen α chain, in which each amino acid is represented by a sphere. The chain is about 1000 amino acids long. It is arranged as a left-handed helix, with three amino acids per turn and with glycine as every third amino acid. Therefore, an α chain is composed of a series of triplet Gly-X-Y sequences, in which X and Y can be any amino acid (although X is commonly proline and Y is commonly hydroxyproline, a form of proline that is chemically modified during collagen synthesis in the cell). (B) A model of part of a collagen molecule, in which three α chains, each shown in a different color, are wrapped around one another to form a triple-stranded helical rod. Glycine is the only amino acid small enough to occupy the crowded interior of the triple helix. Only a short length of the molecule is shown; the entire molecule is 300 nm long. (From a model by B.L. Trus.)

MBOC7_ptr_ch19_1105-1162.indd 1132 02/12/21 12:26 PM

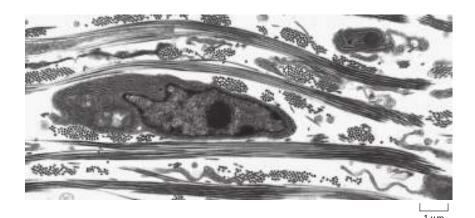

Figure 19–39 A fibroblast surrounded by collagen fibrils in the connective tissue of embryonic chick skin. In this electron micrograph, the fibrils are organized into bundles that run approximately at right angles to one another. Therefore, some bundles are oriented longitudinally, whereas others are seen in cross section. The collagen fibrils are produced by fibroblasts. (From C. Ploetz et al., *J. Struct. Biol.* 106:73–81, 1991. With permission from Elsevier.)

being the principal collagen of skin and bone. It belongs to the class of **fibrillar collagens**, or fibril-forming collagens: after being secreted into the extracellular space, they assemble into higher-order polymers called **collagen fibrils**, which are thin structures (10–300 nm in diameter) many hundreds of micrometers long in mature tissues, where they are clearly visible in electron micrographs (**Figure 19–39**; see also Figure 19–37). Collagen fibrils often aggregate into larger, cablelike bundles, several micrometers in diameter, that are visible in the light microscope as *collagen fibers*.

Collagen types IX and XII are called *fibril-associated collagens* because they decorate the surface of collagen fibrils. They are thought to link these fibrils to one another and to other components in the extracellular matrix. Types IV and VII are *network-forming collagens*: type IV forms a major part of the basal lamina, while type VII molecules form dimers that assemble into specialized structures called *anchoring fibrils*. Anchoring fibrils help attach the basal lamina of multilayered epithelia to the underlying connective tissue and therefore are especially abundant in the skin. There are also a number of "collagen-like" proteins containing short collagen-like segments. These include collagen type XVII, which has a transmembrane domain and is found in hemidesmosomes, and type XVIII, the core protein of a proteoglycan in the basal lamina.

Many proteins appear to have evolved by repeated duplications of an original DNA sequence, giving rise to a repetitive pattern of amino acids. The genes that encode the α chains of most of the fibrillar collagens provide a good example: they are very large (up to 44 kilobases in length) and contain about 50 exons. Most of the exons are 54 or multiples of 54 nucleotides long, suggesting that these collagens originated through multiple duplications of a primordial gene containing 54 nucleotides and encoding exactly six Gly-X-Y repeats (see Figure 19–38).

 $\begin{tabular}{l} \textbf{Table 19-2} provides additional details for some of the collagen types discussed in this chapter. \end{tabular}$

Collagen Chains Undergo a Series of Post-translational Modifications

Individual collagen polypeptide chains are synthesized on membrane-bound ribosomes and injected into the lumen of the endoplasmic reticulum (ER) as larger precursors, called $pro-\alpha$ chains. These precursors not only have the short amino-terminal signal peptide required to direct the nascent polypeptide to the

	Type	Polymerized form	Tissue distribution	Mutant phenotype
Fibril-forming (fibrillar)	I	Fibril	Bone, skin, tendons, ligaments, cornea, internal organs (accounts for 90% of body collagen)	Severe bone defects, fractures (osteogenesis imperfecta)
	II	Fibril	Cartilage, intervertebral disc, notochord, vitreous humor of the eye	Cartilage deficiency, dwarfism (chondrodysplasia)
	III	Fibril	Skin, blood vessels, internal organs	Fragile skin, loose joints, blood vessels prone to rupture (vascular Ehlers–Danlos syndrome)
	V	Fibril (with type I)	As for type I	Fragile skin, loose joints (classical Ehlers- Danlos syndrome)
	XI	Fibril (with type II)	As for type II	Myopia, blindness
Fibril-associated	IX	Lateral association with type II fibrils	Cartilage	Osteoarthritis
	XII	Lateral association with type I fibrils	Tendons	Skeletal and muscle abnormalities
Network-forming	IV	Sheetlike network	Basal lamina	Kidney disease (glomerulonephritis), deafness
	VII	Anchoring fibrils	Beneath stratified squamous epithelia	Skin blistering
Transmembrane	XVII	Nonfibrillar	Hemidesmosomes	Skin blistering
Proteoglycan core protein	XVIII	Nonfibrillar	Basal lamina	Myopia, detached retina, hydrocephalus

Note that types I, IV, V, IX, and XI are each composed of two or three types of α chains (distinct, nonoverlapping sets in each case), whereas types II, III, VII, XVII, and XVIII are composed of only one type of α chain each.

ER but also have, at both their N- and C-terminal ends, additional amino acids, called *propeptides*, that are clipped off at a later step of collagen assembly. Moreover, in the lumen of the ER, selected prolines and lysines are hydroxylated to form *hydroxyproline* and *hydroxylysine*, respectively, and some hydroxylysines are then glycosylated.

Each pro- α chain combines with two others to form a triple-stranded, helical molecule known as *procollagen*. The hydroxyl groups of hydroxyprolines and hydroxylysines (**Figure 19–40**) form interchain hydrogen bonds that help stabilize the triple-stranded helix. The enzyme that catalyzes proline hydroxylation requires ascorbic acid (vitamin C). In *scurvy*, the disease caused by a dietary deficiency of vitamin C that was common in sailors until the nineteenth century, defective pro- α chains fail to form a stable triple helix and are degraded, thereby inhibiting the production of new collagen fibrils. In healthy tissues, collagen is continually degraded and replaced (with a turnover time of months or years, depending on the tissue). In scurvy, replacement fails, and within a few months, with the gradual loss of the preexisting normal collagen in the matrix, blood vessels become fragile, teeth become loose in their sockets, and wounds cease to heal.

After secretion, the propeptides of the fibrillar procollagen molecules are removed by specific proteolytic enzymes outside the cell. This converts the procollagen molecules to collagen, which assemble in the extracellular space to form much larger collagen fibrils. The propeptides have at least two functions. First,

Figure 19–40 Hydroxylysine and hydroxyproline. These modified amino acids are common in collagen. They are formed by enzymes that act after the lysine and proline have been incorporated into procollagen molecules.

MBOC7_ptr_ch19_1105-1162.indd 1134 02/12/21 12:26 PM

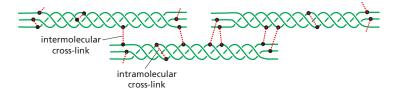

Figure 19–41 Cross-links formed between modified lysine side chains within a collagen fibril. Covalent intramolecular and intermolecular cross-links are formed in several steps. First, the extracellular enzyme lysyl oxidase deaminates certain lysines and hydroxylysines to yield highly reactive aldehyde groups. The aldehydes then react spontaneously to form covalent bonds with each other or with other lysines or hydroxylysines. Most of the cross-links form between the short nonhelical segments at each end of the collagen molecules.

they guide the intracellular formation of the triple-stranded collagen molecules. Second, because they are retained until after secretion, they prevent the intracellular formation of large collagen fibrils, which could be catastrophic for the cell.

After the fibrils have formed in the extracellular space, they are greatly strengthened by the formation of covalent cross-links between lysine residues of the constituent collagen molecules (Figure 19–41). The types of covalent bonds involved are found only in collagen and elastin. If cross-linking is inhibited, the tensile strength of the fibrils is drastically reduced: collagenous tissues become fragile, and structures such as skin, tendons, and blood vessels tend to tear. The extent and type of cross-linking vary from tissue to tissue. Collagen is especially highly cross-linked in the Achilles tendon, for example, where tensile strength is crucial.

Secreted Fibril-associated Collagens Help Organize the Fibrils

In contrast to GAGs, which resist compressive forces, collagen fibrils form structures that resist tensile forces. The fibrils have various diameters and are organized in different ways in different tissues. In mammalian skin, for example, they are woven in a wickerwork pattern so that they resist tensile stress in multiple directions; leather consists of this material, suitably preserved. In tendons, collagen fibrils are organized in parallel bundles aligned along the major axis of tension. In mature bone and in the cornea, they are arranged in orderly plywoodlike layers, with the fibrils in each layer lying parallel to one another but nearly at right angles to the fibrils in the layers on either side. The same arrangement occurs in tadpole skin (Figure 19-42).

The connective-tissue cells themselves determine the size and arrangement of the collagen fibrils. The cells can express one or more genes for the different types of fibrillar collagen molecules. But even fibrils composed of the same mixture of collagens have different arrangements in different tissues. How is this achieved? Part of the answer is that cells can regulate the disposition of the collagen molecules after secretion by guiding collagen fibril formation near the plasma membrane. In addition, cells can influence this organization by secreting, along with their fibrillar collagens, different kinds and amounts of other matrix macromolecules. In particular, they secrete the fibrous protein *fibronectin*, as we discuss later, and this precedes the formation of collagen fibrils and helps guide their organization.

Fibril-associated collagens, such as types IX and XII collagens, are thought to be especially important in organizing collagen fibrils. They differ from fibrillar collagens in the following ways. First, their triple-stranded helical structure is interrupted by one or two short nonhelical domains, which makes the molecules more flexible than fibrillar collagen molecules. Second, they do not aggregate with one another to form fibrils in the extracellular space. Instead, they bind in a periodic manner to the surface of fibrils formed by the fibrillar collagens. Type IX molecules bind to type II collagen-containing fibrils in cartilage, the cornea, and the vitreous of the eye (Figure 19-43), whereas type XII molecules bind to type I collagen-containing fibrils in tendons and various other tissues.

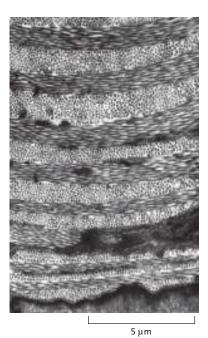

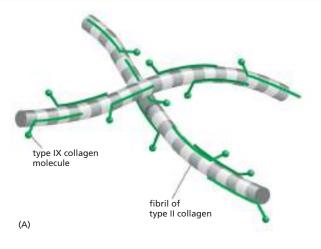

Figure 19–42 Collagen fibrils in the tadpole skin. This electron micrograph shows the plywoodlike arrangement of the fibrils: successive layers of fibrils are laid down nearly at right angles to each other. This organization is also found in mature bone and in the cornea. (Courtesy of Jerome Gross.)

Fibril-associated collagens are thought to mediate the interactions of collagen fibrils with one another and with other matrix macromolecules to help determine the organization of the fibrils in the matrix.

Elastin Gives Tissues Their Elasticity

Many vertebrate tissues, such as skin, blood vessels, and lungs, need to be both strong and elastic in order to function. A network of **elastic fibers** in the extracellular matrix of these tissues gives them the resilience to recoil after transient stretch (**Figure 19–44**). Elastic fibers are at least five times more extensible than a rubber band of the same cross-sectional area. Long, inelastic collagen fibrils are interwoven with the elastic fibers to limit the extent of stretching and prevent the tissue from tearing.

The main component of elastic fibers is **elastin**, a highly hydrophobic protein (about 750 amino acids long), which, like collagen, is unusually rich in proline and glycine but, unlike collagen, is not glycosylated. Soluble *tropoelastin* (the biosynthetic precursor of elastin) is secreted into the extracellular space and assembled into elastic fibers close to the plasma membrane, generally in cell-surface infoldings. After secretion, the tropoelastin molecules become highly cross-linked to one another, generating an extensive network of elastin fibers and sheets. A mechanism similar to the one that operates in cross-linking collagen molecules forms cross-links between lysines in elastin molecules.

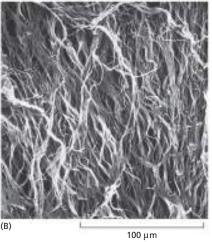

Figure 19–44 Elastic fibers. These scanning electron micrographs show (A) a low-power view of a segment of a dog's aorta and (B) a high-power view of the dense network of longitudinally oriented elastic fibers in the outer layer of the same blood vessel. All the other components have been digested away with enzymes and formic acid. (From K.S. Haas et al., *Anat. Rec.* 230:86–96, 1991. With permission from Wiley-Liss.)

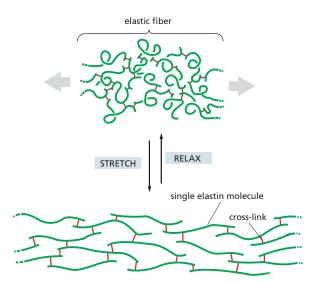

Figure 19–45 Stretching a network of elastin molecules. The molecules are joined together by covalent bonds (red) to generate a cross-linked network. In this model, each elastin molecule in the network can extend and contract in a manner resembling a random coil, so that the entire assembly can stretch and recoil like a rubber band.

The elastin protein is composed largely of two types of short segments that alternate along the polypeptide chain: hydrophobic segments, which are responsible for the elastic properties of the molecule; and alanine- and lysine-rich α -helical segments, which are cross-linked to adjacent molecules. Each segment is encoded by a separate exon. There is still uncertainty concerning the conformation of elastin molecules in elastic fibers and how the structure of these fibers accounts for their rubberlike properties. However, it seems that parts of the elastin polypeptide chain, like the polymer chains in ordinary rubber, adopt a loose "random-coil" conformation, and it is the random-coil nature of the component molecules cross-linked into the elastic fiber network that allows the network to stretch and recoil like a rubber band (Figure 19–45).

Elastin is the dominant extracellular matrix protein in arteries, comprising 50% of the dry weight of the largest artery—the aorta (see Figure 19-44). Mutations in the elastin gene causing a deficiency of the protein in mice or humans result in narrowing of the aorta and other arteries and excessive proliferation of smooth muscle cells in the arterial wall. Apparently, the normal elasticity of an artery is required to restrain the proliferation of these cells.

Elastic fibers do not consist solely of elastin. The elastin core is covered with a sheath of *microfibrils*, each of which has a diameter of about 10 nm. The microfibrils appear before elastin in developing tissues and seem to provide scaffolding to guide elastin deposition. Arrays of microfibrils are elastic in their own right, and in some places they persist in the absence of elastin: they help to hold the lens in its place in the eye, for example. Microfibrils are composed of a number of distinct glycoproteins, including the large glycoprotein *fibrillin*, which binds to elastin and is essential for the integrity of elastic fibers. Mutations in the fibrillin gene result in *Marfan syndrome*, a relatively common human disorder. In the most severely affected individuals, the aorta is prone to rupture; other common effects include displacement of the lens and abnormalities of the skeleton and joints. Affected individuals are often unusually tall and lanky: Abraham Lincoln is suspected to have had the condition.

Cells Govern and Respond to the Mechanical Properties of the Matrix

Cells interact with the extracellular matrix mechanically as well as chemically, and studies in culture suggest that the mechanical interaction can have dramatic effects on the architecture of connective tissue. Thus, when fibroblasts are mixed with a meshwork of randomly oriented collagen fibrils that form a gel in a culture dish, the fibroblasts tug on the meshwork, drawing in collagen from their

MBOC7_ptr_ch19_1105-1162.indd 1137 02/12/21 12:26 PM

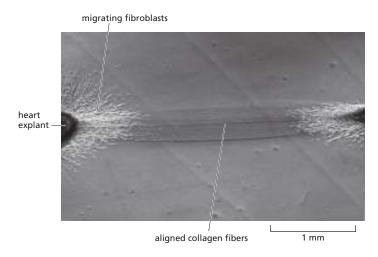

Figure 19–46 The shaping of the extracellular matrix by cells. This micrograph shows a region between two pieces of embryonic chick heart (rich in fibroblasts as well as heart muscle cells) that were cultured on a collagen gel for 4 days. A dense tract of aligned collagen fibers has formed between the explants, presumably as a result of the fibroblasts in the explants tugging on the collagen. (From D. Stopak and A.K. Harris, *Dev. Biol.* 90:383–398, 1982. With permission from Elsevier.)

surroundings and thereby causing the gel to contract to a small fraction of its initial volume. By similar activities, a cluster of fibroblasts surrounds itself with a capsule of densely packed and circumferentially oriented collagen fibers.

If two small pieces of embryonic tissue containing fibroblasts are placed far apart on a collagen gel, the intervening collagen becomes organized into a compact band of aligned fibers that connect the two explants (Figure 19-46). The fibroblasts subsequently migrate out from the explants along the aligned collagen fibers. Thus, the fibroblasts influence the alignment of the collagen fibers, and the collagen fibers in turn affect the distribution of the fibroblasts.

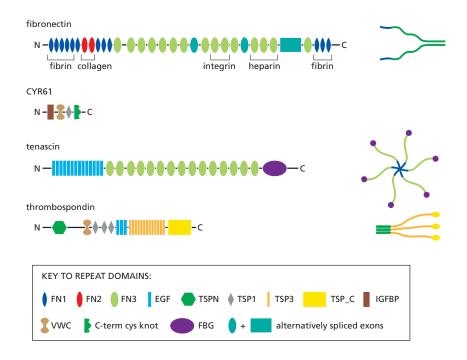

Fibroblasts may have a similar role in organizing the extracellular matrix inside the body. First they synthesize the collagen fibrils and deposit them in the correct orientation. Then they work on the matrix they have secreted, crawling over it and tugging on it so as to create tendons and ligaments and the tough, dense layers of connective tissue that surround and bind together most organs.

In addition to determining the orientation of the collagen fibrils they produce, fibroblasts control the overall density and composition of the extracellular matrix, which varies dramatically in different tissues. Some tissues, such as tendons and cartilage, are composed of dense matrix that is far more rigid and resistant to deformation than the soft, elastic matrix of tissues like fat and the brain. These differences depend on the ability of cells in these tissues to regulate the types of collagen and other proteins produced, the relative rates of matrix protein synthesis and degradation, and the amount of collagen and elastin cross-linking. The density of the matrix, in turn, regulates the behavior of the fibroblasts and other cells that travel through it; for example, the proliferation, migration, and developmental fate of stem cells are influenced by matrix composition and density. Abnormally high matrix density is associated with certain fibrotic diseases and appears to be a risk factor in some forms of cancer.

Fibronectin and Other Multidomain Glycoproteins Help Organize the Matrix

In addition to proteoglycans, collagens, and elastic fibers, the extracellular matrix contains a large and varied assortment of glycoproteins that typically have multiple domains, each with specific binding sites for other matrix macromolecules and for receptors on the surface of cells (Figure 19–47). These proteins therefore contribute to both organizing the matrix and helping cells attach to it. Like the proteoglycans, they also guide cell movements in developing tissues by serving as tracks along which cells can migrate or as repellents that keep cells out of forbidden areas. They can also bind and thereby influence the function of peptide growth factors and other small molecules produced by nearby cells.

MBOC7_ptr_ch19_1105-1162.indd 1138 02/12/21 12:26 PM

The best-understood member of this class of matrix proteins is **fibronectin**, a large glycoprotein found in all vertebrates and important for many cell-matrix interactions. Mutant mice that are unable to make fibronectin die early in embryogenesis because their endothelial cells fail to form proper blood vessels. The defect is thought to result from abnormalities in the interactions of these cells with the surrounding extracellular matrix, which normally contains fibronectin.

Fibronectin is a dimer composed of two very large subunits joined by disulfide bonds at their C-terminal ends. Each subunit contains a series of small repeated domains, or modules, separated by short stretches of flexible polypeptide chain (Figure 19–48). Each domain is usually encoded by a separate exon, suggesting that the fibronectin gene, like the genes encoding many matrix proteins, evolved by multiple exon duplications. In the human genome, there is only one fibronectin gene, containing about 50 exons of similar size, but the transcripts can be spliced in different ways to produce multiple fibronectin isoforms (see Figure 19–48B). The major repeat domain in fibronectin is called the type III fibronectin repeat, which is about 90 amino acids long and occurs at least 15 times in each subunit. This repeat is among the most common of all protein domains in vertebrates.

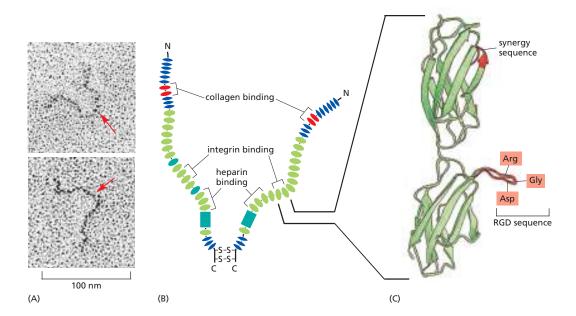

Fibronectin Binds to Integrins

One way to analyze a complex multifunctional protein molecule such as fibronectin is to synthesize individual regions of the protein and test their ability to bind other proteins. By these and other methods, it was possible to show that one region of fibronectin binds to collagen, another to proteoglycans, and another to specific integrins on the surface of various types of cells (see Figure 19–48B). Synthetic peptides corresponding to different segments of the integrin-binding domain were then used to show that binding depends on a specific tripeptide sequence (*Arg-Gly-Asp*, or *RGD*) that is found in one of the type III repeats (see Figure 19–48C). Even very short peptides containing this **RGD sequence** can compete with fibronectin for the binding site on cells, thereby inhibiting the attachment of the cells to a fibronectin matrix.

Several extracellular proteins besides fibronectin also have an RGD sequence that mediates cell-surface binding. Many of these proteins are components of the

Figure 19-47 Complex glycoproteins of the extracellular matrix. Many matrix glycoproteins are large scaffold proteins containing multiple copies of specific protein-interaction domains. Each domain is folded into a discrete globular structure, and many such domains are arrayed along the protein like beads on a string. This diagram shows four representative proteins among the roughly 200 matrix alvcoproteins that are found in mammals. Each protein contains multiple repeat domains, with the names listed in the key at the bottom. Fibronectin, for example, contains numerous copies of three different fibronectin repeats (types I-III, labeled here as FN1, FN2, and FN3). Two type III repeats near the center of the protein contain important binding sites for cell-surface integrins, whereas three nearby type III repeats form a binding site for heparin or heparan sulfate proteoglycans. FN repeats at the N-terminus are involved in binding fibrin or collagen. Other matrix proteins contain repeated sequences resembling those of epidermal growth factor (EGF), a major regulator of cell growth and proliferation; these repeats might serve a similar signaling function in matrix proteins. Other proteins contain domains, such as the insulin-like growth factor-binding protein (IGFBP) repeat, that bind and regulate the function of soluble growth factors. To add more structural diversity, many of these proteins are encoded by RNA transcripts that can be spliced in different ways, adding or removing exons, such as those in fibronectin. Finally, the scaffolding and regulatory functions of many matrix proteins are further expanded by assembly into multimeric forms, as shown at the right: fibronectin forms dimers linked at the C-termini, whereas tenascin and thrombospondin form N-terminally linked hexamers and trimers, respectively. Other domains include four repeats from thrombospondin (TSPN, TSP1, TSP3, TSP_C). VWC, von Willebrand type C; FBG, fibrinogen-like. (Adapted from R.O. Hynes and A. Naba, Cold Spring Harb. Perspect. Biol. 4:a004903, 2012. With permission from Cold Spring Harbor Laboratory Press.)

MBOC7_ptr_ch19_1105-1162.indd 1139 02/12/21 12:26 PM

extracellular matrix, while others are involved in blood clotting. Peptides containing the RGD sequence have been useful in the development of anti-clotting drugs. Some snakes use a similar strategy to cause their victims to bleed: they secrete RGD-containing anti-clotting proteins called *disintegrins* into their venom.

The cell-surface receptors that bind RGD-containing proteins are members of the integrin family, which we describe in detail later. Each integrin specifically recognizes its own small set of matrix molecules, indicating that tight binding requires more than just the RGD sequence. Moreover, RGD sequences are not the only sequence motifs used for binding to integrins: many integrins recognize and bind to other motifs instead.

Tension Exerted by Cells Regulates the Assembly of Fibronectin Fibrils

Fibronectin can exist both in a soluble form, circulating in the blood and other body fluids, and as insoluble *fibronectin fibrils*, in which fibronectin dimers are cross-linked to one another by additional disulfide bonds and form part of the extracellular matrix. Unlike fibrillar collagen molecules, however, which can self-assemble into fibrils in a test tube, fibronectin molecules assemble into fibrils only on the surface of cells, and only where those cells possess appropriate fibronectin-binding proteins—in particular, integrins. The integrins provide a linkage from the fibronectin outside the cell to the actin cytoskeleton inside it. The linkage transmits tension to the fibronectin molecules—provided that they also have an attachment to some other structure—and stretches them, exposing cryptic binding sites in the fibronectin molecules (Figure 19-49). This allows them

a fibronectin dimer. (A) Electron micrographs of individual fibronectin dimer molecules shadowed with platinum; red arrows mark the joined C-termini. (B) The two polypeptide chains are similar but generally not identical (being made from the same gene but from differently spliced mRNAs). They are joined by two disulfide bonds near the C-termini. Each chain is almost 2500 amino acids long and is folded into multiple domains (see Figure 19-47). As indicated, some domains are specialized for binding to a particular molecule. For simplicity, not all of the known binding sites are shown. (C) The three-dimensional structure of the ninth and tenth type III fibronectin repeats, as determined by x-ray crystallography. Both the Arg-Gly-Asp (RGD) and the "synergy sequences shown in red are important for binding to integrins on cell surfaces. (A. from J. Engel et al., J. Mol. Biol. 150:97-120, 1981. With permission from Elsevier; C, from D.J. Leahy, Annu. Rev. Cell Dev. Biol. 13:363-393, 1997. With permission from Annual Reviews.)

Figure 19-48 The structure of

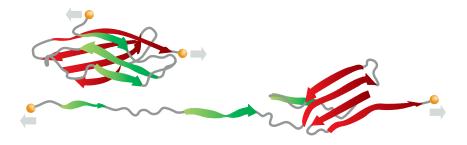

Figure 19–49 Tension-sensing by fibronectin. Some type III fibronectin repeats are thought to unfold when fibronectin is stretched. The unfolding exposes cryptic binding sites that interact with other fibronectin molecules resulting in the formation of fibronectin filaments like those shown in Figure 19–50. (From V. Vogel and M. Sheetz, *Nat. Rev. Mol. Cell Biol.* 7:265–275, 2006. With permission from Springer Nature.)

MBOC7_ptr_ch19_1105-1162.indd 1140 02/12/21 12:26 PM

to bind directly to one another and to recruit additional fibronectin molecules to form a fibril (Figure 19–50). This dependence on tension and interaction with cell surfaces ensures that fibronectin fibrils assemble where there is a mechanical need for them and not in inappropriate locations such as the bloodstream.

Many other extracellular matrix proteins contain multiple copies of the type III fibronectin repeat (see Figure 19–47), and it is possible that tension exerted on these proteins also uncovers cryptic binding sites and thereby influences their behavior.

The Basal Lamina Is a Specialized Form of Extracellular Matrix

Thus far in this section, we have reviewed the general principles underlying the structure and function of the major classes of extracellular matrix components. We now describe how some of these components are assembled into a specialized type of extracellular matrix called the **basal lamina** (also known as the **basement membrane**). This exceedingly thin, tough, flexible sheet of matrix molecules is an essential underpinning of all epithelia. Although small in volume, it has a critical role in the architecture of the body. Like the cadherins, it seems to be one of the defining features common to all multicellular animals, and it seems to have appeared very early in their evolution. The major molecular components of the basal lamina are among the most ancient extracellular matrix macromolecules.

The basal lamina is typically 40–120 nm thick. It lies beneath epithelial cells and also surrounds individual muscle cells, fat cells, and Schwann cells (which wrap around peripheral nerve cell axons to form myelin). The basal lamina thus separates these cells and epithelia from the underlying or surrounding connective tissue and forms the mechanical connection between them. In other locations, such as the kidney glomerulus, a basal lamina lies between two cell sheets and functions as a selective filter (Figure 19–51). Basal laminae have more than simple structural and filtering roles, however. They are able to determine cell polarity; influence cell metabolism; organize the proteins in adjacent plasma membranes; promote cell survival, proliferation, or differentiation; and serve as highways for cell migration.

Laminin and Type IV Collagen Are Major Components of the Basal Lamina

The basal lamina is synthesized by the cells on each side of it: the epithelial cells contribute one set of basal lamina components, while cells of the underlying bed of connective tissue (called the *stroma*, Greek for "bedding") contribute another set (Figure 19–52). Although the precise composition of the mature basal lamina varies from tissue to tissue and even from region to region in the same lamina, it typically contains the glycoproteins *laminin*, *type IV collagen*, and *nidogen*, along with the proteoglycan *perlecan*. Other common basal lamina components are fibronectin and *type XVIII collagen* (an atypical member of the collagen family, forming the core protein of a proteoglycan).

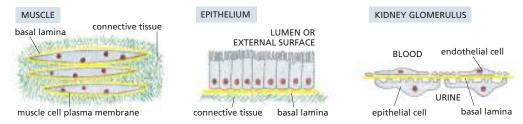

Figure 19–51 Three ways in which the basal lamina is organized. Sheets of basal lamina (yellow) surround certain cells (such as skeletal muscle cells), underlie epithelia, and are interposed between two cell sheets (as in the kidney glomerulus). Note that, in the kidney glomerulus, both cell sheets have gaps in them, and the basal lamina has a filtering as well as a supportive function, helping to determine which molecules will pass into the urine from the blood. The filtration also depends on other protein-based structures, called slit diaphragms, that span the intercellular gaps in the epithelial sheet.

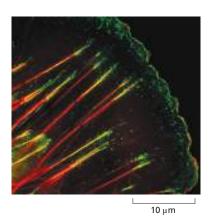

Figure 19-50 Organization of fibronectin into fibrils at the cell surface. This fluorescence micrograph shows the front end of a migrating mouse fibroblast. Extracellular fibronectin is stained green. and intracellular actin filaments are stained red. The fibronectin is initially present as small dotlike aggregates near the leading edge of the cell. It accumulates at focal adhesions (sites of anchorage of actin filaments, discussed later) and becomes organized into fibrils parallel to the actin filaments. Integrin molecules spanning the cell membrane link the fibronectin outside the cell to the actin filaments inside it (see Figure 19-56). Tension exerted on the fibronectin molecules through this linkage is thought to stretch them, exposing binding sites that promote fibril formation. (Courtesy

of Roumen Pankov and Kenneth Yamada.)

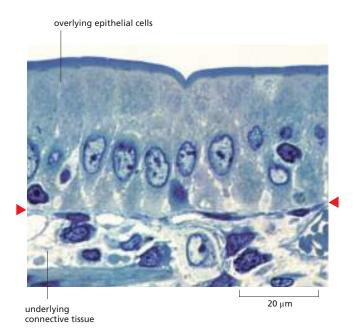

Figure 19–52 The basal lamina supports a sheet of epithelial cells. In this light micrograph of a cross section of the small intestine, the sheet of columnar epithelial cells rests on the basal lamina (red arrowheads). A network of collagen fibrils and other fibers in the underlying connective tissue interacts with the lower face of the basal lamina. (Jose Luis Calvo/ Shutterstock.)

Laminin is the primary organizer of the sheet structure, and, early in development, the basal lamina consists mainly of laminin molecules. Laminins constitute a large family of proteins, each composed of three long polypeptide chains $(\alpha,\beta,$ and $\gamma)$ held together by disulfide bonds and arranged in the shape of an asymmetric bouquet, like a bunch of three flowers whose stems are twisted together at the foot but whose heads remain separate (Figure 19–53). These heterotrimers can self-assemble in vitro into a network, largely through interactions between their heads, although interaction with cells is needed to organize the network into an orderly sheet. Because there are several isoforms of each type of chain, and

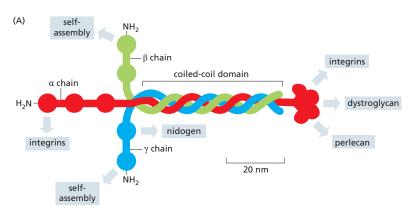

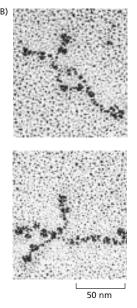

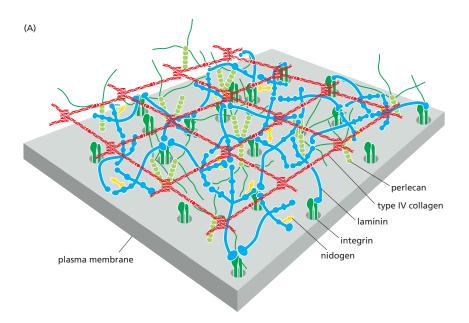

Figure 19–53 The structure of laminin. (A) The best-understood family member is laminin-111, shown here with some of its binding sites for other molecules (gray boxes). Laminins are multidomain glycoproteins composed of three polypeptides (α , β , and γ) that are disulfide-bonded into an asymmetric crosslike structure. Each of the polypeptide chains is more than 1500 amino acids long. Five types of α chains, four types of β chains, and three types of γ chains are known, and various combinations of these subunits can assemble to form a large variety of different laminins, which are named according to numbers assigned to each of their three subunits: laminin-111, for example, contains α 1, β 1, and γ 1 subunits. Each isoform tends to have a specific tissue distribution: laminin-332 is found in skin, laminin-211 in muscle, and laminin-411 in endothelial cells of blood vessels. Through their binding sites for other proteins, laminin molecules play a central part in organizing the basal lamina and anchoring it to cells. (B) Electron micrographs of laminin molecules shadowed with platinum. (B, from J. Engel et al., J. Mol. Biol. 150:97–120, 1981. With permission from Elsevier.)

MBOC7_ptr_ch19_1105-1162.indd 1142 02/12/21 12:26 PM

02/12/21 12:26 PM

these can associate in various combinations, many different laminins can be produced, creating basal laminae with distinctive properties. The laminin $\gamma 1$ chain is, however, a component of most laminin heterotrimers; mice lacking it die during embryogenesis because they are unable to make a basal lamina.

Type IV collagen is a second essential component of a mature basal lamina, and it, too, exists in several isoforms. Like the *fibrillar collagens* that constitute the bulk of the protein in connective tissues such as bone or tendon, type IV collagen molecules consist of three separately synthesized long protein chains that twist together to form a rope-like superhelix; however, they differ from the fibrillar collagens in that the triple-stranded helical structure is interrupted in more than 20 regions, allowing multiple bends. Type IV collagen molecules interact via their terminal domains to assemble extracellularly into a flexible, felt-like network that gives the basal lamina tensile strength.

Laminin and type IV collagen interact with other basal lamina components, such as the glycoprotein nidogen and the proteoglycan perlecan, resulting in a highly cross-linked network of proteins and proteoglycans (Figure 19-54). The laminin molecules that generate the initial sheet structure first join to each other while bound to receptors on the surface of the cells. The cell-surface receptors are primarily members of the integrin family, but another important type of laminin receptor is *dystroglycan*, a highly glycosylated transmembrane protein. Together, these receptors organize basal lamina assembly: they hold the laminin molecules by their feet, leaving the laminin heads positioned to interact so as to form a two-dimensional network. This laminin network then coordinates the assembly of the other basal lamina components.

Interactions between laminin and cell-surface receptors are critical for the adhesion of epithelia to the underlying connective tissue. In the skin, for example, the epithelial outer layer—the epidermis—depends on tight interactions with the basal lamina to keep it attached to the underlying dermis. In people with genetic defects in laminin-332, a key component of the skin basal lamina, the epidermis is poorly attached to the dermis. This causes a blistering disease called *junctional epidermolysis bullosa*, a severe and sometimes lethal condition.

Basal Laminae Have Diverse Functions

The basal lamina can act as a selective barrier to the movement of cells, as well as a filter for molecules. The lamina beneath an epithelium, for example, usually prevents fibroblasts in the underlying connective tissue from making contact

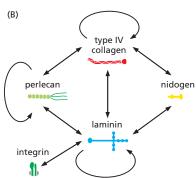

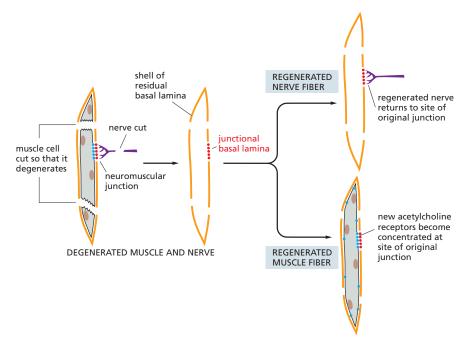

Figure 19-54 A model of the molecular structure of a basal lamina. (A) The basal lamina is formed by specific interactions (B) between the proteins laminin, type IV collagen, and nidogen and the proteoglycan perlecan. Arrows in B connect molecules that can bind directly to each other. There are various isoforms of type IV collagen and laminin, each with a distinctive tissue distribution. Transmembrane laminin receptors (integrins and dystroglycan) in the plasma membrane are thought to organize the assembly of the basal lamina; only the integrins are shown. (Based on H. Colognato and P.D. Yurchenco, Dev. Dvn. 218:213-234, 2000. With permission from John Wiley & Sons.)

MBOC7_ptr_ch19_1105-1162.indd 1143

with the epithelial cells. It does not, however, stop macrophages, lymphocytes, or nerve processes from passing through it, using specialized protease enzymes to cut a hole for their transit. The basal lamina is also important in tissue regeneration after injury. When cells in tissues such as muscles, nerves, and epithelia are damaged or killed, the basal lamina often survives and provides a scaffold along which regenerating cells can migrate. In this way, the original tissue architecture is readily reconstructed.

A particularly striking example of the role of the basal lamina in regeneration comes from studies of the *neuromuscular junction*, the site where the nerve terminals of a motor neuron form a chemical synapse with a skeletal muscle cell (discussed in Chapter 11). In vertebrates, the basal lamina that surrounds the muscle cell separates the nerve-cell and muscle-cell plasma membranes at the synapse, and the synaptic region of the lamina has a distinctive chemical character, with special isoforms of type IV collagen and laminin and a proteoglycan called *agrin*. After a nerve or muscle injury, the basal lamina at the synapse has a central role in reconstructing the synapse at the correct location (Figure 19–55). Defects in components of the basal lamina at the synapse are responsible for some forms of muscular dystrophy, in which muscles develop normally but then degenerate later in life.

Cells Have to Be Able to Degrade Matrix, as Well as Make It

The ability of cells to degrade and destroy extracellular matrix is as important as their ability to make it and bind to it. Rapid matrix degradation is required in processes such as tissue repair, and even in the seemingly static extracellular matrix of adult animals there is a slow, continual turnover, with matrix macromolecules being degraded and resynthesized. This allows bone, for example, to be remodeled so as to adapt to changes in the stresses on it.

From the point of view of individual cells, the ability to cut through matrix is crucial in two ways: it enables them to divide while embedded in matrix, and it enables them to travel through it. Cells in connective tissues generally need to be able to stretch out in order to divide. If a cell lacks the enzymes needed to degrade the surrounding matrix, it is strongly inhibited from dividing and hindered from migrating.

Figure 19–55 Regeneration experiments demonstrating the special character of the junctional basal lamina at a neuromuscular junction. If a frog muscle and its motor nerve are destroyed, the basal lamina around each muscle cell remains intact, and the sites of the old neuromuscular junctions are still recognizable. When the nerve, but not the muscle, is allowed to regenerate (upper right), the junctional basal lamina directs the regenerating nerve to the original synaptic site. When the muscle, but not the nerve, is allowed to regenerate (lower right), the junctional basal lamina causes newly made acetylcholine receptors (blue) to accumulate at the original synaptic site. These experiments show that the junctional basal lamina controls the localization of synaptic components on both sides of the lamina. Some of the molecules responsible for these effects have been identified. Motor neuron axons, for example, deposit agrin in the junctional basal lamina, where it regulates the assembly of acetylcholine receptors and other proteins in the junctional plasma membrane of the muscle cell. Reciprocally, muscle cells deposit a particular isoform of laminin in the junctional basal lamina, and this molecule is likely to interact with specific ion channels on the presynaptic membrane of the neuron.

MBOC7_ptr_ch19_1105-1162.indd 1144 02/12/21 12:26 PM

Localized degradation of matrix components is also required wherever cells have to escape from confinement by a basal lamina. It is needed during normal branching growth of epithelial structures such as glands, for example, to allow the population of epithelial cells to increase, and needed also when white blood cells migrate across the basal lamina of a blood vessel into tissues in response to infection or injury. Matrix degradation is important both for the spread of cancer cells through the body and for their ability to proliferate in the tissues that they invade (discussed in Chapter 20).

In general, matrix components are degraded by extracellular proteolytic enzymes (proteases) that act close to the cells that produce them. Many of these proteases belong to one of two general classes. The largest group, with about 50 members in vertebrates, is the **matrix metalloproteases**, which depend on bound Ca²⁺ or Zn²⁺ for activity. The second group is the **serine proteases**, which have a reactive serine in their active site. Together, metalloproteases and serine proteases cooperate to degrade matrix proteins such as collagen, laminin, and fibronectin. Some metalloproteases, such as the *collagenases*, are highly specific, cleaving particular proteins at a small number of sites. In this way, the structural integrity of the matrix is largely retained, while the limited amount of proteolysis that occurs is sufficient for cell migration. Other metalloproteases may be less specific, but, because they are anchored to the plasma membrane, act just where they are needed; it is this type of matrix metalloprotease that is crucial for a cell's ability to divide when embedded in matrix.

Clearly, the activities of the proteases that degrade the matrix must be tightly controlled if the fabric of the body is not to collapse in a heap. Numerous mechanisms are therefore employed to ensure that matrix proteases are activated only at the correct time and place. Protease activity is generally confined to the cell surface by specific anchoring proteins, by membrane-associated activators, and by the production of specific protease inhibitors in regions where protease activity is not needed.

The proteolytic cleavage of matrix proteins does not always lead simply to their destruction, but sometimes generates protein fragments with specific biological activities. For example, cleavage of type IV collagen by matrix metalloproteases leads to the release of protein fragments that inhibit the local formation of blood vessels. Similarly, cleavage of laminin in certain tissues can generate protein fragments that help govern local cell proliferation.

Matrix Proteoglycans and Glycoproteins Regulate the Activities of Secreted Proteins

The physical properties of extracellular matrix are important for its fundamental roles as a scaffold for tissue structure and as a substrate for cell anchorage and migration. The matrix also has an important impact on cell signaling. Cells communicate with each other by secreting peptide signal molecules, like growth factors and morphogens, that diffuse through the extracellular fluid to influence other cells (discussed in Chapter 15). On the way to their targets, the signal molecules encounter the tightly woven meshwork of the extracellular matrix, which contains a high density of negative charges and protein-interaction domains that can interact with the signal molecules, thereby altering their function in a variety of ways.

The highly charged heparan sulfate chains of proteoglycans, for example, interact with numerous secreted signal molecules, including *fibroblast growth factors* (*FGFs*) and *vascular endothelial growth factor* (*VEGF*), which (among other effects) stimulate a variety of cell types to proliferate. By providing a dense array of growth factor-binding sites, proteoglycans are thought to generate large local reservoirs of these factors, limiting their diffusion and focusing their actions on nearby cells. Similarly, proteoglycans might help generate steep morphogen gradients in an embryo, which can be important in the patterning of tissues during development. FGF activity can also be enhanced by proteoglycans, which oligomerize the FGF molecules and also interact with

MBOC7_ptr_ch19_1105-1162.indd 1145 02/12/21 12:26 PM

cell-surface FGF receptors, enabling the FGF to cross-link and activate its receptors more effectively.

The importance of proteoglycans as regulators of the distribution and activity of signal molecules is illustrated by the severe developmental defects that can occur when specific proteoglycans are inactivated by mutation. In *Drosophila*, for example, the function of several signal proteins during development is governed by interactions with the membrane-associated proteoglycans *Dally* and *Dally-like*. These members of the *glypican* family, like the syndecan proteoglycans described earlier, are membrane-associated proteins linked to multiple heparan sulfate molecules. They are thought to concentrate signal proteins in specific locations and act as co-receptors that collaborate with conventional cell-surface receptor proteins; as a result, they promote signaling in the correct location and prevent it in the wrong locations. In the *Drosophila* ovary, Dally is partly responsible for the restricted localization and function of a signaling protein called Dpp, which blocks differentiation of the germ-line stem cells: when the gene encoding Dally is mutated, Dpp activity is greatly reduced and oocyte development is abnormal.

Several other matrix molecules interact with signal proteins. The type IV collagen of the basal lamina interacts with Dpp in *Drosophila*, for example. Fibronectin contains a type III fibronectin repeat that interacts with VEGF and another domain that interacts with hepatocyte growth factor (HGF), thereby promoting the activities of these factors. As discussed earlier, many matrix glycoproteins contain extensive arrays of binding domains, and the arrangement of these domains is likely to influence the presentation of signal proteins to their target cells (see Figure 19–47).

Finally, many matrix glycoproteins contain domains that bind directly to specific cell-surface receptors, thereby generating signals that influence the behavior of the cells, as we describe in the next section.

Summary

Cells are embedded in an intricate extracellular matrix, which not only binds the cells together but also influences their survival, development, shape, polarity, and migratory behavior. The matrix contains various protein fibers interwoven in a network of glycosaminoglycan (GAG) chains. GAGs are negatively charged polysaccharide chains that (except for hyaluronan) are covalently linked to protein to form proteoglycan molecules. GAGs attract water and occupy a large volume of extracellular space. Proteoglycans are also found on the surface of cells, where they often function as co-receptors to help cells respond to secreted signal proteins. Fiber-forming proteins give the matrix strength and resilience. The fibrillar collagens are rope-like, triple-stranded helical molecules that aggregate into long fibrils in the extracellular space, thereby providing tensile strength. They also form structures to which cells can be anchored, often via large multidomain glycoproteins, such as laminin and fibronectin, that bind to integrins on the cell surface. Elasticity is provided by elastin molecules, which form an extensive cross-linked network of fibers and sheets that can stretch and recoil.

The basal lamina is a specialized form of extracellular matrix that underlies epithelial cells or is wrapped around certain other cell types, such as muscle cells. The basal lamina is organized on a framework of laminin molecules, which are linked together by their side-arms and bind to integrins and other receptors in the basal plasma membrane of overlying epithelial cells. Type IV collagen molecules, together with the protein nidogen and the large proteoglycan perlecan, assemble into a sheetlike mesh that is an essential component of the mature basal lamina. Basal laminae provide mechanical support for epithelia; they form the interface and attachment between epithelia and connective tissue; they serve as filters in the kidney; they act as barriers to keep cells in their proper compartments; they influence cell polarity and cell differentiation; and they guide cell migration during development and tissue regeneration.

CELL-MATRIX JUNCTIONS 1147

CELL-MATRIX JUNCTIONS

Cells make extracellular matrix, organize it, and degrade it. The matrix in turn exerts powerful influences on the cells. The influences are exerted chiefly through transmembrane cell adhesion proteins that act as *matrix receptors*. These proteins tie the matrix outside the cell to the cytoskeleton inside it, but their role goes far beyond simple passive mechanical attachment. Through them, components of the matrix can affect almost any aspect of a cell's behavior. The matrix receptors have a crucial role in epithelial cells, mediating their interactions with the basal lamina beneath them. They are no less important in connective-tissue cells, mediating the cells' interactions with the matrix that surrounds them.

Several types of molecules can function as matrix receptors or co-receptors, including the transmembrane proteoglycans. But the principal receptors on animal cells for binding most extracellular matrix proteins are the integrins. Like the cadherins and the key components of the basal lamina, integrins are part of the fundamental architectural tool kit that is characteristic of multicellular animals. The members of this large family of transmembrane adhesion molecules have a remarkable ability to transmit signals in both directions across the plasma membrane. The binding of a matrix component to an integrin can send a message into the interior of the cell, and conditions in the cell interior can send a signal outward to control binding of the integrin to the matrix. Tension applied to an integrin can cause it to tighten its grip on intracellular and extracellular structures, and loss of tension can loosen its hold, so that molecular signaling complexes fall apart on either side of the membrane. In this way, integrins can serve not only to transmit mechanical and molecular signals but also to convert one type of signal into the other.

Integrins Are Transmembrane Heterodimers That Link the Extracellular Matrix to the Cytoskeleton

There are many varieties of integrins, but they all operate in a similar fashion. An integrin molecule is composed of two noncovalently associated glycoprotein subunits called α and β . Both subunits span the cell membrane and have short intracellular C-terminal tails and large N-terminal extracellular domains (Figure 19–56). The extracellular domains bind to specific amino acid sequence motifs in extracellular matrix proteins or, in some cases, in proteins on the surfaces

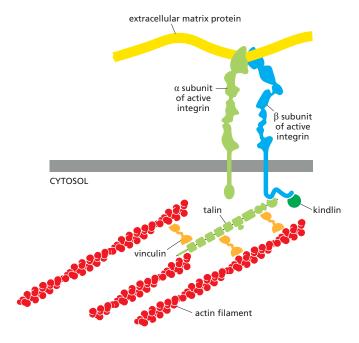

Figure 19-56 The subunit structure of an active integrin molecule, linking extracellular matrix to the actin cytoskeleton. The N-terminal heads of the integrin chains attach directly to an extracellular protein such as fibronectin: the C-terminal intracellular tail of the integrin $\boldsymbol{\beta}$ subunit binds to adaptor proteins that interact with filamentous actin. The best-understood adaptor is a giant protein called talin, which contains a string of multiple domains for binding actin and other proteins, such as vinculin, that help reinforce and regulate the linkage to actin filaments. One end of talin binds to a specific site on the integrin β -subunit cytoplasmic tail: other regulatory proteins. such as kindlin, bind at another site on the tail.

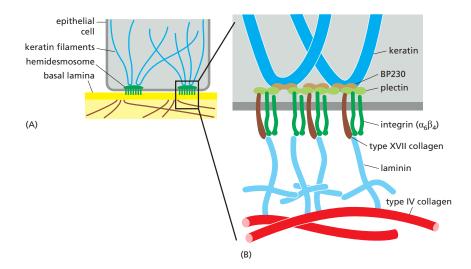

Figure 19-57 Hemidesmosomes. (A) Hemidesmosomes spot-weld epithelial cells to the basal lamina, linking laminin outside the cell to keratin filaments inside it. (B) Molecular components of a hemidesmosome. A specialized integrin $(\alpha_6\beta_4)$ integrin) spans the membrane. attaching to keratin filaments intracellularly via adaptor proteins called plectin and BP230, and attaching to laminin extracellularly. The adhesive complex also contains, in parallel with the integrin, an unusual collagen family member known as collagen type XVII; this has a membrane-spanning domain attached to its extracellular collagen region. Defects in any of these components can give rise to a blistering disease of the skin. One such disease, called bullous pemphigoid, is an autoimmune disease in which the immune system develops antibodies against collagen XVII or BP230.

of other cells. The best-understood binding site for integrins is the RGD sequence mentioned earlier (see Figure 19–48), which is found in fibronectin and other extracellular matrix proteins. Some integrins bind a Leu-Asp-Val (LDV) sequence in fibronectin and other proteins. Additional integrin-binding sequences exist in laminins and collagens.

Humans contain 24 types of integrins, which are formed from the products of 8 different β -chain genes and 18 different α -chain genes that are dimerized in different combinations. Each integrin dimer has specific properties and functions. Moreover, because the same integrin molecule in different cell types can have different ligand-binding specificities, it seems that additional cell type–specific factors can interact with integrins to modulate their binding activity. The binding of integrins to their matrix ligands is also affected by the concentration of Ca²⁺ and Mg²⁺ in the extracellular medium, reflecting the presence of divalent cation-binding domains in the α and β subunits. The divalent cations influence both the affinity and the specificity of the binding of an integrin to its extracellular ligands.

The intracellular portion of an integrin dimer binds to a complex of several different proteins, which together form a linkage to the cytoskeleton. For all but one of the 24 varieties of human integrins, this intracellular linkage is to actin filaments. These linkages depend on proteins that assemble at the short cytoplasmic tails of the integrin subunits (see Figure 19–56). A large adaptor protein called *talin* is a component of the linkage in many cases, but numerous additional proteins are also involved. Like the actin-linked cell-cell junctions formed by cadherins, the actin-linked cell-matrix junctions formed by integrins may be either small, inconspicuous, and transient or large, prominent, and durable. Examples of the latter are the *focal adhesions* that form when fibroblasts have sufficient time to establish strong attachments to the rigid surface of a culture dish, and the *myoten-dinous junctions* that attach muscle cells to their tendons.

In epithelia, the most prominent cell–matrix attachment sites are the hemidesmosomes, where a specific type of integrin anchors the cells to laminin in the basal lamina. Here, uniquely, the intracellular attachment is to keratin intermediate filaments, via the intracellular adaptor proteins plectin and BP230 (Figure 19–57).

Integrin Defects Are Responsible for Many Genetic Diseases

Although there is some overlap in the activities of the different integrins—at least five bind laminin, for example—it is the diversity of integrin functions that is more remarkable. Table 19–3 lists some varieties of integrins and the problems that result when individual integrin α or β chains are defective.

The $\beta 1$ subunit forms dimers with at least 12 distinct α subunits and is found on almost all vertebrate cells: $\alpha_5\beta_1$ is a fibronectin receptor and $\alpha_6\beta_1$ is a laminin

MBOC7_ptr_ch19_1105-1162.indd 1148 02/12/21 12:26 PM

receptor on many types of cells. Mutant mice that cannot make any β_1 integrins die early in embryonic development. Mice that are only unable to make the α_7 subunit (the partner for β_1 in muscle) survive but develop muscular dystrophy (as do mice that cannot make the laminin ligand for the $\alpha_7\beta_1$ integrin).

The β_2 subunit forms dimers with at least four types of α subunit and is expressed exclusively on the surface of white blood cells, where it has an essential role in enabling these cells to fight infection. The β_2 integrins mainly mediate cell-cell rather than cell-matrix interactions, binding to specific ligands on another cell, such as an endothelial cell. The ligands are members of the Ig superfamily of cell-cell adhesion molecules. We have already described an example earlier in the chapter: an integrin of this class ($\alpha_L\beta_2$, also known as LFA1) on white blood cells enables them to attach firmly to the Ig family protein ICAM1 on vascular endothelial cells at sites of infection (see Figure 19–28B). People with the genetic disease *leukocyte adhesion deficiency* fail to synthesize functional β_2 subunits. As a consequence, their white blood cells lack the entire family of β_2 receptors, and they suffer repeated bacterial infections.

The β_3 integrins are found on blood platelets (as well as various other cells), and they bind several matrix proteins, including the blood clotting factor *fibrinogen*. Platelets have to interact with fibrinogen to mediate normal blood clotting, and humans with *Glanzmann disease*, who are genetically deficient in β_3 integrins, suffer from defective clotting and bleed excessively.

Integrins Can Switch Between an Active and an Inactive Conformation

A cell crawling through a tissue—a fibroblast or a macrophage, for example, or an epithelial cell migrating along a basal lamina—has to be able both to make and to break attachments to the matrix, and to do so rapidly if it is to travel quickly. Similarly, a circulating white blood cell has to be able to switch on or off its tendency to bind to endothelial cells in order to crawl out of a blood vessel at a site of inflammation. Furthermore, the making and breaking of the extracellular attachments in all these cases has to be coupled to the prompt assembly and disassembly of

MBOC7_ptr_ch19_1105-1162.indd 1149 02/12/21 12:26 PM

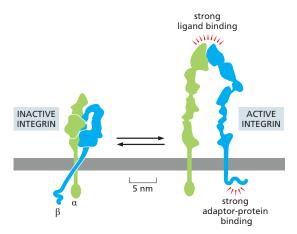

Figure 19–58 Integrins exist in two major activity states. Inactive (folded) and active (extended) structures of an integrin molecule, based on data from x-ray crystallography and other methods.

cytoskeletal attachments inside the cell. The integrin molecules that span the membrane and mediate the attachments cannot simply be passive, rigid objects with sticky patches at their two ends. They must be able to switch between an active state, where they readily form attachments, and an inactive state, where they do not.

Structural studies, using a combination of electron microscopy and x-ray crystallography, suggest that integrins exist in multiple structural conformations that reflect different states of activity (Figure 19–58). In the inactive state, the external segments of the integrin dimer are folded together into a compact structure that binds poorly to matrix proteins. In this state, the cytoplasmic tails of the dimer are hooked together, preventing their interaction with cytoskeletal linker proteins. In the active state, the two integrin subunits are unhooked at the membrane to expose the intracellular binding sites for cytoplasmic adaptor proteins, and the external domains unfold and extend, like a pair of legs, to expose a high-affinity matrix-binding site at the tips of the subunits. Thus, the switch from inactive to active states depends on a major conformational change that simultaneously exposes the external and internal ligand-binding sites at the ends of the integrin molecule. External matrix binding and internal cytoskeleton linkages are thereby coupled.

Switching between the inactive and active states is regulated by a variety of mechanisms, depending on the needs of the cell. In some cases, activation occurs by an "outside-in" mechanism: the binding of an external matrix protein, such as the RGD sequence of fibronectin, can drive some integrins to switch from the low-affinity inactive state to the high-affinity active state. As a result, binding sites for talin and other cytoplasmic adaptor proteins are exposed on the tail of the β chain. The binding of these adaptor proteins then leads to attachment of actin filaments to the intracellular end of the integrin molecule (see Figure 19–56). In this way, when the integrin catches hold of its ligand outside the cell, the cell reacts by tying the integrin molecule to the cytoskeleton, so that force can be applied at the point of cell attachment.

The chain of cause and effect can also operate in reverse. This "inside-out" integrin-activation process generally depends on intracellular regulatory signals that stimulate the ability of talin and other proteins to interact with the β chain of the integrin. Talin competes with the integrin α chain for its binding site on the tail of the β chain. Thus, when talin binds to the β chain, it blocks the intracellular $\alpha\!-\!\beta$ linkage, allowing the two legs of the integrin molecule to spring apart.

The regulation of "inside-out" integrin activation is particularly well understood in platelets, where an extracellular signal protein called thrombin binds to a specific G-protein-coupled receptor (GPCR) on the cell surface and thereby activates an intracellular signaling pathway that leads to integrin activation (Figure 19–59). It is likely that similar signaling pathways govern integrin activation in numerous other cell types.

MBOC7_ptr_ch19_1105-1162.indd 1150 02/12/21 12:26 PM

CELL-MATRIX JUNCTIONS 1151

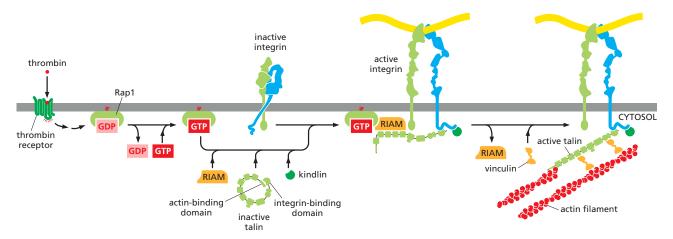

Figure 19–59 Activation of integrins by intracellular signaling. Signals received from outside the cell can act through intracellular signaling proteins to stimulate integrin activation. In platelets, as illustrated here, the extracellular signal protein thrombin activates a G-protein–coupled receptor on the cell surface, thereby initiating a signaling pathway that leads to activation of Rap1, a member of the monomeric GTPase family. Activated Rap1 interacts with the protein RIAM, which then recruits talin to the plasma membrane. Prior to this recruitment, talin is held in an inactive state by an interaction between tis C-terminal actin-binding domain and its N-terminal integrin-binding domain. When it is recruited by RIAM to the plasma membrane, talin unfolds to expose its binding sites for integrin and actin. Together with another protein called kindlin, talin interacts with the integrin β chain to trigger integrin activation. Talin then interacts with actin and with adaptor proteins such as vinculin, resulting in the formation of multiple actin linkages (see Figure 19–56 and Figure 19–61).

Integrins Cluster to Form Strong Adhesions

Integrins, like other cell adhesion molecules, differ from cell-surface receptors for hormones and for other extracellular soluble signal molecules in that they usually bind their ligand with lower affinity and are present at a 10- to 100-fold higher concentration on the cell surface. The Velcro principle, mentioned earlier in the context of cadherin adhesion (see Figure 19–6C), operates here too. After their activation, integrins cluster together to create a dense plaque in which many integrin molecules are anchored to cytoskeletal filaments. The resulting protein structure can be remarkably large and complex, as seen in the focal adhesion made by a fibroblast on the fibronectin-coated surface of a culture dish.

The assembly of mature cell–matrix junctional complexes depends on the recruitment of dozens of different scaffolding and signaling proteins. Talin is a major component of many cell–matrix complexes, but numerous other proteins also make important contributions. These include the *integrin-linked kinase* (ILK) and its binding partners *pinch* and *parvin*, which together form a trimeric complex that serves as an organizing hub at many junctions. Cell–matrix junctions also employ several actin-binding proteins, such as vinculin, *zyxin*, *VASP*, and α -actinin, to promote the assembly and organization of actin filaments. Another critical component of many cell–matrix junctions is the *focal adhesion kinase* (FAK), which interacts with multiple components in the junction and serves an important function in signaling, as we describe shortly.

Extracellular Matrix Attachments Act Through Integrins to Control Cell Proliferation and Survival

Like other transmembrane cell adhesion proteins, integrins do more than just create attachments. They also activate intracellular signaling pathways and thereby allow control of almost any aspect of the cell's behavior according to the nature of the surrounding matrix and the state of the cell's attachments to it.

Many cells will not grow or proliferate in culture unless they are attached to extracellular matrix; nutrients and soluble mitogens in the culture medium are not enough. For some cell types, including epithelial, endothelial, and muscle

MBOC7_ptr_ch19_1105-1162.indd 1151 02/12/21 12:26 PM

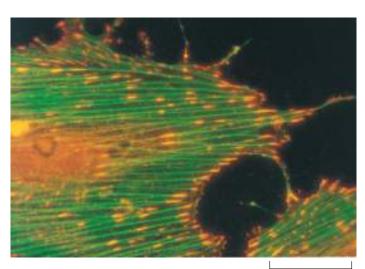

cells, even cell survival depends on such attachments. When these cells lose contact with the extracellular matrix, they undergo apoptosis. This dependence of cell growth, proliferation, and survival on attachment to a substratum is known as **anchorage dependence**, and it is mediated mainly by integrins and the intracellular signals they generate. Mutations that disrupt or override this form of control, allowing cells to escape from anchorage dependence, occur in cancer cells and play a major part in their invasive behavior.

Our understanding of anchorage dependence has come mainly from studies of cells living on the surface of matrix-coated culture dishes. For connective-tissue cells that are normally surrounded by matrix on all sides, this is a far cry from the natural environment. Walking over a two-dimensional plain is very different from clambering through a three-dimensional jungle. The types of contacts that cells make with a rigid substratum are not the same as those, much less well studied, that they make with the deformable web of fibers of the extracellular matrix, and there are substantial differences in cell behavior in the two contexts. Nevertheless, it is likely that the same basic principles apply. Both *in vitro* and *in vivo*, intracellular signals generated at cell–matrix adhesion sites are crucial for cell proliferation and survival.

Integrins Recruit Intracellular Signaling Proteins at Sites of Cell–Matrix Adhesion

The mechanisms by which integrins signal into the cell interior are complex, involving several pathways, and integrins and conventional signaling receptors often influence one another and work together to regulate cell behavior, as we have already emphasized. The Ras–MAP kinase pathway (see Figure 15–50), for example, can be activated both by conventional signaling receptors and by integrins, but cells often need both kinds of stimulation of this pathway at the same time to give sufficient activation to induce cell proliferation. Integrins and conventional signaling receptors also cooperate to promote cell survival (discussed in Chapters 15 and 18).

One of the best-studied modes of integrin signaling depends on a cytoplasmic protein tyrosine kinase called focal adhesion kinase (FAK). In studies of cells cultured on plastic dishes, focal adhesions are often prominent sites of tyrosine phosphorylation (Figure 19–60), and FAK is one of the major tyrosine-phosphorylated proteins found at these sites. When integrins cluster at cell-matrix contacts, FAK is recruited to the integrin β subunit by intracellular adaptor proteins such as talin or *paxillin* (which binds to one type of integrin α subunit). The clustered FAK molecules phosphorylate each other on a specific tyrosine, creating a

10 μm

Figure 19-60 Tyrosine phosphorylation at focal adhesions. A fibroblast cultured on a fibronectin-coated substratum and stained with fluorescent antibodies: actin filaments are stained green and proteins that contain phosphotyrosine are red, giving orange where the two components overlap. The actin filaments terminate at focal adhesions, where the cell attaches to the substratum by means of integrins. Proteins containing phosphotyrosine are also concentrated at these sites, reflecting the local activation of FAK and other protein kinases. Signals generated at such adhesion sites help regulate cell division, growth, and survival. (Courtesy of Keith Burridge.)

MBOC7_ptr_ch19_1105-1162.indd 1152 02/12/21 12:26 PM

CELL-MATRIX JUNCTIONS 1153

phosphotyrosine-docking site for members of the Src family of cytoplasmic tyrosine kinases. In addition to phosphorylating other proteins at the adhesion sites, these kinases then phosphorylate FAK on additional tyrosines, creating docking sites for a variety of additional intracellular signaling proteins. In this way, outside-in signaling from integrins, via FAK and Src family kinases, is relayed into the cell in much the same way as receptor tyrosine kinases generate signals (as discussed in Chapter 15).

Cell-Matrix Adhesions Respond to Mechanical Forces

Like the cell-cell junctions we described earlier, cell-matrix junctions can sense and respond to the mechanical forces that act on them. Most cell-matrix junctions, for example, are connected to a contractile actin network that tends to pull the junctions inward. When cells are attached to a rigid matrix that strongly resists such pulling forces, the cell-matrix junction is able to sense the resulting high tension and trigger a response in which it recruits additional integrins and other proteins to increase the junction's ability to withstand that tension. Cell attachment to a relatively soft matrix generates less tension and therefore a less robust response. These mechanisms allow cells to sense and respond to differences in the rigidity of extracellular matrices in different tissues.

We saw earlier that mechanotransduction at cadherin-based cell-cell junctions likely depends on junctional proteins that change their structure when the junction is stretched by tension (see Figure 19-12). The same is true for cell-matrix junctions. Talin, for example, includes a large number of binding sites for the actin-regulatory protein vinculin. Many of these sites are hidden inside folded protein domains but are exposed when those domains are unfolded by stretching the protein (Figure 19-61). The N-terminal end of talin binds integrin and the C-terminal end binds actin (see Figure 19-56); thus, when actin filaments are pulled by myosin motors inside the cell, the resulting tension stretches the talin rod, thereby exposing vinculin-binding sites. The vinculin molecules then recruit

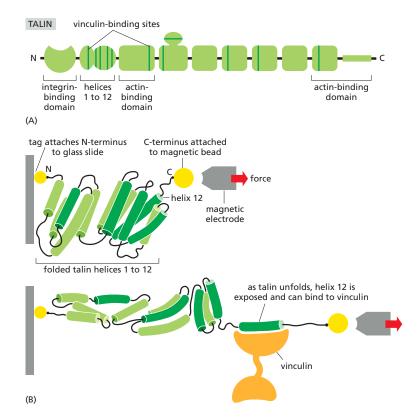

Figure 19-61 Talin is a tension sensor at cell-matrix junctions. Tension across cell-matrix junctions stimulates the local recruitment of vinculin and other actin-regulatory proteins, thereby strengthening the junction's attachment to the cytoskeleton. The experiment presented here tested the hypothesis that tension is sensed by the talin adaptor protein that links integrins to actin filaments (see Figure 19-56). (A) The long, flexible talin protein is divided into a series of folded domains, some of which contain vinculin-binding sites (dark green lines) that are thought to be hidden and therefore inaccessible. One domain near the N-terminus, for example, comprises a folded bundle of 12 α helices containing five vinculin-binding sites. (B) This experiment tested the hypothesis that tension stretches the 12-helix domain, thereby exposing vinculin-binding sites. A fragment of talin containing this domain was attached to an apparatus in which the domain could be stretched, as shown here. The fragment was labeled at its N-terminus with a tag that sticks to the surface of a glass slide on a microscope stage. The C-terminal end of the fragment was bound to a tiny magnetic bead, so the talin fragment could be stretched using a small magnetic electrode. The solution around the protein contained fluorescently tagged vinculin proteins. After the talin protein was stretched, excess vinculin solution was washed away, and the microscope was used to determine if any fluorescent vinculin proteins were bound to the talin protein. In the absence of stretching (top), most talin molecules did not bind vinculin. When the protein was stretched (bottom), two or three vinculin molecules were bound (only one is shown here for clarity). (Adapted from A. del Rio et al., Science 323:638-641, 2009.)

MBOC7_ptr_ch19_1105-1162.indd 1153 02/12/21 12:26 PM

and organize additional actin filaments. Tension thereby increases the strength of the junction.

Summary

Integrins are the principal cell-surface receptors used by animal cells to bind to the extracellular matrix: they function as transmembrane linkers between the extracellular matrix and the cytoskeleton. Most integrins connect to actin filaments, while those at hemidesmosomes bind to intermediate filaments. Integrin molecules are heterodimers, and the binding of extracellular matrix ligands or intracellular activator proteins such as talin results in a dramatic conformational switch from an inactive to an active state. This creates an allosteric coupling between binding to matrix outside the cell and binding to the cytoskeleton inside it, allowing the integrin to convey signals in both directions across the plasma membrane. Complex assemblies of proteins become organized around the intracellular tails of activated integrins, producing intracellular signals that can influence almost any aspect of cell behavior, from proliferation and survival, as in the phenomenon of anchorage dependence, to cell polarity and guidance of migration. Integrin-based cell-matrix junctions are also capable of mechanotransduction: they can sense and respond to mechanical forces acting across the junction.

THE PLANT CELL WALL

Each cell in a plant deposits, and is in turn completely enclosed by, an elaborate extracellular matrix called the plant cell wall. It was the thick cell walls of cork, visible in a primitive microscope, that in 1665 enabled Robert Hooke to observe and name cells for the first time. The walls of neighboring plant cells, cemented together to form the intact plant (Figure 19-62), are generally thicker, stronger,

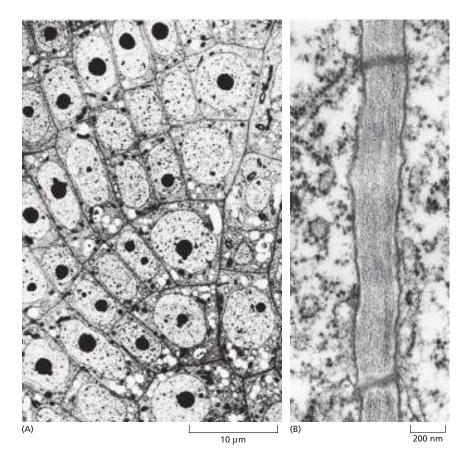

Figure 19-62 Plant cell walls. (A) Electron micrograph of the root tip of a rush, showing the organized pattern of cells that results from an ordered sequence of cell divisions in cells with relatively rigid cell walls. In this growing tissue, the cell walls are still relatively thin, appearing as fine black lines between the cells in the micrograph. (B) Section of a typical cell wall separating two adjacent plant cells. The two dark transverse bands correspond to plasmodesmata that span the wall (see Figure 19-27). (A, courtesy of C. Busby and B. Gunning, Eur. J. Cell Biol. 21: 214-223, 1980. With permission from Elsevier. B, courtesy of Jeremy Burgess.)

MBOC7 ptr ch19 1105-1162.indd 1154 02/12/21 12:26 PM THE PLANT CELL WALL 1155

and, most important of all, more rigid than the extracellular matrix produced by animal cells. In evolving relatively rigid walls, which can be up to many micrometers thick, early plant cells forfeited the ability to crawl about and adopted a sedentary lifestyle that has persisted in all present-day plants.

The Composition of the Cell Wall Depends on the Cell Type

All cell walls in plants have their origin in dividing cells, as the cell plate forms during cytokinesis to create a new partition wall between the daughter cells (discussed in Chapter 17). The new cells are usually produced in special regions called *meristems*, and they are generally small in comparison with their final size. To accommodate subsequent cell growth, the walls of the newborn cells, called **primary cell walls**, are thin and extensible, although tough. Once cell growth stops, the primary wall is sometimes retained without major modification, but, more commonly, a rigid **secondary cell wall** is produced by depositing new layers of matrix inside the old ones. These new layers generally have a composition that is significantly different from that of the primary wall. The most common additional polymer in secondary walls is **lignin**, a complex network of covalently linked phenolic compounds found in the walls of the xylem vessels and fiber cells of woody tissues.

Although the cell walls of higher plants vary in both composition and organization, they are all constructed, like animal extracellular matrices, using a structural principle common to all fiber-composites, including fiberglass and reinforced concrete. One component provides tensile strength, while another, in which the first is embedded, provides resistance to compression. While the principle is the same in plants and animals, the chemistry is different. Unlike the animal extracellular matrix, which is rich in protein and other nitrogen-containing polymers, the plant cell wall is made almost entirely of polymers that contain no nitrogen, including *cellulose* and lignin. For a sedentary organism that depends on ${\rm CO_2}$, ${\rm H_2O}$, and sunlight, these two abundant biopolymers represent "cheap," carbon-based structural materials, helping to conserve the scarce fixed nitrogen available in the soil that generally limits plant growth. Thus trees, for example, make a huge investment in the cellulose and lignin that compose the bulk of their biomass.

In the cell walls of higher plants, the tensile fibers are made from the poly-saccharide cellulose, the most abundant organic macromolecule on Earth, tightly linked into a network by *cross-linking glycans*. In primary cell walls, the matrix in which the cross-linked cellulose network is embedded is composed of *pectin*, a highly hydrated network of polysaccharides rich in galacturonic acid. Secondary cell walls contain additional molecules to make them rigid and permanent; lignin, in particular, forms a hard, waterproof filler in the interstices between the other components. All of these molecules are held together by a combination of covalent and noncovalent bonds to form a highly complex structure, whose composition, thickness, and architecture depend on the cell type.

The plant cell wall thus has a "skeletal" role in supporting the structure of the plant as a whole, a protective role as an enclosure for each cell individually, and a transport role, helping to form channels for the movement of fluid in the plant. When plant cells become specialized, they generally adopt a specific shape and produce specially adapted types of walls, according to which the different types of cells in a plant can be recognized and classified. We focus here, however, on the primary cell wall and the molecular architecture that underlies its remarkable combination of strength, resilience, and plasticity, as seen in the growing parts of a plant.

The Tensile Strength of the Cell Wall Allows Plant Cells to Develop Turgor Pressure

The aqueous extracellular environment of a plant cell consists of the fluid contained in the walls that surround the cell. Although the fluid in the plant cell wall contains more solutes than does the water in the plant's external milieu (for example, soil), it is still hypotonic in comparison with the cell interior. This osmotic

MBOC7_ptr_ch19_1105-1162.indd 1155 02/12/21 12:26 PM

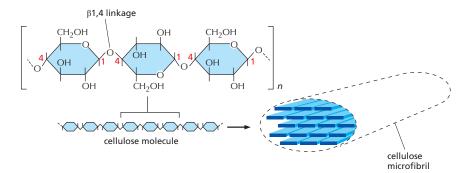

Figure 19–63 Cellulose. Cellulose molecules are long, unbranched chains of β 1,4-linked glucose units. Each glucose residue is inverted with respect to its neighbors, and the resulting disaccharide repeat occurs hundreds of times in a single cellulose molecule. In most higher plant cells, about 18 individual cellulose molecules assemble in parallel to form a strong, hydrogen-bonded cellulose microfibril.

imbalance causes the cell to develop a large internal hydrostatic pressure, or **turgor pressure**, which pushes outward on the cell wall, just as an inner tube pushes outward on a bicycle tire. The turgor pressure increases just to the point where the cell is in osmotic equilibrium, with no net influx of water despite the salt imbalance. The turgor pressure generated in this way may reach 10 or more atmospheres, about five times that in the average car tire. This pressure is vital to plants because it is the main driving force for cell expansion during growth, and it provides much of the mechanical rigidity of living plant tissues. Compare the wilted leaf of a dehydrated plant, for example, with the turgid leaf of a well-watered one. It is the mechanical strength of the cell wall that allows plant cells to sustain this internal pressure.

The Primary Cell Wall Is Built from Cellulose Microfibrils Interwoven with a Network of Pectic Polysaccharides

Cellulose gives the primary cell wall tensile strength. Each cellulose molecule consists of a linear chain of at least 500 glucose residues that are covalently linked to one another to form a ribbonlike structure, which is stabilized by hydrogen bonds within the chain (Figure 19–63). In addition, hydrogen bonds between adjacent cellulose molecules cause them to stick together in overlapping parallel arrays, forming bundles of about 18 cellulose chains, all of which have the same polarity. These highly ordered crystalline aggregates, many micrometers long, are called cellulose microfibrils, and they have a tensile strength comparable to that of steel. Sets of microfibrils are arranged in layers, or lamellae, with each microfibril about 20–40 nm from its neighbors and connected to them by long cross-linking glycan molecules, which are attached by hydrogen bonds to the surface of the microfibrils. The primary cell wall consists of several such lamellae arranged in a plywoodlike network (Figure 19–64).

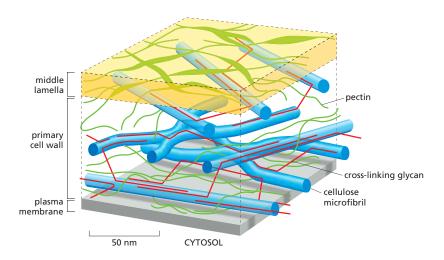

Figure 19-64 Scale model of a portion of a primary plant cell wall showing the two major polysaccharide networks. The orthogonally arranged layers of cellulose microfibrils (blue) are tied into a network by the cross-linking glycans (red) that form hydrogen bonds with the microfibrils. This network is accompanied by a network of pectin polysaccharides (green). The network of cellulose and cross-linking alveans provides tensile strenath, while the pectin network resists compression. Cellulose, cross-linking glycans, and pectin are typically present in roughly equal amounts in a primary cell wall. The middle lamella is especially rich in pectin, and it cements adjacent cells together.

MBOC7_ptr_ch19_1105-1162.indd 1156 02/12/21 12:26 PM

THE PLANT CELL WALL 1157

The **cross-linking glycans** are a heterogeneous group of branched polysaccharides that bind tightly to the surface of each cellulose microfibril and thereby help to cross-link the microfibrils into a complex network. There are many classes of cross-linking glycans, but they all have a long linear backbone composed of one type of sugar (glucose, xylose, or mannose) from which short side chains of other sugars protrude. The backbone sugar molecules form hydrogen bonds with the surface of cellulose microfibrils, cross-linking them in the process. Both the backbone and the side-chain sugars vary according to the plant species and its stage of development.

The network of cellulose microfibrils and cross-linking glycans includes another cross-linked polysaccharide network that is based on **pectins** (see Figure 19–64). Pectins are a heterogeneous group of branched polysaccharides that contain many negatively charged galacturonic acid units. Because of their negative charge, pectins are highly hydrated and associated with a cloud of cations, resembling the glycosaminoglycans of animal cells in the large amount of space they occupy (see Figure 19–33). When Ca²⁺ is added to a solution of pectin molecules, it cross-links them to produce a semirigid gel (it is pectin that is added to fruit juice to make jam or jelly). Certain pectins are particularly abundant in the *middle lamella*, the specialized region that cements together the walls of adjacent cells (see Figure 19–64); here, Ca²⁺ cross-links are thought to help hold cell wall components together. Although covalent bonds also play a part in linking the components, very little is known about their nature. Regulated separation of cells at the middle lamella underlies such processes as the ripening of tomatoes and the abscission (detachment) of leaves in the fall.

In addition to the two polysaccharide-based networks that form the bulk of all plant primary cell walls, proteins are present, contributing up to about 5% of the wall's dry mass. Many of these proteins are enzymes, responsible for wall turnover and remodeling, particularly during growth. Another class of wall proteins, like collagen, contains high levels of hydroxyproline. These proteins are thought to strengthen the wall, and they are produced in greatly increased amounts as a local response to attack by pathogens. From the genome sequence of *Arabidopsis*, it has been estimated that more than 700 genes are required to synthesize, assemble, and remodel the plant cell wall.

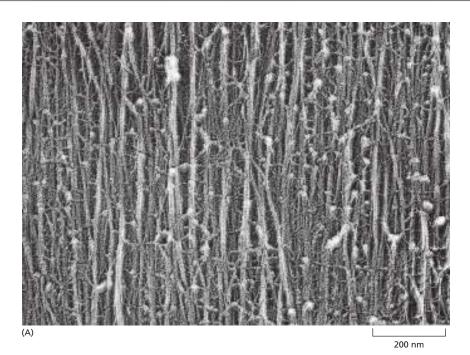

Oriented Cell Wall Deposition Controls Plant Cell Growth

Once a plant cell has left the meristem where it is generated, it can grow dramatically, commonly by more than a thousand times in volume. The manner of this expansion determines the final shape of each cell, and hence the final form of the plant as a whole. Turgor pressure inside the cell drives the expansion, but it is the behavior of the cell wall that governs its direction and extent. Complex wall-remodeling activities are required, as well as the deposition of new wall materials. Because of their crystalline structure, the individual cellulose microfibrils in the wall are unable to stretch, and this gives them a crucial role in the process. For the cell wall to stretch or deform, the microfibrils must either slide past one another or become more widely separated, or both. The orientation of the microfibrils in the innermost layers of the wall governs the direction in which the cell expands. Cells in plants therefore anticipate their future morphology by controlling the orientation of the cellulose microfibrils that they deposit in the wall (Figure 19–65).

Unlike most other matrix macromolecules, which are made in the endoplasmic reticulum and Golgi apparatus and are secreted, cellulose is spun out from the surface of the cell by a plasma membrane-bound enzyme complex (*cellulose synthase*), which uses as its substrate the sugar nucleotide UDP-glucose supplied from the cytosol. Each enzyme complex, or *rosette*, is a radial array of six trimers, each containing the protein products of three separate cellulose synthase (*CESA*) genes (see Figure 19–66). Three *CESA* genes are required for primary cell wall synthesis and a different three for secondary cell wall synthesis.

As they are being synthesized, the nascent cellulose chains assemble into microfibrils. These are spun out on the extracellular surface of the plasma

MBOC7_ptr_ch19_1105-1162.indd 1157 02/12/21 12:26 PM

membrane, forming a layer, or lamella, in which all the microfibrils have more or less the same alignment (see Figure 19–64). Each new lamella is deposited internally to the previous one, so that the wall consists of concentrically arranged lamellae, with the oldest on the outside. The most recently deposited microfibrils in elongating cells commonly lie perpendicular to the axis of cell elongation, although the orientation of the microfibrils in the outer lamellae that were laid down earlier may be different (see Figure 19–65B and C).

Microtubules Orient Cell Wall Deposition

An important clue to the mechanism that dictates microfibril orientation came from observations of the microtubules in plant cells. These are frequently arranged in the cortical cytoplasm with the same orientation as the cellulose microfibrils that are currently being deposited in the cell wall in that region. These cortical microtubules form a *cortical array* close to the cytosolic face of the plasma membrane, held there by poorly characterized proteins. The congruent orientation of the cortical array of microtubules (lying just inside the plasma membrane) and cellulose microfibrils (lying just outside) is seen in many types and shapes of plant cells and is present during both primary and secondary cell wall deposition, suggesting a causal relationship.

This suggestion can be tested by treating a plant tissue with a microtubule-depolymerizing drug so as to disassemble the entire system of cortical microtubules. The consequences for subsequent cellulose deposition, however, are not as straightforward as might be expected. The drug treatment does not disrupt the production of new cellulose microfibrils, and in some cases cells can continue to deposit new microfibrils in the preexisting orientation. Any developmental switch in the orientation of the microfibril pattern that would normally occur between successive lamellae, however, is invariably blocked. It seems that a preexisting orientation of microfibrils can be propagated even in the absence of microtubules, but any change in the deposition of cellulose microfibrils requires that intact microtubules be present to determine the new orientation.

These observations are consistent with the following model. The cellulose-synthesizing rosettes embedded in the plasma membrane spin out long cellulose

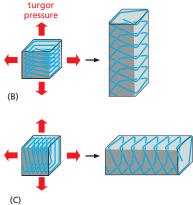

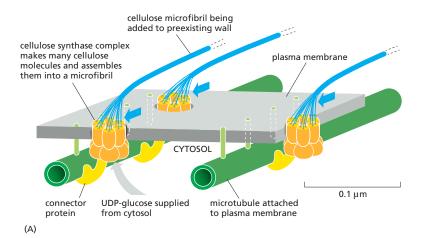

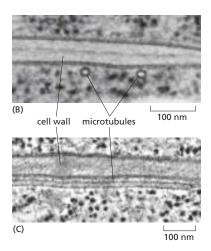

Figure 19-65 Cellulose microfibrils influence the direction of cell elongation. (A) The orientation of cellulose microfibrils in the primary cell wall of an elongating carrot cell is shown in this electron micrograph of a shadowed replica from a rapidly frozen and deep-etched cell wall. The cellulose microfibrils are aligned parallel to one another and perpendicular to the axis of cell elongation. The microfibrils are crosslinked by, and interwoven with, a complex web of matrix molecules (compare with Figure 19-64). (B, C) The cells in B and C start off with identical shapes (shown here as cubes) but with different net orientations of cellulose microfibrils in their walls. Although turgor pressure is uniform in all directions, cell wall loosening allows each cell to elongate only in a direction perpendicular to the orientation of the innermost laver of microfibrils, which have great tensile strength. Cell expansion occurs in concert with the insertion of new wall material. The final shape of an organ, such as a shoot, is determined in part by the direction in which its component cells can expand. (A, courtesy of Brian Wells and Keith Roberts.)

MBOC7_ptr_ch19_1105-1162.indd 1158 02/12/21 12:26 PM

THE PLANT CELL WALL 1159

molecules. As the synthesis of cellulose molecules and their self-assembly into microfibrils proceeds, the distal end of each microfibril presumably forms indirect cross-links to the previous layer of wall material, orienting the new microfibril in parallel with the old ones as it becomes integrated into the texture of the wall. Because the microfibril is stiff, the rosette at its growing, proximal end has to move as it deposits the new material. Traveling in the plane of the membrane, the rosette moves in the direction defined by the way in which the far end of the microfibril is anchored in the existing wall. In this way, each layer of microfibrils would tend to be spun out from the membrane in the same orientation as the layer laid down previously, with the rosettes following the direction of the preexisting oriented microfibrils outside the cell. Oriented microtubules inside the cell, however, can force a change in the direction in which the rosettes move: they can create boundaries in the plasma membrane that act like the banks of a canal to constrain rosette movement (Figure 19-66). In this view, cellulose synthesis can occur independently of microtubules; but it is constrained spatially when cortical microtubules are present to define membrane microdomains within which the enzyme complex can move.

In this way, plant cells can change their direction of expansion by a sudden change in the orientation of their cortical array of microtubules. Because plant cells cannot move (being constrained by their walls), the entire morphology of a multicellular plant presumably depends on a coordinated, highly patterned deployment of cortical microtubule orientations during plant development. It is not known how these orientations are controlled, although it has been shown that the microtubules can reorient rapidly in response to extracellular stimuli, including plant growth regulators such as ethylene and auxins (discussed in Chapter 15).

Microtubules are not, however, the only cytoskeletal elements that influence wall deposition. Local foci of cortical actin filaments can also direct the deposition of new wall material at specific sites on the cell surface, contributing to the elaborate final shaping of many differentiated plant cells.

Summary

Plant cells are surrounded by a tough extracellular matrix, or cell wall, which is responsible for many of the unique features of a plant's lifestyle. The wall is composed of a network of cellulose microfibrils and cross-linking glycans, embedded in a highly cross-linked matrix of pectin polysaccharides. In secondary cell walls, lignin may be deposited to make them waterproof, hard, and woody. A cortical array of microtubules can control the orientation of newly deposited cellulose microfibrils, which in turn determine the direction of cell expansion and therefore the final shape of the cell and, ultimately, of the plant as a whole.

Figure 19–66 One model of how the orientation of newly deposited cellulose microfibrils might be determined by the orientation of cortical microtubules.

(A) The large cellulose synthase complexes, or rosettes, are integral membrane proteins that synthesize cellulose microfibrils on the outer face of the plasma membrane. Each rosette contains six enzyme trimers, resulting in the synthesis of the 18 cellulose chains that make up a cellulose microfibril in many plant cells (see Figure 19-63). The distal ends of the stiff microfibrils become integrated into the texture of the wall, and their elongation at the proximal end pushes the synthase complex along in the plane of the membrane. Because the cortical array of microtubules is attached to the plasma membrane in a way that confines this complex to defined membrane channels, the orientation of these microtubules-when they are present - determines the axis along which the new microfibrils are laid down. (B, C) Two electron micrographs show the tight association of the cortical microtubules with the plasma membrane. One shows the microtubules in cross section while the other shows a microtubule in longitudinal section. Both emphasize the constant gap of about 20 nm between membrane and microtubule. (B and C, courtesy of Andrew Staehelin.)

PROBLEMS

Which statements are true? Explain why or why not.

- **19–1** Given the numerous processes inside cells that are regulated by changes in Ca^{2+} concentration, it seems likely that Ca^{2+} -dependent cell-cell adhesions are also regulated by changes in Ca^{2+} concentration.
- **19–2** Tight junctions perform two distinct functions: they seal the space between cells to restrict paracellular flow, and they fence off plasma membrane domains to prevent the mixing of apical and basolateral membrane proteins.
- **19–3** The elasticity of elastin derives from its high content of α helices, which act as molecular springs.
- **19–4** Integrins can convert mechanical signals into intracellular molecular signals.
- **19–5** If the entire cortical array of microtubules were disassembled by drug treatment, new cellulose microfibrils would be laid down in random orientations.

Discuss the following problems.

- 19–6 Comment on the following (1922) quote from Warren Lewis, who was one of the pioneers of cell biology. "Were the various types of cells to lose their stickiness for one another and for the supporting extracellular matrix, our bodies would at once disintegrate and flow off into the ground in a mixed stream of cells."
- 19–7 Cell adhesion molecules were originally identified using antibodies raised against cell-surface components to block cell aggregation. In the adhesion-blocking assays, the researchers found it necessary to use antibody fragments, each with a single binding site (so-called Fab fragments), rather than intact IgG antibodies, which are Y-shaped molecules with two identical binding sites. The Fab fragments were generated by digesting the IgG antibodies with papain, a protease, to separate the two binding sites (Figure Q19–1). Why do you suppose it was necessary to use Fab fragments to block cell aggregation?

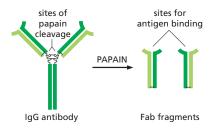

Figure Q19-1 Production of Fab fragments from IgG antibodies by digestion with papain (Problem 19-7).

19–8 The food-poisoning bacterium *Clostridium per-fringens* makes a toxin that binds to members of the claudin

family of proteins, which are the main constituents of tight junctions. When the C-terminus of the toxin is bound to a claudin, the N-terminus can insert into the adjacent cell membrane, forming holes that kill the cell. The portion of the toxin that binds to the claudins has proven to be a valuable reagent for investigating the properties of tight junctions. MDCK cells are a common choice for studies of tight junctions because they can form an intact epithelial sheet with high transepithelial electrical resistance (low ion permeability). MDCK cells express two claudins: claudin-1, which is not bound by the toxin, and claudin-4, which is.

When an intact MDCK epithelial sheet is incubated with the C-terminal toxin fragment, claudin-4 disappears, becoming undetectable within 24 hours. In the absence of claudin-4, the cells remain healthy and the epithelial sheet appears intact. The mean number of strands in the tight junctions that link the cells also decreases over 24 hours from about four to about two, and they are less highly branched. A functional assay for the integrity of the tight junctions shows that transepithelial resistance decreases dramatically in the presence of the toxin fragment, but the resistance can be restored by washing out the toxin fragment (Figure Q19–2A). Curiously, the toxin fragment produces these effects only when it is added to the basolateral side of the sheet; it has no effect when added to the apical surface (Figure Q19–2B).

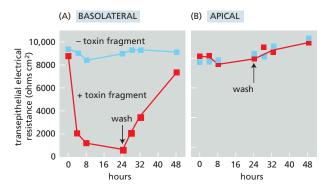

Figure Q19–2 Effects of *Clostridium* toxin fragment on the barrier function of MDCK cells (Problem 19–8). (A) Addition of toxin fragment from the basolateral side of the epithelial sheet. (B) Addition of toxin fragment from the apical side of the epithelial sheet. For a given voltage, a higher resistance (ohms cm²) gives less paracellular current.

- A. How can it be that two tight-junction strands remain, even though all of the claudin-4 has disappeared?
- B. Why do you suppose the toxin fragment works when it is added to the basolateral side of the epithelial sheet but not when added to the apical side?
- **19–9** The glycosaminoglycan polysaccharide chains that are linked to specific core proteins to form the proteoglycan components of the extracellular space are highly negatively charged. How do you suppose these negatively

MBOC7_ptr_ch19_1105-1162.indd 1160 02/12/21 12:26 PM

PROBLEMS 1161

charged polysaccharide chains help to establish a hydrated gel-like environment around the cell? How would the properties of these molecules differ if the polysaccharide chains were uncharged?

19–10 At body temperature, L-aspartate in proteins is converted to its optimal isomer D-aspartate at an appreciable rate. Most proteins in the body have a very low level of D-aspartate, if it can be detected at all. Elastin, however, has a fairly high level of D-aspartate. Moreover, the amount of D-aspartate increases in direct proportion to the age of the person from whom the sample was taken. Why do you suppose that most proteins have little if any D-aspartate, while elastin has levels of D-aspartate that increase steadily with age?

19–11 It is not an easy matter to assign particular functions to specific components of the basal lamina, because the overall structure is a complicated composite material with both mechanical and signaling properties. Nidogen, for example, cross-links two central components of the basal lamina by binding to the laminin γ chain and to type IV collagen. Given such a key role, it was surprising that mice with a homozygous knockout of the gene for nidogen-1 were entirely healthy, with no abnormal phenotype. Similarly, mice homozygous for a knockout of the gene for nidogen-2 also appeared completely normal. By contrast, mice that were homozygous for a defined mutation in the gene for the laminin γ chain, which eliminated just the binding site for nidogen, died at birth with severe defects in lung and kidney formation. The mutant portion of the laminin γ chain is thought to have no other function than to bind nidogen and does not affect laminin structure or its ability to assemble into the basal lamina. How would you explain these genetic observations, which are summarized in Table Q19-1? What would you predict would be the phenotype of a mouse that was homozygous for knockouts of both nidogen genes?

TABLE Q19–1 Phenotypes of mice with genetic defects in components of the basal lamina (Problem 19–11)		
Protein	Genetic defect	Phenotype
Nidogen-1	Gene knockout (-/-)	None
Nidogen-2	Gene knockout (-/-)	None
Laminin γ chain	Nidogen binding-site deletion (+/-)	None
Laminin γ chain	Nidogen binding-site deletion (-/-)	Dead at birth
+/- stands for heterozygous, -/- stands for homozygous.		

19–12 Discuss the following statement: "The basal lamina of muscle fibers serves as a molecular bulletin board, in which adjoining cells can post messages that direct the differentiation and function of the underlying cells."

19–13 Platelets are flat, disc-like cells with a surface area of about $20~\mu m^2$. They have about 80,000 integrin molecules on their surface. If the transmembrane portion of an integrin approximates a cylinder with a 10-nm diameter, how tightly packed are integrins on the surface of a platelet? Imagine that the surface area of the platelet is represented as a grid containing 80,000 squares, each containing one integrin. What is the average distance from one integrin to its neighbor? (Assume each integrin is at the center of its square.)

19–14 The affinity of integrins for matrix components can be modulated by changes to their cytoplasmic domains: a process known as inside-out signaling. You have identified a key region in the cytoplasmic domains of $\alpha_{IIb}\beta_3$ integrin that seems to be required for inside-out signaling (Figure Q19-3). Substitution of alanine for either D723 in the β chain or R995 in the α chain leads to a high level of spontaneous activation, under conditions where the wildtype chains are inactive. Your advisor suggests that you convert the aspartate in the β chain to an arginine (D723R) and the arginine in the α chain to an aspartate (R995D). You compare all three α chains (R995, R995A, and R995D) against all three β chains (D723, D723A, and D723R). You find that all pairs have a high level of spontaneous activation, except D723 versus R995 (the wild type) and D723R versus R995D, which have low levels. On the basis of these results, how do you think the $\alpha_{IIb}\beta_3$ integrin is held in its inactive state?

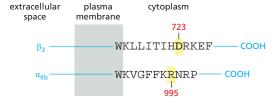

Figure Q19–3 Schematic representation of $α_{IID}β_3$ integrin (Problem 19–14). (From P.E. Hughes et al., *J. Biol. Chem.* 271:6571–6574, 1996. With permission from American Society for Biochemistry and Molecular Biology.)

19–15 Your boss is coming to dinner! All you have for a salad is some wilted, day-old lettuce. You vaguely recall that there is a trick to rejuvenating wilted lettuce, but you cannot remember what it is. Should you soak the lettuce in saltwater, soak it in tap water, or soak it in sugar water, or maybe just shine a bright light on it and hope that photosynthesis will perk it up?

19–16 A plant must be able to respond to changes in the water status of its surroundings. It does so by the flow of water molecules through water channels called aquaporins. The hydraulic conductivity of a single aquaporin is $4.4 \times 10^{-22} \, \text{m}^3$ per second per MPa (megapascal) of pressure. What does this correspond to in terms of water molecules per second at atmospheric pressure? [Atmospheric pressure is 0.1 MPa (1 bar) and the concentration of water is 55.5 M.]

Cancer

CHAPTER

About one in five of us will die of cancer, but that is not why we devote a chapter to this disease. Cancer cells break the most basic rules of cell behavior by which multicellular organisms are built and maintained, and they exploit every kind of opportunity to do so. These transgressions, while often tragic, help to reveal what the normal rules are and how they are enforced. As a result, cancer research helps to illuminate the fundamentals of cell biology—especially cell signaling (Chapter 15), the cell cycle and cell growth (Chapter 17), apoptosis (Chapter 18), and the control of tissue architecture (Chapters 19 and 22). Of course, with a deeper understanding of these normal processes, we also gain a deeper understanding of the disease and better tools to treat it.

In this chapter, we first consider what cancer is and describe the natural history of the disease from a cellular standpoint. We then discuss the molecular changes that make a cell cancerous. And we end the chapter by considering how our enhanced understanding of the molecular basis of cancer is leading to improved methods for its prevention and treatment.

CANCER AS A MICROEVOLUTIONARY PROCESS

The body of an animal operates as a society or ecosystem, whose individual members are cells that reproduce by cell division and organize themselves into collaborative assemblies called *tissues*. This ecosystem is very peculiar, however, because self-sacrifice—as opposed to survival of the fittest—is the rule. Ultimately, all of the somatic cell lineages in animals dedicate their existence to the support of the germ cells, which alone have a chance of continued survival (discussed in Chapter 21). Because the genome of the somatic cells is the same as that of the germ-cell lineage that gives rise to sperm or eggs, through their self-sacrifice the somatic cells help to propagate copies of their own genes.

Unlike free-living cells such as bacteria or yeast, which compete to survive, the cells of a multicellular organism must be committed to collaboration. To coordinate their behavior, the cells send, receive, and interpret an elaborate set of extracellular signals that serve as *social controls*, directing cells how to act (discussed in Chapter 15). As a result, each cell normally behaves in a socially responsible manner—resting, growing, dividing, differentiating, or dying—as needed for the good of the organism.

Molecular disturbances that upset this harmony mean trouble for a multicellular society. In a human body with more than 10¹³ cells, billions of cells experience mutations every day, potentially disrupting the social controls. Most dangerously, a mutation may give one cell a selective advantage, allowing it to grow and divide slightly more vigorously and survive more readily than its neighbors. In this way, a mutated cell can become a founder of a growing mutant clone. Over time, repeated rounds of mutation, competition, and natural selection operating within the population of somatic cells can cause matters to go from bad to worse, jeopardizing the future of the multicellular organism. These are the basic ingredients of cancer: it is a disease in which an individual mutant clone of cells begins by prospering at the expense of its neighbors. In the end—as the

Cancer as a Microevolutionary Process

Cancer-critical Genes: How They Are Found and What They Do

Cancer Prevention and Treatment: Present and Future

MBOC7_ptr_ch20_1163-1216.indd 1163 02/12/21 12:24 PM

Figure 20–1 Metastasis. Malignant tumors typically give rise to metastases, making the cancer hard to eradicate. Shown in this fusion image is a whole-body scan of a patient with metastatic non-Hodgkin's lymphoma (NHL). The background image of the body's tissues was obtained by CT (computed x-ray tomography) scanning. Overlaid on this image, a PET (positron emission tomography) scan reveals the tumor tissue (yellow), detected by its unusually high uptake of radioactively labeled fluorodeoxyglucose (FDG). High FDG uptake occurs in cells with unusually active glucose uptake and metabolism, a characteristic of cancer cells (see Figure 20–18). The yellow spots in the abdominal region reveal multiple metastases. (Courtesy of S.S. Gambhir.)

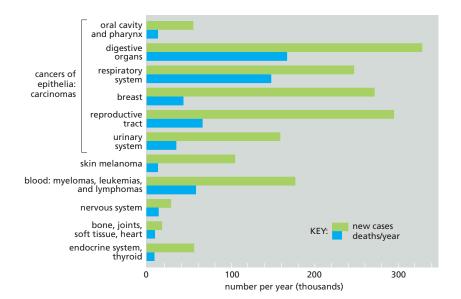

clone evolves over time and spreads—it can destroy the entire cellular society (Movie 20.1).

In this section, we discuss the development of cancer as a microevolutionary process that takes place within the course of a human life span in a subpopulation of cells in the body. As we shall see, the process depends on the same principles of mutation and natural selection that have driven the evolution of living organisms on Earth for billions of years.

Cancer Cells Bypass Normal Proliferation Controls and Colonize Other Tissues

Cancer cells are defined by two heritable properties: (1) they reproduce in defiance of the normal restraints on cell growth and division, and (2) they invade and colonize territories normally reserved for other cells. It is the combination of these properties that makes cancers particularly dangerous. An abnormal cell that goes through successive and inappropriate rounds of growth and division to proliferate out of control will give rise to a tumor, or *neoplasm*—literally, a new growth. As long as the *neoplastic* cells have not yet become invasive, however, the tumor is said to be **benign**. For most types of such neoplasms, removing or destroying the mass locally usually achieves a complete cure.

A tumor is considered a true cancer only if it is **malignant**; that is, when its cells have acquired the ability to invade surrounding tissue. Invasiveness is an essential characteristic of cancer cells. It allows them to break loose, enter blood or lymphatic vessels, and form secondary tumors called **metastases** at other sites in the body (**Figure 20–1**). In general, the more widely a cancer spreads, the harder it becomes to eradicate. It is metastases that usually kill the cancer patient by causing failure of a vital organ.

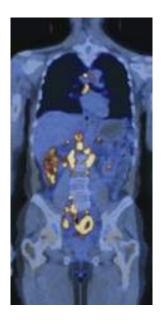

Figure 20-2 Cancer incidence and mortality in the United States. The estimated total number of new cases diagnosed in 2018 in the United States was 1,762,450, and total cancer deaths were 606,880. Note that deaths reflect cases diagnosed at many different stages and that well under half of the people who develop cancer die of it. The most common cancers are those of the digestive organs (including colon, pancreas, and liver), respiratory system (primarily lung and bronchus), reproductive tract (prostate and uterine), and breast. Skin cancers other than melanomas are not included in these figures, as almost all are cured easily and many are unrecorded. Each broad category has many subdivisions according to the specific cell type, the location in the body, and the microscopic appearance of the tumor. The data for the United Kingdom are similar. However, incidences are different in some other parts of the world, reflecting widespread exposures to different infectious agents and environmental toxins. (Data from American Cancer Society, Cancer Facts & Figures 2019.)

MBOC7_ptr_ch20_1163-1216.indd 1164 02/12/21 12:24 PM

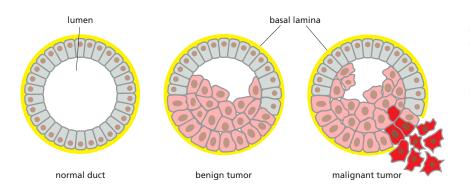

Figure 20–3 Benign versus malignant tumors. A benign glandular tumor (pink cells; an adenoma) remains inside the basal lamina (yellow) that marks the boundary of the normal structure (a duct, in this example). In contrast, a malignant glandular tumor (red cells; an adenocarcinoma) can develop from a benign tumor cell, and it destroys the integrity of the tissue, as shown. There are many different forms that such tumors may take.

Cancers are traditionally classified according to the tissue and cell type from which they arise. Carcinoma is the name given to cancers arising from epithelial cells, and they are by far the most common cancers in humans, accounting for about 85% of cancers. Most of the normal cell turnover by proliferation and death in adults occurs in epithelia, and the cell types that undergo the most cell division cycles have the greatest probability of accumulating the multiple mutations needed to become cancerous. In addition, epithelial tissues are the most likely to be exposed to the various forms of physical and chemical damage that favor the development of cancer. Figure 20–2 shows the types of cancers diagnosed in the United States, together with their incidence and death rates. After carcinomas, the next most common cancer types include the various myelomas, leukemias, and lymphomas, derived from white blood cells and their precursors (hemopoietic cells). Sarcomas that arise from connective tissue or muscle cells and cancers derived from cells of the nervous system are much less common.

In parallel with the set of names for malignant tumors, there is a related set of names for benign tumors: an *adenoma*, for example, is a benign epithelial tumor with a glandular organization; the corresponding type of malignant tumor is an *adenocarcinoma* (Figure 20–3).

Most cancers have characteristics that reflect their origin. Thus, for example, the cells of a *basal-cell carcinoma*, derived from a keratinocyte stem cell in the skin, generally continue to synthesize cytokeratin intermediate filaments, whereas the cells of a *melanoma*, derived from a pigment cell in the skin, will often (but not always) continue to make pigment granules. Cancers originating from different cell types are, in general, very different diseases. Basal-cell carcinomas of the skin, for example, are only locally invasive and rarely metastasize, whereas melanomas can become much more malignant and often form metastases. Basal-cell carcinomas are readily cured by surgery or local irradiation, whereas malignant melanomas, once they have metastasized widely, are frequently fatal.

Later, we shall see that there is also a different, newer way to classify cancers, one that cuts across the traditional classification by site of origin: we can now classify many of them in terms of the mutations that make the particular tumor cells cancerous. The final section of the chapter will show how this information can be crucial to the design and choice of treatments.

Most Cancers Derive from a Single Abnormal Cell

Even after a cancer has metastasized, we can usually trace its origins to a single **primary tumor**, arising in a specific organ. The primary tumor is thought to arise by cell division from a single cell that initially experienced some heritable change. Subsequently, additional changes have accumulated in some of the descendants of this cell, allowing them to outgrow, out-divide, and often outlive their neighbors.

By the time it is first detected, a typical human cancer will have been developing for many years and will already contain a billion cancer cells or more (Figure 20-4). Tumors will usually also contain a variety of other cell types and

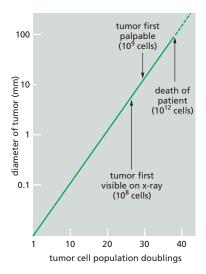

Figure 20–4 The growth of a typical human tumor, such as a tumor of the breast. The diameter of the tumor is plotted on a logarithmic scale. Years may elapse before the tumor becomes noticeable. The doubling time for a typical breast tumor, for example, is about 100 days. However, particularly aggressive tumors may grow much more rapidly.

MBOC7_ptr_ch20_1163-1216.indd 1165 02/12/21 12:24 PM

associated extracellular matrix, termed the *tumor stroma*. For example, fibroblasts will be present in the supporting connective tissue associated with a carcinoma, in addition to immune cells and vascular endothelial cells. How can we be sure that the cancer cells are the clonal descendants of a single abnormal cell?

One way of proving clonal origin is through molecular analysis of the chromosomes in tumor cells. In almost all individuals with *chronic myelogenous leukemia* (*CML*), for example, we can distinguish the leukemic white blood cells from the individual's normal cells by a specific chromosomal abnormality: the so-called *Philadelphia chromosome*, created by a translocation between the long arms of chromosomes 9 and 22 (Figure 20–5). When the DNA at the site of translocation is cloned and sequenced, it is found that the site of breakage and rejoining of the translocated fragments is identical in all the leukemic cells in any given individual, but that this site differs slightly (by a few hundred or thousand base pairs) from one individual to another. This is the expected result if, and only if, the cancer in each individual arises from a unique accident occurring in a single cell. (We will see later how this particular translocation promotes the development of CML by creating a novel hybrid gene encoding a protein that promotes cell proliferation.)

Many other lines of evidence, from a variety of different cancers, point to the same conclusion: most cancers originate from a single aberrant cell.

Cancer Cells Contain Somatic Mutations

If a single abnormal cell is to give rise to a tumor, it must pass on its abnormality to its progeny: the aberration has to be heritable. Thus, the development of a clone of cancer cells depends on genetic changes. The tumor cells contain **somatic mutations**: they have one or more shared detectable abnormalities in their DNA sequence that distinguish them from the normal cells surrounding the tumor, as in the example of CML just described. (The mutations are called *somatic* because they occur in the soma, or body cells, not in the germ line.) Cancers are also driven by *epigenetic changes*—persistent, heritable changes in gene expression that result from modifications of chromatin structure without alteration of the cell's DNA sequence. But somatic mutations that alter a DNA sequence appear to be a fundamental and universal feature, and cancer is in this sense a genetic disease.

Factors that cause genetic changes tend to provoke the development of cancer. Thus, **carcinogenesis** (the generation of cancer) can be linked to *mutagenesis* (the production of a change in the DNA sequence). This correlation is particularly clear for two classes of external agents: (1) *chemical carcinogens* (which typically cause simple changes in the nucleotide sequence), and (2) *radiation*, such as x-rays (which typically cause chromosome breaks and translocations) or ultraviolet (UV) light (which causes specific DNA base alterations).

As would be expected, people who have inherited a genetic defect in one of several DNA repair mechanisms, causing their cells to accumulate mutations at an elevated rate, run a heightened risk of cancer. Those with the disease *xero-derma pigmentosum*, for example, have defects in the system that repairs DNA damage induced by UV light, and they have a greatly increased incidence of skin cancers. Overall, inherited mutations are thought to play a role in 5–10% of all cancers, whereas somatic mutations and epigenetic changes are much more prevalent.

A Single Mutation Is Not Enough to Change a Normal Cell into a Cancer Cell

It is estimated that there are 3.7×10^{13} cells in an average-sized human (not counting bacteria), and that 10^{16} cell divisions occur within the body over the course of a typical lifetime. This cell proliferation occurs primarily in epithelia and the hemopoietic system and is balanced by cell death to maintain normal tissue homeostasis. Even in an environment that is free of mutagens, mutations would

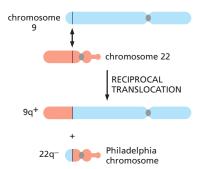

Figure 20–5 The translocation between chromosomes 9 and 22 responsible for chronic myelogenous leukemia. The normal structures of chromosomes 9 and 22 are shown at the top. When a reciprocal translocation occurs between them at the indicated site, the result is the abnormal pair at the bottom. The smaller of the two resulting abnormal chromosomes (22q⁻) is called the Philadelphia chromosome, after the city where the abnormality was first recorded.

occur spontaneously at an estimated rate of three per cell division, corresponding to about 10^{-6} mutations per gene per cell division. This unavoidable error rate is set by fundamental limitations on the accuracy of DNA replication and repair (see pp. 253–254). This means that, over the course of a typical lifetime, every single human gene will have undergone mutation somewhere in the body on roughly 10^{10} separate occasions. Among the resulting mutant cells, there will be many that have sustained deleterious mutations in genes that regulate cell growth and division, causing the cells to disobey the normal rules controlling cell turnover. Given the huge number of unavoidable mutations in a large organism like ourselves, the problem of cancer might seem to be not why it occurs, but why it occurs so infrequently.

If a mutation in a single gene were enough to convert a typical healthy cell into a cancer cell, we would not be viable organisms. Many lines of evidence indicate that the development of a cancer typically requires that a substantial number of independent, rare genetic and epigenetic accidents occur in the lineage that emanates from a single cell. One such indication comes from epidemiological studies of the incidence of cancer as a function of age (Figure 20–6). If a single mutation were responsible for cancer, occurring with a fixed probability per year, the chance of developing cancer in any given year of life should be independent of age. In fact, for most types of cancer, the incidence rises steeply with age—as would be expected if cancer is caused by a progressive, random accumulation of a set of mutations in a single lineage of cells. Notably, however, cancer incidence declines markedly among the very elderly. One interpretation of this phenomenon is that decreased cell proliferation, which is characteristic of declining stem cell function in octogenarians, provides fewer opportunities for mutation.

As discussed later, these indirect arguments linking the number of accumulated mutations to cancer development have now been confirmed by systematically sequencing the genomes of the tumor cells from individual cancer patients and cataloging the mutations that they contain.

Many Cancers Develop Gradually Through Successive Rounds of Random Inherited Change Followed by Natural Selection

For those cancers known to have a specific external cause, the disease does not usually become apparent until long after exposure to the causal agent. The incidence of lung cancer, for example, does not begin to rise steeply until after decades of heavy smoking (Figure 20–7). Similarly, the incidence of leukemias in those exposed to intense radiation in Hiroshima and Nagasaki did not show a marked rise until about 5 years after the explosion of the atomic bombs. And industrial workers exposed for a limited period to chemical carcinogens do not usually develop the cancers characteristic of their occupation until 10, 20, or even more years after the exposure. During this long incubation period, the prospective cancer cells undergo a succession of changes, and the same presumably applies to cancers where the initial genetic lesion has no such obvious external cause.

The fact that the development of a cancer requires a gradual accumulation of mutations in a number of different genes within a cell helps to explain the well-known phenomenon of **tumor progression**, whereby an initial mild disorder of cell behavior evolves gradually into a full-blown cancer (**Figure 20–8**).

At each stage of progression, some individual cell acquires an additional mutation or epigenetic change that gives it a selective advantage over its neighbors, making it better able to thrive in its environment—an environment that, inside a tumor, may be harsh, with low levels of oxygen, scarce nutrients, and the natural barriers to growth presented by the surrounding normal tissues. The larger the number of tumor cells, the higher the chance that at least one of them will undergo a change that favors it over its neighbors. Thus, as the tumor grows, progression accelerates. The offspring of the best-adapted cells continue to divide, eventually producing the dominant clones in a developing lesion

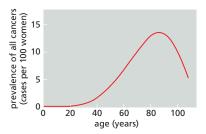

Figure 20–6 Cancer prevalence as a function of age. Age versus malignant cancer prevalence is plotted for women in the Surveillance, Epidemiology, and End Results (SEER) 9 cancer registries for the year 2000. The prevalence of cancer rises steeply as a function of age. If only a single mutation were required to trigger a cancer and the mutation had an equal chance of occurring at any time, the prevalence of cancer would be the same at all ages. (Data from C. Harding et al., Cancer 118:1371–1386, 2012, doi 10.1002 /cncr.26376.)

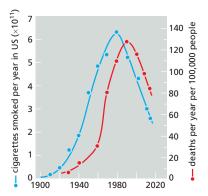

Figure 20–7 Smoking and lung cancer. A major increase in cigarette smoking that started in the early 1900s (blue line) caused a dramatic rise in lung cancer deaths (red line) after a lag time of about 20 years. Because cigarette smoking peaked in 1980, lung cancer deaths are now declining after a similar lag. (Data from National Center for Health Statistics, Centers for Disease Control and Prevention, 2017.)

MBOC7_ptr_ch20_1163-1216.indd 1167 02/12/21 12:24 PM

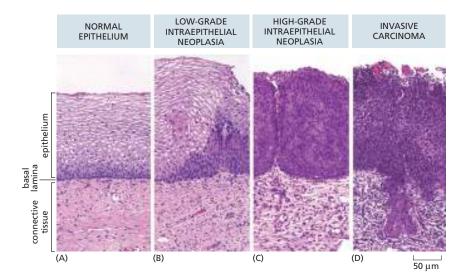

Figure 20-8 Stages of progression in the development of cancer of the epithelium of the uterine cervix. Pathologists use standardized terminology to classify the types of disorders they see in tissue slices like those shown here. (A) In a stratified squamous epithelium, dividing cells are confined to the basal layer. (B) In this low-grade intraepithelial neoplasia (right half of image), dividing cells can be found throughout the lower third of the epithelium; the superficial cells are still flattened and show signs of differentiation. (C) In highgrade intraepithelial neoplasia, cells in all the epithelial layers are proliferating and exhibit defective differentiation. (D) True malignancy begins when the cells move through or destroy the basal lamina that underlies the epithelium and invade the underlying connective tissue. (Courtesy of Andrew J. Connolly.)

(Figure 20–9). Thus, tumor progression involves a large element of chance and usually takes many years, which may be why the majority of us will die of causes other than cancer.

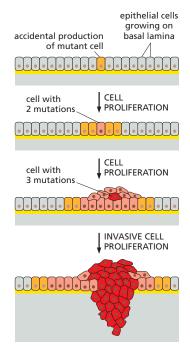

Just as in the evolution of plants and animals, a kind of speciation often occurs: the original cancer cell lineage can diversify to give many genetically different subclones of cells. These may coexist in the same mass of tumor tissue; or they may migrate and colonize separate environments suited to their individual quirks, where they settle, thrive, and progress as independently evolving metastases. As new mutations arise within each tumor mass, different subclones may gain an advantage and come to predominate, only to be overtaken by others or outgrown by their own sub-subclones. The large amount of genetic diversity in most tumors is one of the chief factors that make cancer cures difficult; it also increases the importance of detecting a tumor as early as possible.

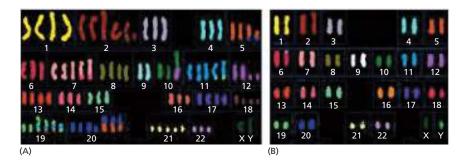

Cancers Can Evolve Abruptly Due to Genetic Instability

If cancer cells evolved exclusively through the gradual accumulation of single deleterious mutations, then the time scale of transformation from premalignant disease to metastatic cancer should be predictable for a particular cancer type. However, this is not the case. As in the evolution of species, cancer evolution may proceed through long periods with no discernible change punctuated by the sudden generation of new phenotypes. The "Big Bang" theory of cancer evolution posits that in addition to gradual mutagenesis and selection for the fittest cells, periodic, cataclysmic genome disruption can promote rapid steps in the evolution of a cancer cell toward malignancy.

Unlike normal dividing cells, most human cancer cells accumulate genetic changes at an abnormally rapid rate and are said to be **genetically unstable**. This instability provides a selective advantage by speeding the process of tumor progression—allowing the subsequent accumulation of many additional mutations

Figure 20–9 Clonal evolution during tumor progression. In this schematic diagram, a tumor develops through repeated rounds of mutation and proliferation, giving rise to a clone of fully malignant cancer cells. At each step, a single cell undergoes a mutation that either enhances cell proliferation or decreases cell death, so that its progeny become the dominant clone in the tumor. Proliferation of each clone hastens the occurrence of the next step of tumor progression by increasing the size of the cell population that is at risk of undergoing an additional mutation. The final step depicted here is invasion through the basal lamina, an initial step in metastasis. In reality, there may be more than the three steps shown here, depending on the tumor type, and a combination of genetic and epigenetic changes is involved. Not shown here is the fact that, over time, a variety of competing subclones will often arise in a tumor. As we will discuss later, this heterogeneity complicates cancer therapies.

required to produce a cancer. But the extent of the instability and its molecular origins differ from cancer to cancer and from individual to individual, both in severity and in character. In some cases, the karyotype—the set of chromosomes as they appear at mitosis—is normal or nearly so, but many point mutations are detected in individual genes, suggesting a failure of the repair mechanisms that normally correct errors in the replication or maintenance of DNA sequences. Often, however, the cancer cell karyotype is severely disordered, with many chromosomal breaks and rearrangements, resulting in many deletions, duplications, and amplifications of parts of the genome (Figure 20-10). Such highly disrupted genomes indicate that catastrophic events have occurred, likely due to defects in chromosome duplication or segregation during mitosis. For example, a common feature of many cancer cells is a failure to correctly attach all of the chromosomes to the mitotic spindle, which can result in chromosome breakage or aneuploidy, the gain or loss of individual chromosomes. More dramatically, mitotic defects can also lead to the isolation of a single chromosome in one of the daughter cells within a "micronucleus," where it is prone to massive DNA damage and chromosomal rearrangement, termed "chromothripsis" (Figure 20-11).

Figure 20-10 Chromosome complements (karyotypes) of colon cancers showing different kinds of genetic instability. (A) The karyotype of a typical cancer shows many gross abnormalities in chromosome number and structure. Considerable variation can also exist from cell to cell (not shown). (B) The karyotype of a tumor that has a stable chromosome complement with few chromosomal anomalies: the genetic abnormalities in these tumors are mostly invisible, having been created by defects in DNA repair. All of the chromosomes in this figure were stained as in Figure 4-11, the DNA of each human chromosome being marked with a different combination of fluorescent dyes. (Courtesy of Wael Abdel-Rahman and Paul Edwards.)

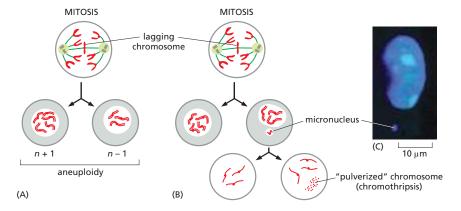

Figure 20-11 Chromosome segregation defects can give rise to aneuploidy and/or chromothripsis. Correct chromosome segregation requires that replicated copies of each chromosome, termed sister chromatids, are attached to opposite spindle poles. A mistake in this process is depicted in which one sister of a chromatid pair is attached to both spindle poles and is therefore pulled in opposite directions during anaphase, causing it to lag behind in the center of the cell, resulting in a lagging chromosome. (A) A lagging chromosome may end up in the same daughter cell as its sister, resulting in an euploidy with n + 1 and n - 1 karyotypes (n = chromosome number). (B) Another possible outcome is that the lagging chromosome remains separated from the rest of the chromosomes in the daughter cell, forming its own "micronucleus" in the following interphase. DNA replication in micronuclei is frequently incomplete, and DNA damage accumulates, but this does not delay the cell cycle. In the next mitosis, the isolated chromosome is prone to undergo fragmentation during chromosome condensation, in a process called chromothripsis. (C) Micronuclei can persist over several generations of cell division, undergoing rounds of chromosome fragmentation and reassembly, or they can be reincorporated into a daughter cell nucleus (Movie 20.2). The fluorescence micrograph shows a primary nucleus and a micronucleus present in the same cell. Nuclear DNA staining (blue) appears uneven due to normal nuclear substructures. (C, from M.L. Leibowitz et al., Annu. Rev. Genet. 49:183–211, 2015. With permission from Annual Reviews.)

MBOC7_ptr_ch20_1163-1216.indd 1169 02/12/21 12:24 PM

From an evolutionary perspective, none of this should be a surprise: anything that increases the probability of random changes in gene function that are heritable from one cell generation to the next—and that are not too deleterious—will likely speed the evolution of a clone of cells toward malignancy, thereby causing this property to be selected for during tumor progression. Genome instability likely also contributes to the heterogeneity of cancer cells frequently observed within an individual tumor. By leading to multiple aberrant karyotypes, chromosome mis-segregation, aneuploidy—and more rarely chromothripsis—all act to shuffle the genetic cards, allowing cancer cells to sample a variety of different phenotypes and for different clones to coexist within a population.

Some Cancers May Harbor a Small Population of Stem Cells

Self-renewing tissues, where cell division continues throughout life, are the breeding ground for the great majority of human cancers. They include the epidermis (the outer epithelial layer of the skin), the epithelial lining of the digestive and reproductive tracts, and the bone marrow, where blood cells are generated (see Chapter 22). With each cell division cycle comes the chance of mutation, which can be amplified dramatically by environmental factors. As a result, there is a strong correlation between the frequency of cell division and the incidence of cancer in a particular tissue (Figure 20–12).

In almost all proliferating tissues, renewal depends on the presence of stem cells, which divide to give rise to terminally differentiated cells, which do not divide. This creates a mixture of cells that are genetically identical and closely related by lineage but are in different states of differentiation. Many tumors similarly appear to consist of populations of cells in various states of differentiation. A comparison of tumor development to the normal homeostasis of stem cell-derived tissues may help us better understand the origin of some cancers and also why some tumors are so resistant to treatment.

To consider the implications, it is helpful to consider how normal stem-cell systems operate. When a normal stem cell divides, each daughter cell has a choice—it can remain a stem cell or it can commit to a pathway leading to differentiation. A stem-cell daughter remains in place to generate more cells in the future. A committed daughter typically undergoes some rounds of cell proliferation (as a so-called *transit amplifying cell*), but it then stops dividing, terminally differentiates, and eventually is discarded and replaced (it may die by apoptosis, with recycling of its materials, or be shed from the body). Therefore, stem cells tend to be vastly outnumbered by the cells that are committed to terminal differentiation. However, though few and far between and often relatively slowly dividing, stem cells carry the entire responsibility for maintenance of the tissue

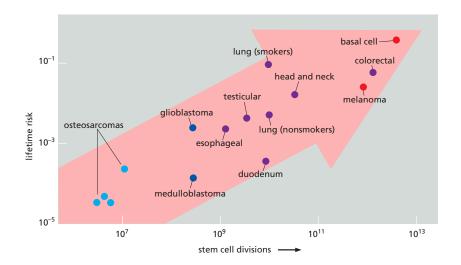

Figure 20-12 The lifetime cancer risk is correlated with the division rate of the cell of origin of the cancer. This plot shows the relationship between the number of stem cell divisions in a given tissue and the lifetime risk of cancer in that tissue. At the lower extreme are osteosarcomas (cancers that originate in bone), which are derived from mesenchymal cells that divide infrequently and rarely give rise to cancer. In contrast, epithelial cells of the skin and digestive tract are highly proliferative and give rise to malignancies much more frequently. Dots represent specific cancer types and are colored to indicate their classification: sarcoma (light blue); neuronal (dark blue); carcinoma (purple); and skin (red). Note that environmental factors strongly amplify the risk of many cancers, such as for lung cancer between smokers and nonsmokers. (Data from C. Tomasetti and B. Vogelstein, Science 347:78-81, 2015, doi 10.1126/science.1260825.)

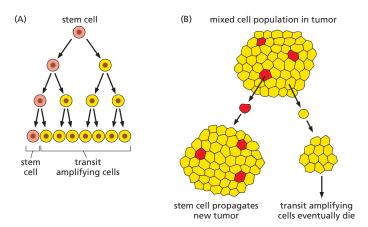

Figure 20–13 Cancer stem cells can be responsible for a tumor's growth and yet remain only a small part of the tumorcell population. (A) Lineage of stem cells producing transit amplifying cells. (B) How a small proportion of cancer stem cells can maintain a tumor. Although the much more abundant transit amplifying cells will eventually die, the number of cancer stem cells will increase slowly but steadily to produce a growing tumor.

over the long term. In a healthy body, feedback controls regulate the process, adjusting the balance of cell-fate choices, cell proliferation, and cell death in a way that corrects for any departure from proper cell population numbers.

During the development of cancer, mutations have the potential to subvert the normal cellular differentiation program in multiple ways; for example, by leading to an overproliferation of transit amplifying cells or to an inhibition of their terminal differentiation or death. More insidious, however, are mutations that lead to the generation of cancer stem cells. Some tumors appear to exhibit this etiology: they consist of rare **cancer stem cells** capable of self-renewal, together with much larger numbers of dividing transit amplifying cells that are derived from the cancer stem cells but have a limited capacity for self-renewal (Figure 20–13).

Evidence for the existence of cancer stem cells comes from experiments in which individual cells from a cancer are tested for their ability to give rise to fresh tumors when implanted into a mouse. It has been known for more than half a century that there is usually only a small chance—typically much less than 1% that a tumor cell chosen at random and tested in this way will generate a new tumor. This by itself does not prove that the tumor cells are heterogeneous: like seeds scattered on difficult ground, each of them may have only a small chance of finding a spot where it can survive and grow. Modern technologies for sorting cells have shown, however, that subpopulations of cancer cells expressing markers typically found on the surface of stem cells have a greatly enhanced ability to found new tumors. Moreover, the new tumors consist of mixtures of cells that express the stem cell markers and cells that do not, all generated from the same founder cell that expressed the markers. The cancer stem-cell phenomenon, whatever its basis, implies that even when the tumor cells are genetically similar, they may be phenotypically diverse. A treatment that wipes out tumor cells in one state will often allow survival of others that remain a danger. Radiotherapy or a cytotoxic drug, for example, may selectively kill off the rapidly dividing cells, reducing the tumor volume to almost nothing, and yet spare a few slowly dividing cells that go on to resurrect the disease. This greatly adds to the difficulty of cancer therapy, and it is part of the reason why treatments that seem at first to succeed often end in relapse and disappointment.

A Common Set of Hallmarks Typically Characterizes Cancerous Growth

Clearly, to produce a cancer, a cell must acquire a range of aberrant properties—a collection of subversive new skills—as it evolves. Different cancers require different combinations of these properties. Nevertheless, cancers all share some common hallmarks. These defining properties are commonly combined with other features, such as genetic instability, that help the miscreants to arise

MBOC7_ptr_ch20_1163-1216.indd 1171 02/12/21 12:24 PM

and thrive. A list of the key attributes of cancer cells in general would include the following:

- 1. Altered homeostasis that results in cells growing and dividing at a faster rate than they die
- 2. Bypass of normal limits to cell proliferation
- 3. Evasion of cell-death signals
- 4. Altered cellular metabolism
- 5. Manipulation of the tissue environment to support cell survival and to evade a deleterious immune response
- Escape of cells from their home tissues and proliferation in foreign sites (metastasis)

Below we discuss these key features in more detail. In the next section of the chapter, we examine the mutations and molecular mechanisms that underlie these and other properties of cancer cells.

Cancer Cells Display an Altered Control of Growth and Homeostasis

Mutability and large cell population numbers create opportunities for mutations to occur, but the driving force for development of a cancer has to come from some sort of *selective advantage* possessed by the mutant cells. Most obviously, a mutation or epigenetic change can confer such an advantage by increasing the rate at which a clone of cells proliferates or by enabling it to continue proliferating when normal cells would stop or die. One of the most important properties of many types of cancer cells is that they fail to undergo apoptosis when a normal cell would do so (Figure 20–14).

Cancer cells that can be grown in culture or cultured cells artificially engineered to contain the types of mutations encountered in cancers typically show a **transformed** phenotype. They are abnormal in their shape, their motility, their responses to growth factors in the culture medium, and, most characteristically, in the way they react to contact with the culture dish and with one another. Whereas most normal cells will not divide unless they are attached to the surface, transformed cells will often divide even if held in suspension. More generally, transformed cells no longer require all of the positive signals from their surroundings that normal cells require. In addition, transformed cells fail to recognize some negative influences. Thus, for example, normal cells become inhibited from moving and dividing when the culture reaches confluence (where the cells are touching one another), while transformed cells continue moving and dividing even after confluence, and so pile up in layer upon layer in the culture dish (Figure 20–15).

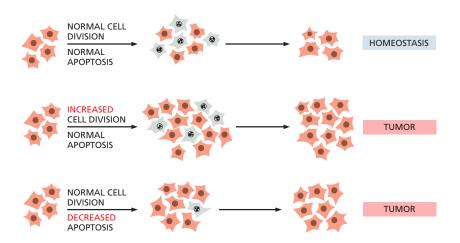

Figure 20–14 Both increased cell division and decreased apoptosis can contribute to tumorigenesis. In normal tissues, apoptosis balances cell division to maintain homeostasis (see Movie 18.1). During the development of cancer, either an increase in cell division or an inhibition of apoptosis can lead to the increased cell numbers important for tumorigenesis. The cells fated to undergo apoptosis are gray in this diagram. Both an increase in cell division and a decrease in apoptosis commonly contribute to tumor growth.

MBOC7_ptr_ch20_1163-1216.indd 1172 02/12/21 12:24 PM

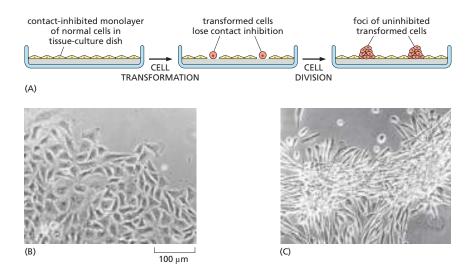

Figure 20–15 Loss of contact inhibition by cancer cells in cell culture. Most normal cells stop proliferating once they have carpeted the dish with a single layer of cells: proliferation seems to depend on contact with the dish and to be inhibited by contacts with other cells—a phenomenon known as contact inhibition. Cancer cells, in contrast, usually disregard these restraints and continue to grow, so that they pile on top of one another (Movie 20.3).

(A) Schematic drawing. (B and C) Light micrographs of normal (B) and transformed (C) fibroblasts. (B and C, courtesy of Lan Bo Chen.)

Cancer cells also misbehave in their natural environment, embedded in a tissue. For example, normal cells of the gut epithelium are constantly turning over through rounds of cell division and death, but maintain their barrier function by seamlessly extruding old or damaged cells into the gut lumen. Once detached from the matrix and matrix-associated survival signals, these cells die through a form of apoptosis. By overriding normal death signals, transformed cells may be able to survive after their ejection from the epithelium. However, because the normal direction of cell extrusion is into the lumen of the gut, they would nevertheless be swept away through the waste canal. However, some of the mutations selected for during cancer progression can change the direction of extrusion, thereby enabling the tumor cells to cross the basement membrane and invade the surrounding tissue, potentially leading to metastasis (Figure 20–16).

In conclusion, by disobeying the normal etiquette of where to live and when to die, cancer cells both evade growth suppression and explore new opportunities to prosper and multiply.

Human Cancer Cells Escape a Built-in Limit to Cell Proliferation

Many normal human cells have a built-in limit to the number of times that they can divide when stimulated to proliferate in culture: they permanently stop dividing after a certain number of population doublings (25–50 for human fibroblasts, for example). This cell-division-counting mechanism is termed **replicative cell senescence**, and it generally depends on the progressive shortening of the telomeres at the ends of chromosomes, a process that eventually changes their structure (discussed in Chapter 17). As discussed in Chapter 5, the maintenance

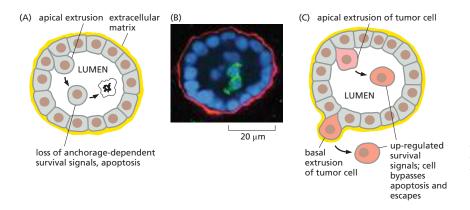

Figure 20-16 The direction in which a cell extrudes from an epithelium has important consequences for its fate. (A) Under normal conditions, as cells proliferate in a tissue such as the gut or mammary epithelium and become more crowded, they are extruded into the lumen to maintain cell number. Extruded cells generally undergo apoptosis due to loss of survival signals. (B) Fluorescence micrograph of a cluster of mammary epithelial cells grown in three-dimensional (3D) culture and stained for its basal boundary (red) and nuclei (blue). As the sac of tissue grows, the central cells occupying the lumen undergo apoptosis as shown by staining with caspase-3 (green). (C) Tumor cells with up-regulated survival signals that have been extruded apically might survive but are likely to be eliminated nevertheless; for example, by excretion through the digestive tract or by secretion from the mammary gland. In contrast, tumor cells that have been extruded basally can more readily initiate invasion. (B, courtesy of J. Debnath.)

MBOC7_ptr_ch20_1163-1216.indd 1173 02/12/21 12:24 PM

of telomere DNA during S phase depends on the enzyme *telomerase*, which maintains a special telomeric DNA sequence that promotes the formation of protein cap structures to protect chromosome ends. Because many proliferating human cells (stem cells being an exception) are deficient in telomerase, their telomeres shorten with every division, and their protective caps deteriorate, creating a DNA damage signal because the unprotected chromosome ends resemble double-strand breaks. Eventually, the altered chromosome ends trigger a permanent cell-cycle arrest or cause the cell to die.

Human cancer cells avoid replicative cell senescence in one of two ways. Most often, they reactivate the telomerase gene as they proliferate, so that their telomeres do not shorten or become uncapped; alternatively, they can evoke a mechanism based on a DNA repair process that depends on homologous recombination for elongating their chromosome ends (called ALT). Regardless of the strategy used, the result is that the cancer cells continue to proliferate under conditions when normal cells would stop due to telomere erosion.

Cancer Cells Have an Abnormal Ability to Bypass Death Signals

A large multicellular organism requires powerful safety mechanisms that guard against the trouble caused by damaged and deranged cells. These mechanisms are essential because, as previously explained, a large number of mutated cells will inevitably be produced. Normally, internal disorder gives rise to danger signals in the faulty cell, activating protective measures to reverse and cure this disorder or, failing that, activating decisions that lead to cell death by apoptosis (see Chapter 18). To survive, cancer cells require mutations to elude or break through these defenses designed to eliminate defective cells.

Cancer cells generally contain mutations that drive the cell into an abnormal state, where metabolic processes may be unbalanced and essential cell components may be produced in ill-matched proportions. States of this type, where the cell's homeostatic mechanisms are inadequate to cope with an imposed disturbance, are loosely referred to as states of *cell stress*. As one example, chromosome breakage and other forms of DNA damage are commonly observed during the development of cancer, reflecting the genetic instability that cancer cells display. Thus, to survive and divide without limit, a prospective cancer cell must accumulate changes that disable the normal safety mechanisms that would otherwise cause a cell that is stressed to commit suicide by apoptosis.

While cancer cells tend to avoid apoptosis, this does not mean that they rarely die. On the contrary, in the interior of a large solid tumor, cell death often occurs on a massive scale: living conditions are difficult, with severe competition among the cancer cells for oxygen and nutrients. Most of these cells die by an alternative cell-death mechanism termed necrosis (Figure 20–17).

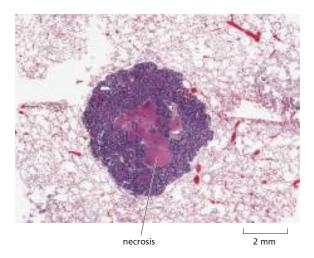

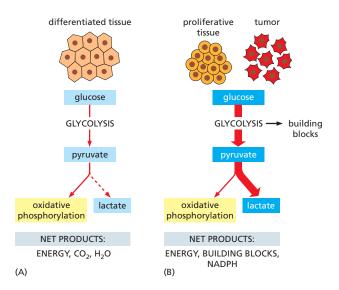

Figure 20–17 The interior of a large tumor is deprived of oxygen and nutrients. This cross section of a colon adenocarcinoma that has metastasized to the lung shows colorectal cancer cells that have formed a cohesive nodule (darkstaining region). The metastasis has central pink areas of necrosis where dying cancer cells have outgrown their blood supply and burst open, releasing their contents. Such anoxic regions are common in the interior of tumors. (Courtesy of Andrew J. Connolly.)

The tumor grows because the cell birthrate outpaces the cell death rate, but often by only a small margin. For this reason, the time that a tumor takes to double in size can be far longer than the cell-cycle time of the tumor cells.

Cancer Cells Have Altered Sugar Metabolism

Given sufficient oxygen, differentiated cells in most adult tissues will fully oxidize almost all the carbon in the glucose they take up to CO₂, which is eventually exhaled by the lungs as a waste product. A growing tumor needs nutrients in abundance to provide the building blocks to make new macromolecules. Correspondingly, most tumors are metabolically more similar to a growing embryo than to normal adult tissue. Tumor cells consume glucose avidly, importing it from the blood at a rate that can be as much as 100 times higher than that for neighboring normal cells. Moreover, only a fraction of this imported glucose is fully oxidized to CO₂ by mitochondrial oxidative phosphorylation, which normally enables highly efficient production of ATP. Instead, the metabolism of carbon atoms from glucose is rewired to support the production of raw materials for the synthesis of the proteins, nucleic acids, and lipids that enable cellular proliferation (Figure 20-18). In other words, even though glycolysis is a much less efficient mode of ATP production than oxidative phosphorylation, it can continue unabated in cancer cells that find themselves in an oxygen-poor environment, and it has the critical added benefit of producing abundant cellular building blocks.

This tendency of tumor cells to de-emphasize oxidative phosphorylation even when oxygen is plentiful, while at the same time taking up large quantities of glucose, is necessary for the rapid proliferation of many cancer cells and is called the *Warburg effect*—so named because Otto Warburg first noticed the phenomenon in the early twentieth century. It is this abnormally high glucose uptake that allows tumors to be selectively imaged in whole-body scans (see Figure 20–1), thereby providing one way to monitor cancer progression and responses to treatment.

The Tumor Microenvironment Influences Cancer Development

While the cancer cells in a tumor are the bearers of dangerous mutations and are often grossly abnormal, the other cells in the tumor—especially those of the supporting connective tissue, or **stroma**—are far from passive bystanders. The development of a tumor relies on a two-way communication between the cancer cells and tumor stroma, just as the normal development of epithelial organs relies on communication between epithelial cells and mesenchymal cells (discussed in Chapter 22).

Figure 20-18 The Warburg effect in tumor cells reflects a dramatic change in glucose uptake and sugar metabolism. (A) Cells that are not proliferating will normally oxidize nearly all of the glucose that they import from the blood to produce ATP through oxidative phosphorylation that takes place in their mitochondria. Only when deprived of oxygen will these cells generate most of their ATP from glycolysis, converting the pyruvate produced to lactate in order to regenerate the NAD+ that they need to keep glycolysis going (see Figure 2-50). (B) Tumor cells, by contrast, will generally produce abundant lactate even in the presence of oxygen. This results from a greatly increased rate of glycolysis that is fed by a very large increase in the rate of glucose import. In this way, tumor cells resemble the rapidly proliferating cells in embryos, which likewise require for biosynthesis a large supply of the smallmolecule building blocks that can be produced from imported glucose (see also Figure 2-60).

MBOC7_ptr_ch20_1163-1216.indd 1175 02/12/21 12:24 PM

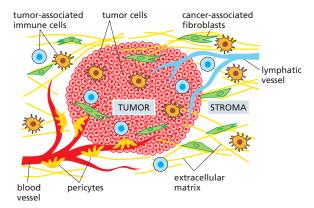

Figure 20–19 The tumor microenvironment plays a role in tumorigenesis. Tumors consist of many cell types, including cancer cells, endothelial cells, pericytes (vascular smooth muscle cells), fibroblasts, and inflammatory white blood cells. Communication among these and other cell types plays an important part in tumor development. Note, however, that only the cancer cells in a tumor are thought to contain mutations that make them genetically abnormal.

The stroma provides a framework for the tumor. As for normal connective tissue, the stroma is composed of fibroblasts and inflammatory white blood cells and of the endothelial cells that form blood and lymphatic vessels with their attendant smooth muscle cells (Figure 20–19). As a carcinoma progresses, the cancer cells induce changes in this stroma by secreting signal proteins that alter the behavior of the stromal cells and proteolytic enzymes that modify the extracellular matrix. The stromal cells in turn act back on the tumor cells by secreting signal proteins that stimulate cancer cell growth and division and proteases that further remodel the extracellular matrix. In these ways, the tumor and its stroma evolve together, like weeds and the ecosystem that they invade, and the tumor can become dependent on its particular stromal cells. Experiments using mice indicate that the growth of some transplanted carcinomas depends on the tumor-associated fibroblasts and that normal fibroblasts will not suffice.

Cancer cells have a complex interaction with the cells of the immune system that are present in the stroma, which have the potential to destroy the tumor if it is recognized as aberrant tissue but can also promote tumor growth by providing signals that stimulate cancer cell proliferation. The tumor can manipulate the immune system to its advantage in at least two ways. First, tumors may invoke an inflammatory reaction similar to what occurs when normal tissue is damaged, which helps them acquire the stroma they need for survival and growth. Tumors have therefore been likened to unhealed wounds, eliciting some of the same responses, including an increase in the permeability of nearby blood vessels, which allows the flow of signaling molecules in and out of the vessels, and the deposition of extracellular matrix. Tumors also stimulate the formation of new blood vessels, a process termed angiogenesis, which promotes survival of a tumor as it grows larger and becomes hypoxic in its interior. Second, and of equal importance, the tumor establishes an immunosuppressive microenvironment by blocking the activation of white blood cells that could lead to its destruction. Strategies that override this ability of a tumor to suppress an immune response have recently emerged as powerful tools in cancer therapy, and they are described in the last section of this chapter.

Cancer Cells Must Survive and Proliferate in a Foreign Environment

In order to kill us, cancer cells generally need to spread and multiply at new sites in the body through a process called metastasis. This is the most deadly—and least understood—aspect of cancer, being responsible for 90% of cancer-associated deaths. By spreading through the body, a cancer becomes almost impossible to eradicate by either surgery or local irradiation. **Metastasis** is itself a multistep process: the cancer cells first have to invade local tissues and vessels, move through the circulation, leave the vessels, and then establish new cellular colonies

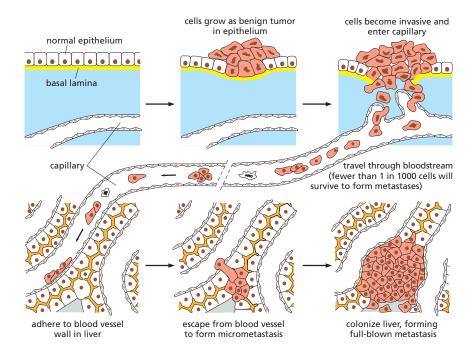

Figure 20-20 Steps in the process of metastasis. This example illustrates the spread of a tumor from its site of origin (such as the bladder) to another organ (such as the liver). Tumor cells may enter the bloodstream directly by crossing the wall of a blood vessel, as diagrammed here, or, more commonly perhaps, by crossing the wall of a lymphatic vessel that ultimately discharges its contents (lymph) into the bloodstream. Tumor cells that have entered a lymphatic vessel often become trapped in lymph nodes along the way, giving rise to lymph-node metastases. Studies in animals show that typically fewer than one in every thousand malignant tumor cells introduced into the bloodstream is viable after 24 hours, and that less than 0.1% of these surviving circulating tumor cells (CTCs) will colonize a new tissue so as to produce a detectable tumor at a new site.

at distant sites (Figure 20–20). Each of these events is complex, and most of the molecular mechanisms involved are not yet clear, but the last step—colonization of distant sites—is rate limiting.

For a cancer cell to become malignant, it must break free of constraints that keep normal cells in their proper places and prevent them from invading neighboring tissues. Invasiveness is thus one of the defining properties of malignant tumors, which show a disorganized pattern of growth and ragged borders, with extensions into the surrounding tissue (see, for example, Figure 20–8). Although the underlying molecular changes are not well understood, invasiveness almost certainly requires a disruption of the adhesive mechanisms that normally keep cells tethered to their proper neighbors and to the extracellular matrix.

The next step in metastasis—the establishment of colonies in distant organs—begins with entry into the circulatory system: the invasive cancer cells must penetrate the wall of a blood or lymphatic vessel. Lymphatic vessels, being larger and having more flimsy walls than blood vessels, allow cancer cells to enter in small clumps; such clumps may then become trapped in lymph nodes, giving rise to lymph-node metastases. The cancer cells that enter blood vessels, in contrast, do so singly or, more rarely, in small clusters. With modern techniques for sorting cells according to their surface properties, it has become possible to detect these *circulating tumor cells (CTCs)* in samples of blood from cancer patients, even though they are only a minute fraction of the total blood-cell population. Notably, in a mouse model, CTC clusters gave rise to metastases at a significantly higher rate than single CTCs did. Presumably the adhesion of epithelial-derived cancer cells to one another helps to override death signals and suppress apoptosis.

Of the cancer cells that enter the lymphatics or bloodstream, only a tiny proportion succeed in making their exit, settling in new sites, and surviving and proliferating there as founders of metastases. To discover which of the later steps in metastasis present cancer cells with the greatest difficulties, one can label the cells with a fluorescent dye or green fluorescent protein (GFP), inject them into the bloodstream of a mouse, and then monitor their fate (Movie 20.4). In such experiments, one observes that many cells survive in the circulation, lodge in small vessels, and exit into the surrounding tissue, regardless of whether they come from a tumor that metastasizes or one that does not. Some cells die immediately after they enter foreign tissue; others survive entry into the foreign tissue but

MBOC7_ptr_ch20_1163-1216.indd 1177 02/12/21 12:24 PM

fail to proliferate. Still others divide a few times and then stop, forming micrometastases containing ten to several thousand cells. Very few establish full-blown metastases. Experiments show that fewer than one in thousands, perhaps one in millions, manages this feat. The final step of colonization seems to be the most difficult: like the Vikings who landed on the inhospitable shores of Greenland, the migrant cells may fail to survive in the alien environment or they may only thrive there for a short while to found a little colony—a *micrometastasis*—that then dies out (Movie 20.5).

Many cancers are discovered before they have managed to found metastatic colonies, and these can be cured by destruction of the primary tumor. But on occasion, an undetected, distant micrometastasis will remain dormant for many years, only to reveal its presence by erupting into growth to form a large secondary tumor long after the primary tumor has been removed.

Summary

Cancer cells, by definition, grow and proliferate in defiance of normal controls (that is, they are neoplastic) and gain the ability to invade surrounding tissues and colonize distant organs (that is, they are malignant). By giving rise to secondary tumors, or metastases, they become difficult to eradicate by surgery or local irradiation. Cancers are thought to originate from a single cell that has experienced an initial mutation, but the progeny of this cell must undergo many further changes to become cancerous. Tumor progression usually takes many years and reflects the operation of a Darwinian-like process of evolution, in which somatic cells undergo mutation and epigenetic changes accompanied by natural selection and occasional bursts of genomic chaos that give rise to heterogeneity.

Cancer cells acquire a variety of special properties as they evolve, multiply, and spread. Their mutant genomes enable them to grow and divide in defiance of the signals that normally keep cell proliferation under tight control. As part of the evolutionary process of tumor progression, cancer cells acquire a collection of additional abnormalities, including defects in the controls that permanently stop cell division or induce apoptosis in response to cell stress or DNA damage and defects in the mechanisms that normally keep cells from straying from their proper place. All of these changes increase the ability of cancer cells to survive, grow, and divide in their original tissue and then to metastasize, founding new colonies in foreign environments. The evolution of a tumor also depends on other cells present in the tumor microenvironment, collectively called stromal cells, that the cancer attracts and manipulates.

Because many changes are needed to confer this collection of asocial behaviors, it is not surprising that most cancer cells are genetically and/or epigenetically unstable. This instability is thought to be selected for in the clones of aberrant cells that are able to produce tumors, because it greatly accelerates the accumulation of the further genetic and epigenetic changes that are required for tumor progression.

CANCER-CRITICAL GENES: HOW THEY ARE FOUND AND WHAT THEY DO

As we have seen, cancer depends on the accumulation of heritable changes in somatic cells; that is, changes that are transmitted by a cell to its progeny. To understand it at a molecular level we need to identify the mutations and epigenetic alterations involved and to discover how they give rise to cancerous cell behavior. Finding the relevant cells is often easy; they are favored by natural selection and call attention to themselves by giving rise to tumors. But how do we identify those genes that have undergone cancer-promoting changes among all the other genes in the cancerous cells? A typical cancer depends on a whole set of mutations and epigenetic changes that are never exactly the same in two different patients, although there are commonalities among certain tumor types. In addition, a given cancer cell will also contain a large number of somatic mutations that are accidental by-products—so-called *passengers* rather than *drivers*—of its genetic instability, and it can be difficult to distinguish these incidental changes

from those changes that have a causative role in the disease. Despite these difficulties, many of the genes that are repeatedly altered in human cancers have been identified over the past 40 years. We will call such genes, for want of a better term, *cancer-critical genes*, meaning all genes whose alteration can contribute to the causation or evolution of cancer.

In this section, we shall first discuss how cancer-critical genes are identified. We shall then examine their functions and the parts they play in conferring on cancer cells the properties outlined in the first part of the chapter. We shall end the section by discussing colon cancer as an extended example, showing how a succession of changes in cancer-critical genes enables a tumor to evolve from one pattern of bad behavior to another that is worse.

The Identification of Gain-of-Function and Loss-of-Function Cancer Mutations Has Traditionally Required Different Methods

Cancer-critical genes are grouped into two broad classes, according to whether the cancer risk arises from too much activity of the gene product or too little. Genes of the first class, in which a gain-of-function mutation can drive a cell toward cancer, are called **proto-oncogenes**; their mutant, overactive or overexpressed forms are called **oncogenes**. Genes of the second class, in which a loss-of-function mutation can contribute to cancer, are called **tumor suppressor genes**. In either case, the mutation may lead toward cancer directly (by causing cells to proliferate when they should not) or indirectly; for example, by causing genetic or epigenetic instability and so hastening the occurrence of other inherited changes that directly stimulate tumor growth. Those genes whose alteration results in genomic instability represent a subclass of cancer-critical genes that are sometimes called *genome maintenance genes*.

As we shall see, mutations in oncogenes and tumor suppressor genes can have similar effects in promoting the development of cancer; overproduction of a signal for cell proliferation, for example, can result from either kind of mutation. Thus, from the point of view of a cancer cell, oncogenes and tumor suppressor genes—and the mutations that affect them—are flip sides of the same coin. The techniques that led to the discovery of these two categories of genes, however, are quite different.

The mutation of a single copy of a proto-oncogene that converts it to an oncogene has a dominant, growth-promoting effect on a cell (Figure 20–21A). Thus,

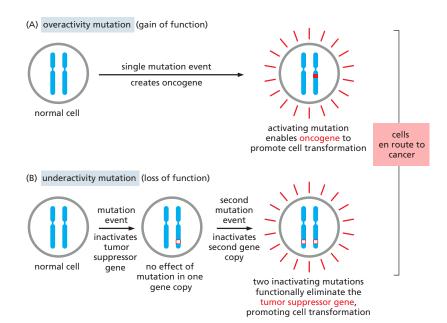

Figure 20-21 Cancer-critical mutations fall into two readily distinguishable categories, dominant and recessive. In this diagram, activating mutations are represented by solid red boxes, inactivating mutations by hollow red boxes. (A) Oncogenes act in a dominant manner: a gain-of-function mutation in a single copy of the cancer-critical gene can drive a cell toward cancer. (B) Mutations in tumor suppressor genes, on the other hand, generally act in a recessive manner: the function of both alleles of the cancercritical gene must be lost to drive a cell toward cancer. Although in this diagram the second allele of the tumor suppressor gene is inactivated by mutation, it is often inactivated instead by loss of the second chromosome. Not shown is the fact that mutation of some tumor suppressor genes can have an effect even when only one of the two gene copies is damaged.

MBOC7_ptr_ch20_1163-1216.indd 1179 02/12/21 12:24 PM

we can identify the oncogene by its effect when it is <code>added</code>—by DNA transfection, for example, or through transduction with a viral vector—to the genome of a suitable type of tester cell or experimental animal. In the case of the tumor suppressor gene, on the other hand, the cancer-causing alleles produced by the change are generally recessive: often (but not always) both copies of the normal gene must be removed or inactivated in the diploid somatic cell before an effect is seen (<code>Figure 20-21B</code>). This calls for a different experimental approach, one focusing on discovering what is <code>missing</code> in the cancer cell.

We begin by discussing a few examples of each class of cancer-critical genes to illustrate basic principles. These examples are chosen also for their historical importance: the experiments that led to their discovery—at different times and by different methods—marked turning points in the understanding of cancer.

Retroviruses Led to the Identification of Oncogenes

The search for the genetic causes of human cancer took a circuitous route, beginning with clues that came from the study of **tumor viruses**. Although viruses are involved only in a minority of human cancers, a set of viruses that infect animals provided critical early tools for studying cancer.

One of the first animal viruses to be implicated in cancer was discovered in chickens more than 100 years ago, when an infectious agent that causes connective-tissue tumors, or sarcomas, was identified as a virus—the *Rous sarcoma virus*. Like all the other *RNA tumor viruses* discovered since, it is a **retrovirus**. When it infects a cell, its RNA genome is copied into DNA by reverse transcription, and the DNA is inserted into the host genome, where it can persist and be inherited by subsequent generations of cells. Something in the DNA inserted by the Rous sarcoma virus made the host cells cancerous, but what was it? The answer was a surprise. It turned out to be a piece of DNA that was unnecessary for the virus's own survival or reproduction; instead, it was a passenger, a gene called *v-Src*, that the virus had picked up on its travels. *v-Src* was unmistakably similar, but not identical, to a gene—*c-Src*—that is found in all vertebrate genomes and encodes a protein tyrosine kinase. *c-Src* had evidently been taken up accidentally by the retrovirus from the genome of a previously infected host cell, and it had undergone mutation in the process to become an oncogene (*v-Src*).

This Nobel Prize-winning finding was followed by a flood of discoveries of other viral oncogenes carried by retroviruses that cause cancer in nonhuman animals. Each such oncogene turned out to have a counterpart proto-oncogene in the normal vertebrate genome. As was the case for *Src*, these other oncogenes generally differed from their normal counterparts, either in structure or in level of expression.

But how did this relate to typical human cancers, in which retroviruses were not known to play a role? In an assay to identify human oncogenes, DNA was extracted from human tumor cells, broken into fragments, and introduced into cultured mouse cells. Occasional colonies of abnormally proliferating cells began to appear in the culture dish that showed a transformed phenotype, outgrowing the untransformed cells in the culture and piling up in layer upon layer (see Figure 20-15). Each colony was a clone originating from a single cell that had incorporated a DNA fragment that drove cancerous behavior. Once isolated and sequenced, the DNA fragments were found to contain a human version of a gene already known from study of a retrovirus that caused tumors in rats—an oncogene called *v-Ras*. The newly discovered oncogene was clearly derived by mutation from a normal human gene, one of a small family of proto-oncogenes called Ras. This discovery in the early 1980s of the same oncogene in human tumor cells and in an animal tumor virus was electrifying. The implication that cancers are caused by mutations in a limited number of cancer-critical genes transformed our understanding of the molecular biology of cancer.

As discussed in Chapter 15, normal Ras proteins are monomeric GTPases that help transmit signals from cell-surface receptors to the cell interior (see Movie 15.7). The *Ras* oncogenes isolated from human tumors contain point

02/12/21 12:24 PM

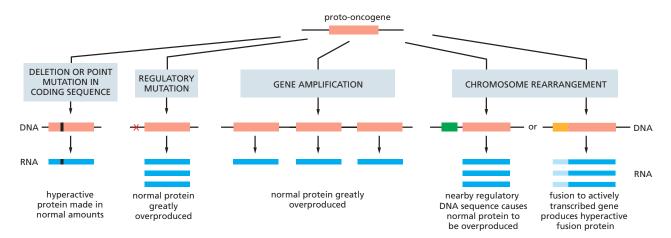

Figure 20-22 The types of accidents that can convert a proto-oncogene into an oncogene.

mutations that create a hyperactive Ras protein that cannot shut itself off by hydrolyzing its bound GTP to GDP. Because this makes the protein hyperactive, its effect is dominant; that is, only one of the cell's two gene copies needs to change to have an effect. One or another of the three human *Ras* family members is mutated in about 30% of all human cancers. *Ras* genes are thus among the most important of all cancer-critical genes.

Genes Mutated in Cancer Can Be Made Overactive in Many Ways

Figure 20–22 summarizes the types of accidents that can convert a protooncogene into an oncogene. (1) A small change in DNA sequence such as a point
mutation or deletion may produce a hyperactive protein when it occurs within a
protein-coding sequence or lead to protein overproduction when it occurs within a
regulatory region for that gene. (2) Gene amplification events, such as those that
can be caused by errors in DNA replication, may produce extra gene copies; this
can lead to overproduction of the protein. (3) A chromosomal rearrangement—
involving the breakage and rejoining of the DNA helix—may either change the
protein-coding region, resulting in a hyperactive fusion protein, or alter the control regions for a gene so that a normal protein is overproduced.

As one example, the receptor for the extracellular signal protein *epidermal growth factor* (*EGF*) can be activated by a deletion that removes part of its extracellular domain, causing it to be active even in the absence of EGF (**Figure 20–23**). The mutant EGF receptor thus produces an inappropriate stimulatory signal, like a faulty doorbell that rings even when nobody is pressing the button. Mutations

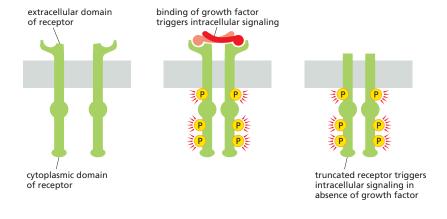

Figure 20–23 Mutation of the epidermal growth factor (EGF) receptor can make it active even in the absence of EGF, and consequently oncogenic. Normally, binding of EGF to the receptor's extracellular domain leads to phosphorylation of the intracellular domain, which activates signaling. Truncation of the extracellular domain leads to hyperphosphorylation and inappropriate activation. Other types of activating mutations are observed in different cancers.

MBOC7_ptr_ch20_1163-1216.indd 1181 02/12/21 12:24 PM

of this type are frequently found in the most common type of human brain tumor, called glioblastoma.

As another example, the *Myc protein*, which acts in the nucleus to stimulate cell growth and division (see Chapter 17), generally contributes to cancer by being overproduced in its normal form. In some cases, the gene is amplified; that is, errors of DNA replication lead to the creation of large numbers of gene copies in a single cell. Or a point mutation can stabilize the protein, which normally turns over very rapidly. More commonly, the overproduction appears to be due to a change in a regulatory element that acts on the gene. For example, a chromosomal translocation can inappropriately bring powerful gene regulatory sequences next to the *Myc* protein-coding sequence, so as to produce unusually large amounts of *Myc* mRNA. Thus, in Burkitt's lymphoma, a translocation brings the *Myc* gene under the control of sequences that normally drive the expression of antibody genes in B lymphocytes. As a result, the mutant B cells tend to proliferate excessively and form a tumor. Different specific chromosome translocations are common in other cancers.

Studies of Rare Hereditary Cancer Syndromes First Identified Tumor Suppressor Genes

Identifying a gene that has been inactivated in the genome of a cancer cell requires a different strategy from finding a gene that has become hyperactive: one cannot, for example, use a cell transformation assay to identify something that simply is not there. The key insight that led to the discovery of the first tumor suppressor gene came from studies of a rare type of human cancer, **retinoblastoma**, which arises from cells in the retina of the eye that are converted to a cancerous state by an unusually small number of mutations. As often happens in biology, the discovery arose from examination of a special case, but it turned out to reveal a gene of widespread importance.

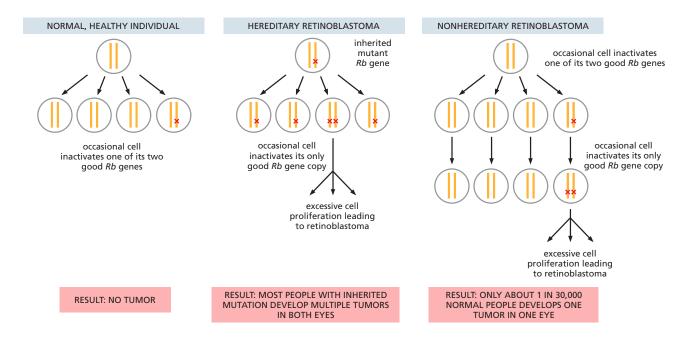

Retinoblastoma occurs in childhood, and tumors develop from neural precursor cells in the immature retina. About one child in 20,000 is afflicted. One form of the disease is hereditary, and the other is not. In the hereditary form, multiple tumors usually arise independently, affecting both eyes; in the nonhereditary form, only one eye is affected, and by only one tumor. A few individuals with retinoblastoma have a visibly abnormal karyotype, with a deletion of a specific band on chromosome 13 that, if inherited, predisposes an individual to the disease. Deletions of this same region are also encountered in tumor cells from some patients with the nonhereditary disease, which suggested that the cancer was caused by loss of a critical gene in that location.

By mapping the location of this chromosomal deletion, it was possible to identify the Rb gene. It was then discovered that those who suffer from the hereditary form of the disease have a deletion or loss-of-function mutation present in one copy of the Rb gene in every somatic cell. These cells are predisposed to becoming cancerous but do not do so if they retain one good copy of the gene. The retinal cells that are cancerous are defective in both copies of Rb because of a somatic event that has eliminated the function of the previously good copy.

In individuals with the nonhereditary form of the disease, by contrast, the noncancerous cells show no defect in either copy of *Rb*, while the cancerous cells have become defective in both copies. These nonhereditary retinoblastomas are very rare because they require two independent events that inactivate the same gene on two chromosomes in a single retinal cell lineage (Figure 20–24).

The *Rb* gene is also missing in several common types of sporadic cancer, including carcinomas of lung, breast, and bladder. These more common cancers arise by a more complex series of genetic changes than does retinoblastoma, and they make their appearance much later in life. But in all of them, it seems, loss of *Rb* function is frequently a major step in the progression toward malignancy.

The *Rb* gene encodes the **Rb** protein, which is a universal regulator of the cell cycle in almost all cells of the body (see Figure 17–59). It acts as one of the main brakes on progress through the cell-division cycle, and its loss can allow cells to enter the cell cycle inappropriately, as we discuss later.

Both Genetic and Epigenetic Mechanisms Can Inactivate Tumor Suppressor Genes

For tumor suppressor genes, it is their inactivation that is dangerous. This inactivation can occur in many ways, with different combinations of mishaps serving to eliminate or cripple both gene copies. The first copy may, for example, be lost by a small chromosomal deletion or inactivated by a point mutation due to a random error in DNA replication. The second copy is more commonly eliminated by a less specific mechanism that is likely to occur in cells progressing toward cancer that have become genetically unstable. For example, the chromosome carrying the remaining normal copy may be lost from the cell or damaged due to errors in chromosome segregation (see Figure 20–11) or the normal gene, along with neighboring genetic material, may be replaced by a mutant version through either a *mitotic recombination* event or a *gene conversion* that accompanies it (see pp. 305–306). Epigenetic changes provide another important way to permanently inactivate a tumor suppressor gene. Most commonly, the C nucleotides in CG sequences in its promoter may become methylated in a heritable manner, which can irreversibly silence the gene in a cell and in all of its progeny (see pp. 435–436). Figure 20–25

Figure 20–24 The genetic mechanisms that cause retinoblastoma. In the hereditary form, all cells in the body lack one of the normal two functional copies of the *Rb* tumor suppressor gene, and tumors arise from a clone of cells where the remaining copy is lost or inactivated by a somatic event (either mutation or epigenetic silencing). In the nonhereditary form, all cells initially contain two functional copies of the gene, and the tumor arises because both copies are lost or inactivated through the coincidence of two somatic events in a single line of cells.

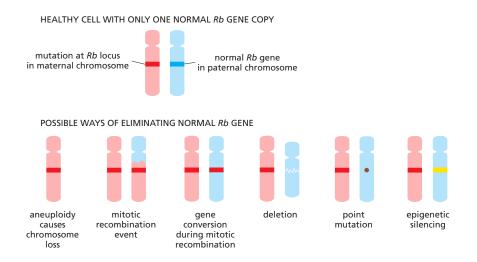

Figure 20–25 Six ways of inactivating the remaining good copy of a tumor suppressor gene through changes in DNA sequence or an epigenetic mechanism. A cell that is defective in only one of its two copies of a tumor suppressor gene—for example, the *Rb* gene—usually behaves as a normal, healthy cell; the diagrams show how this cell may lose the function of the other gene copy as well and thereby progress toward cancer.

MBOC7_ptr_ch20_1163-1216.indd 1183 02/12/21 12:24 PM

summarizes the range of ways in which the remaining good copy of a tumor suppressor gene can be lost through a DNA sequence or epigenetic change, using the $\it Rb$ gene as an example.

Systematic Sequencing of Cancer Cell Genomes Has Transformed Our Understanding of the Disease

Methods such as those we have described above shone a spotlight on a set of cancer-critical genes that were identified in a piecemeal fashion. Meanwhile, the rest of the cancer cell genome remained in darkness: it was a mystery how many other mutations might lurk there, of what types, in which varieties of cancer, at what frequencies, with what variations from individual to individual, and with what consequences. With the sequencing of the human genome and the dramatic advances in DNA sequencing technology (see Figure 8–44), it has become possible to see the whole picture—to view cancer cell genomes in their entirety. This transforms our understanding of the disease.

Cancer cell genomes can be scanned systematically in several different ways. At one extreme—the most costly, but no longer prohibitively so—one can determine a tumor's complete genome sequence. More cheaply, one can focus just on the 21,000 or so genes in the human genome that code for protein (the so-called *exome*), looking for mutations in the cancer cell DNA that alter the amino acid sequence of the product or prevent its synthesis (Figure 20-26). In addition, DNA sequencing enables a survey of the genome for regions that have undergone deletion or duplication to reveal copy number variations and the loss or gain of chromosomes (aneuploidy). The genome can also be scanned for epigenetic changes to reveal changes in methylation patterns of DNA or other changes that accompany transcriptional silencing or activation without affecting DNA sequence. Systematic sequencing of RNAs can reveal alterations in levels of gene expression by analysis of mRNAs (see Figure 7-5), as well as levels of regulatory noncoding RNAs. Finally, to measure the expression of known cancercritical genes directly by detecting their protein products, tumor cell lysates can be surveyed quantitatively using mass spectrometry. These approaches involve comparing cancer cells with normal controls-ideally, noncancerous cells originating in the same tissue and from the same individual.

A combination of the high-throughput methods described above has been applied to more than 10,000 tumors spanning 33 cancer types through a consortium called The Cancer Genome Atlas, which is coordinated by the National Institutes of Health. Other international and freely available resources, including COSMIC, the Catalog of Somatic Mutations in Cancer, are continually compiling new cancer data. As we discuss below, these large-scale projects have shed important new light on what types of alterations are present in a cancer genome, what kinds of genes or pathways are altered across and within cancer types, how

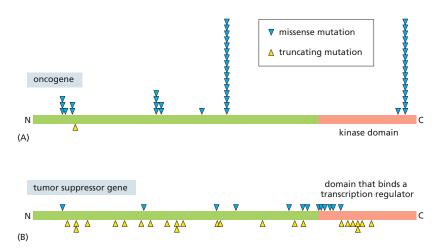

Figure 20-26 The distinct types of DNA sequence changes found in oncogenes compared to those in tumor suppressor genes. In this diagram, mutations that change an amino acid are denoted by blue arrowheads, whereas mutations that truncate the polypeptide chain are marked by yellow arrowheads. (A) As in this example (the PIK3CA gene, which produces a phosphoinositide 3-kinase subunit), oncogene mutations can be detected by the fact that the same nucleotide change is repeatedly found among the missense mutations in a gene. (B) As in this example (the Rb gene), for tumor suppressor genes missense mutations that abort protein synthesis by creating stop codons predominate. Note that only a few of the possible mutations in a protein-coding sequence are likely to be activating, while inactivation can be a consequence of missense, nonsense, and frameshift mutations. (Adapted from B. Vogelstein et al., Science 339:1546-1558, 2013.)

heterogeneous the cancer cells within a tumor are, and how the patterns of alterations evolve over time during disease progression and treatment.

Many Cancers Have an Extraordinarily Disrupted Genome

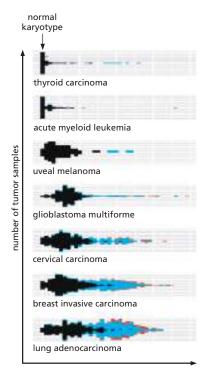

Cancer genome analysis reveals, first of all, the scale of gross genetic disruption in cancer cells. This varies greatly among cancer types and from one cancer patient to another, both in severity and in character. As discussed previously (see p. 1169) the chromosomal karyotype may appear normal, yet is riddled with numerous point mutations in individual genes due to a failure of the repair mechanisms that normally correct errors in the replication or maintenance of DNA sequences. Frequently, however, the karyotype is extremely disrupted, with many chromosomal breaks and rearrangements and chromosome sequences that are completely scrambled, indicating that extensive fragmentation of the DNA occurred followed by random re-assembly (as in chromothripsis; see Figure 20–11). From the pattern of changes, one can infer that disruptive events have occurred repeatedly during the evolution of the tumor, with a progressive increase in genetic disorder.

A common feature of many human cancers is an euploidy—a change in chromosome karyotype from the normal number (46). A study of chromosome-level gain or loss across a panel of more than 10,000 cancer genomes revealed that most cancer types harbor a characteristic pattern of chromosomal abnormalities, with different arms or whole chromosomes altered at different frequencies. In many cases, the entire set of chromosomes was doubled or quadrupled because of complete failures in cell division, generating polyploid cells that subsequently experience additional chromosome gain and loss. Almost 90% of all the cancers surveyed showed some level of an euploidy. Figure 20-27 depicts a subset of the data showing selected tumor types, each of which displays a unique pattern of aneuploidy. Thus, for example, whereas 74% of thyroid carcinomas displayed a normal karyotype, less than 5% of glioblastoma and cervical carcinoma tumors possessed the normal chromosome number. Although the degree of aneuploidy is often characteristic of a cancer class, heterogeneity is also apparent. For example, one subset of glioblastomas is characterized by gain of chromosome 7 and loss of chromosome 10, but this combination of defects is not present in all cases, indicating that there are multiple pathways of genome disorder that can lead to different cancer subtypes.

Cancer genome studies also illuminate the underlying defects that bring about genome disruption. In ovarian cancers, for example, chromosome breaks, translocations, and deletions are very common, and these aberrations correlate with a high frequency of mutations and epigenetic silencing in the genes needed for repair of DNA double-strand breaks by homologous recombination, especially *Brca1* and *Brca2* (see pp. 300–301). In a subset of endometrial cancers, on the other hand, one instead finds many point mutations scattered throughout the genome, which could for example be caused by mutation of enzymes required for proofreading during DNA replication (see pp. 267–269). Thus, different cancers and cancer subtypes possess highly variable mutation rates, ranging from one base substitution per exome in some pediatric cancers to thousands of mutations per exome in mutagen-induced malignancies such as lung cancer and melanoma.

Epigenetic and Chromatin Changes Contribute to Most Cancers

So far we have focused primarily on the mutations in cancer-critical genes that contribute directly to the hallmarks of cancer. Equally important to the genesis of cancer, however, are changes that modify gene expression epigenetically, without altering the DNA sequence. As discussed previously, increased methylation of DNA in the promoter region of a gene such as Rb can permanently silence it. In addition, reversible covalent modifications such as methylation and acetylation also occur on the histone proteins that package DNA into chromatin. These

number of chromosome arms

Figure 20-27 The prevalence of aneuploidy among different tumor types. For each tumor type, the total number of chromosome arms detected is plotted on the X axis. The number of chromosome arms in a normal karvotype is indicated. Genome doubling status is also shown (black, not double; blue, one genome doubling; red, two or more genome doublings). The number of tumor samples possessing the respective arm numbers is represented by the length of the bar on the Y axis for each tumor type. Note that samples from some tumor types predominantly possess a normal karyotype, while samples from other tumor types display extreme heterogeneity with a dramatic increase in chromosome arm numbers because of extensive aneuploidy. (Adapted from A.M. Taylor et al., Cancer Cell 33:676-689, 2018.)

MBOC7_ptr_ch20_1163-1216.indd 1185 02/12/21 12:24 PM

histone marks modulate gene expression by altering the conformation and accessibility of chromatin to regulatory factors such as transcription factors and chromatin remodeling complexes (see Chapter 7). An important finding of large-scale genome sequencing projects is that roughly 50% of human cancers harbor mutations in chromatin proteins, which includes mutations in enzymes that add, remove, or recognize covalent marks on histones and DNA. Many of the resulting defects have the potential to cause heritable, epigenetic changes that modulate gene expression and contribute to tumorigenesis.

Frequently, genetic and epigenetic changes cooperate to cause cancer (Figure 20–28). In some cases, epigenetic changes precede characteristic oncogenic mutations and can even lead to them, such as when epigenetic silencing of genes required for the repair of DNA damage acts to increase mutation rates. In other cases, an accidental change in DNA sequence can disrupt chromatin and epigenetic regulation. One example is a gain-of-function mutation in the gene encoding isocitrate dehydrogenase (IDH), which is known to be a frequent initiating event in several cancers including glioma, leukemia, and other tumors. The mutant IDH produces elevated levels of a metabolite, 2-hydroxyglutarate, which acts to inhibit enzymes that demethylate DNA. Therefore, DNA in IDH-mutant cells becomes hypermethylated at random sites in the genome. Just as for DNA mutations, those epigenetic changes that provide a selective advantage in growth or survival will allow the affected cell and its descendants to persist and accumulate further changes, thereby contributing to cancer progression.

The indirect effect of mutant IDH on DNA hypermethylation illustrates another important point: metabolic conditions affect the status of chromatin, which in turn can influence gene expression. Notably, only a minority of cancers with aberrant DNA methylation can be explained by an underlying genetic event. These observations suggest that environmental conditions, which may not themselves be mutagenic, can provide a source of epigenetic changes. Many DNA- and histone-modifying enzymes require metabolites as cofactors, providing a potential link between known risk factors for human cancer, such as diet and inflammation, and cancer development.

In addition to modulating the expression of individual genes, epigenetic changes can also have more global effects on the chromatin state, thereby influencing gene networks that underlie programs of cellular behavior. For example, different patterns of gene expression determined by epigenetic marks could restrict the ability of a cell to activate apoptosis or prevent it from exiting the cell cycle and undergoing differentiation. Evidence for such changes in cancer comes from characterization of rare pediatric brain tumors that lack somatic mutations and instead display aberrant DNA methylation profiles.

It is crucial to remember that altered patterns of gene activation and silencing due to epigenetic regulation are a normal feature of cellular differentiation, enabling the same genome to produce and maintain a multitude of different cell types through precise developmental programs (see Chapter 21). Thus, as for other properties of cancer cells, epigenetic changes do not represent new biology, but rather the subversion of existing cellular mechanisms.

Hundreds of Human Genes Contribute to Cancer

Among the billions of somatic mutations now identified in cancer cells, how can we discover which of them are **drivers** of cancer; that is, causal factors in the development of the disease? Clearly, most will be merely **passengers**—mutations that happen to have occurred in the same cell as the driver mutations, thanks to genetic instability, but are irrelevant to the development of the cancer. One criterion is frequency of occurrence. Driver mutations affecting a gene that play a part in the disease will be seen repeatedly, in many different individuals with a particular type of cancer. In contrast, a passenger mutation that confers no selective advantage on the cancer cell is likely to be encountered only rarely.

By compiling the genome sequence data for different types of cancer, each with its own set of identified driver mutations, we can develop a comprehensive

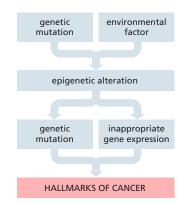

Figure 20–28 Epigenetic and genetic mechanisms can cooperate to promote the evolution of cancer. Both genetic mutations and environmental factors (such as metabolic state) can lead to epigenetic changes. As indicated, these epigenetic changes can in turn increase the rate at which genetic as well as further epigenetic changes accumulate—thereby speeding the process of cancer progression by altering gene expression in ways that promote cancer cell proliferation and are inherited in clones of cells.

catalog of those genes that are strongly suspected to be cancer-critical for at least one type of tumor. Current estimates put the total number of such genes at around 300, about 1% of the genes in the human genome. These cancer-critical genes are amazingly diverse, revealing an unexpected breadth of mechanisms. Whereas some of the new cancer genes encode classical signaling and cell-cycle proteins that might be anticipated to become mutated in cancer cells, others populate new and sometimes surprising categories. These include functions as diverse as metabolism, chromatin biology, RNA splicing, protein homeostasis, and cell differentiation. It is clear that alterations in any of these processes can contribute, in one tissue or another, to the evolution of cells with the cancerous properties that were listed on page 1172.

Clearly, the molecular changes that cause cancer are complex. As we now explain, however, the complexity is not quite as daunting as it might initially seem.

Disruptions in a Handful of Key Pathways Are Common to Many Cancers

Some genes, like *Rb* and *Ras*, are mutated in many cases of cancer and in cancers of many different types. The involvement of genes such as *Rb* and *Ras* in cancer is no surprise, now that we understand their normal functions: they control fundamental processes of cell division and growth. But even these common culprits feature in considerably less than half of individual cases. What is happening to the control of these processes in the many cases of cancer where, for example, *Rb* is intact or *Ras* is not mutated? What part do mutations in the hundreds of other cancer-critical genes play in the development of the disease? With our increasing knowledge of the normal functions of the genes in the human genome, it is becoming easier to detect patterns in the cataloged driver mutations and to give some simplifying answers to these questions.

In order to clarify the type of patterns revealed, consider the deadly disease *glioblastoma*—the most common type of human brain cancer. Analysis of the genomes of tumor cells from 91 individuals identified a total of at least 79 genes that were mutated in more than one individual. The normal functions of most of these genes were known or could be guessed, allowing them to be assigned to specific biochemical or regulatory pathways. Three functional groupings stood out, accounting for 21 of the recurrently mutated genes. One group consists of genes in the *Rb pathway* (that is, *Rb* itself, along with genes that directly regulate *Rb*); this pathway governs initiation of the cell-division cycle. Another consists of genes in the same regulatory subnetwork as *Ras*—referred to as the *RTK/Ras/PI 3-kinase pathway*, after three of its core components; this pathway serves to transmit signals for cell growth and cell division from outside the cell to the cell interior. A third grouping consists of genes in a pathway regulating responses to stress and DNA damage—the *p53 pathway*. We shall have more to say about these pathways below.

For the 91 glioblastomas, 74% had identifiable mutations in all three pathways. If one were to trace these three pathways further upstream and include all the components, known and unknown, on which they depend, this percentage would almost certainly be even higher. In other words, in almost every case of glioblastoma, there are mutations that disrupt each of three fundamental controls: the control of cell growth, the control of cell division, and the control of responses to stress and DNA damage.

Strikingly, in any given tumor-cell clone, there is a strong tendency for no more than one gene to be mutated in each pathway. Evidently, what matters for tumor evolution is the disruption of the control mechanism, and not the genetic means by which that is achieved. Thus, for example, in an individual whose tumor cells have no mutation in *Rb* itself, there is generally a mutation in some other component of the Rb pathway, producing a similar biological effect. This indicates that there is no further selection for a mutant in a pathway if the pathway has been disabled by a mutation elsewhere.

Similar patterns are seen in other types of cancers. A survey of many specimens of the major variety of ovarian cancer, for example, identified 67% of individuals

MBOC7_ptr_ch20_1163-1216.indd 1187 02/12/21 12:24 PM

Figure 20–29 The three major cellular pathways that contribute to tumorigenesis. The specific examples listed here are described in this chapter. Cell-cycle events controlled by Rb are described in detail in Chapter 17.

as having mutations in the Rb pathway, 45% in the Ras/PI 3-kinase pathway (defined more narrowly than in the glioblastoma study), and more than 96% in the p53 pathway. Allowing for additional pathway components not included in the analysis, it seems that most cases of this type of cancer, too, have mutations disrupting the same three controls, leading to misregulated cell growth, misregulated cell proliferation, and an abnormal disregard of stress and DNA damage.

It seems that these three fundamental controls are subverted in one way or another in virtually every type of cancer. However, because specialized tissues can depend on different mechanisms to relay environmental signals to the core control machinery, these controls are open to subversion in a different set of ways in different types of cancers. In fact, one can find examples of driver mutations in practically all the major signaling pathways through which cells communicate during development and tissue maintenance (discussed in Chapters 15, 21, and 22).

Figure 20–29 outlines the three central pathways just described, abbreviating them as cell cycle, cell proliferation, and cell survival. We have previously discussed Rb (see pp. 1182–1183) and devoted an entire chapter to cell-cycle controls (Chapter 17). Some important details of the other two control pathways in Figure 20–29 are reviewed next.

Mutations in the PI 3-kinase/Akt/mTOR Pathway Drive Cancer Cells to Grow

Cell proliferation is not simply a matter of progression through the cell cycle; it also requires coordinated cell growth, which involves complex anabolic processes through which the cell synthesizes all the necessary macromolecules from small-molecule precursors (Figure 20–30). Cancer depends, therefore, not only on a loss of restraints on cell-cycle progression but also on a disrupted control of cell growth.

Downstream of RTK/Ras activation, the PI 3-kinase/Akt/mTOR intracellular signaling pathway is critical for cell growth control. As described in Chapter 15, various extracellular signal proteins, including insulin and insulin-like growth factors, normally activate this pathway. In cancer cells, however, the pathway is activated by mutation so that the cell can grow in the absence of such signals. The resulting abnormal activation of the protein kinases Akt and mTOR not only stimulates protein synthesis but also greatly increases both glucose uptake and the production of the acetyl CoA in the cytosol required for cell lipid synthesis, as outlined in Figure 20–30B.

The abnormal activation of the PI 3-kinase/Akt/mTOR pathway, which normally occurs early in the process of tumor progression, helps to explain the excessive rate of glycolysis that is observed in tumor cells, known as the Warburg effect, as discussed earlier (see Figure 20–18). As expected from our previous discussion, cancers can activate this pathway in many different ways. Thus, for example, a growth factor receptor can become abnormally activated, as in Figure 20–23. Also very common in cancers is the loss of the phosphatase and tensin homolog (PTEN) phosphatase that normally functions to counteract this pathway. PTEN suppresses the PI 3-kinase/Akt/mTOR pathway by dephosphorylating the phosphatidylinositol 3,4,5-trisphosphate [PI(3,4,5)P₃]

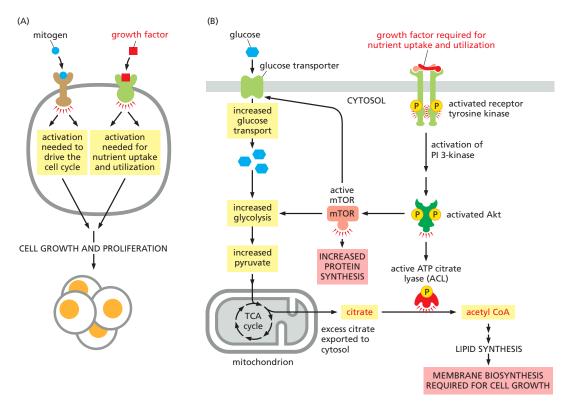

Figure 20–30 Cells seem to require two types of signals to proliferate. (A) In order to multiply successfully, most normal cells require both extracellular signals that drive cell-cycle progression (shown here as *blue* mitogen) and extracellular signals that drive cell growth (shown here as *red* growth factor). How mitogens activate signaling through the Rb pathway to drive entry into the cell cycle is described in Figure 17–59. (B) Diagram of the signaling system involving activation of Akt and mTOR that drives cell growth through greatly stimulating glucose uptake and utilization, including a conversion of the excess citric acid produced from sugar intermediates in mitochondria into the acetyl CoA that is needed in the cytosol for lipid synthesis and new membrane production. As indicated, protein synthesis is also increased. This system becomes abnormally activated early in tumor progression. TCA cycle indicates the tricarboxylic acid cycle (citric acid cycle).

molecules that the PI 3-kinase generates (see p. 920). *PTEN* is commonly mutated in tumors.

Mutations in the p53 Pathway Enable Cancer Cells to Survive and Proliferate Despite Stress and DNA Damage

That cancer cells must break the normal rules governing cell growth and cell division is obvious: that is part of the definition of cancer. It is not so obvious why cancer cells should also be abnormal in their response to stress and DNA damage, and yet this too is an almost universal feature. The gene that lies at the center of this response, the p53 gene, is mutated in about 50% of all cases of cancer—a higher proportion than for any other known cancer-critical gene. When we include with p53 the other genes that are closely involved in its function, we find that most cases of cancer harbor mutations in the p53 pathway. Why should this be? To answer, we must first consider the normal function of this pathway.

In contrast to Rb, most cells in the body contain very little **p53** protein under normal conditions: although the protein is synthesized, it is rapidly degraded. Mice in which both copies of the gene have been deleted or inactivated typically appear normal in all respects except one—they universally develop cancer before 10 months of age. These observations suggest that p53 has a function that is required only in special circumstances. In fact, cells raise their concentration of p53 protein in response to a whole range of conditions that have only one obvious thing in common: they are, from the cell's point of view, pathological, putting the cell in danger of death or serious injury. These conditions include DNA damage,

MBOC7_ptr_ch20_1163-1216.indd 1189 02/12/21 12:24 PM

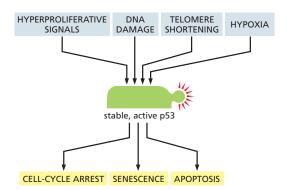

Figure 20–31 Modes of action of the p53 tumor suppressor. The p53 protein is a cellular stress sensor. In response to hyperproliferative signals, DNA damage, hypoxia, telomere shortening, and various other stresses, the p53 levels in the cell rise. As indicated, this may either arrest cell cycling in a way that allows the cell to adjust and survive, trigger cell suicide by apoptosis, or cause cell senescence—an irreversible cell-cycle arrest that stops damaged cells from dividing.

which puts the cell at risk from a faulty genome; telomere loss or shortening, also dangerous to the integrity of the genome; hypoxia, which deprives the cell of the oxygen it needs to maintain mitochondrial respiration; osmotic stress, which causes the cell to swell or shrivel; and oxidative stress, which generates dangerous levels of highly reactive free radicals.

Yet another form of stress that can activate the p53 pathway arises, it seems, when regulatory signals are so intense or uncoordinated as to drive the cell beyond its normal limits and into a danger zone where its mechanisms of control and coordination break down, as in an engine driven too fast. The p53 concentration rises, for example, when *Myc* is overexpressed to oncogenic levels.

All these circumstances call for desperate action, which may take either of two forms: the cell can block any further progress through the division cycle in order to take time out to repair or recover from the pathological condition or it can accept that it must die, and do so in a way that minimizes damage to the organism. A good death, from this point of view, is a death by apoptosis. In apoptosis, the cell is phagocytosed by its neighbors and its contents are efficiently recycled. A bad death is a death by necrosis. In necrosis, the cell bursts or disintegrates and its contents are spilled into the extracellular space, inducing inflammation.

The p53 pathway, therefore, behaves as a sort of antenna, sensing the presence of a wide range of dangerous conditions and, when any are detected, triggering appropriate action—either a temporary or permanent arrest of cell cycling or suicide by apoptosis (Figure 20–31). These responses serve to prevent deranged cells from proliferating. Cancer cells are indeed generally deranged, and their survival and proliferation thus depend on inactivation of the p53 pathway. If the p53 pathway were active in them, they would be halted in their tracks or die (Movie 20.6). For example, if the p53 pathway is functional, a cell with unrepaired DNA damage will stop dividing or die; it cannot proliferate.

The p53 protein performs its job mainly by acting as a transcription regulator (see Movie 17.8). Indeed, the most common mutations observed in p53 in human tumors are in its DNA-binding domain, where they cripple the ability of p53 to bind to its DNA target sequences. As discussed in Chapter 17, the p53 protein exerts its inhibitory effects on the cell cycle, in part at least, by inducing the transcription of p21, which encodes a protein that binds to and inhibits the cyclin-dependent kinase (Cdk) complexes required for progression through the cell cycle. By blocking the kinase activity of these Cdk complexes, the p21 protein prevents the cell from progressing through S phase and replicating its DNA.

The mechanism by which p53 induces apoptosis includes stimulation of the expression of many pro-apoptotic genes, as described in Chapter 18.

Studies Using Mice Help to Define the Functions of Cancer-critical Genes

The ultimate test of a gene's role in cancer has to come from investigations in the intact, mature organism. The most favored organism for experimental studies is the mouse. To explore the function of a candidate oncogene or tumor suppressor

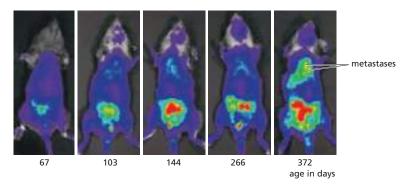

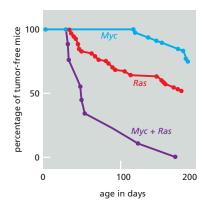

Figure 20–32 Monitoring tumor growth and metastasis in a mouse with a luminescent reporter. A mouse was genetically engineered in a way that allows both copies of its *PTEN* tumor suppressor gene to be inactivated in the prostate gland, simultaneously with the prostate-specific activation of a gene engineered to produce the enzyme luciferase (derived from fireflies). After an injection of luciferin (the substrate molecule for luciferase) into the mouse's bloodstream, the cells in the prostate emit light and can be detected by their bioluminescence in a live mouse, as seen in the 67-day-old animal at the left. Cells lacking the PTEN phosphatase enzyme contain elevated amounts of the Akt activator, Pl(3,4,5)P₃, and this causes the prostate cells to proliferate abnormally, progressing over time to form a cancer. In this way, the process of metastasis could be followed in the same animal over the course of a year. The light intensity in these experiments is proportional to the number of prostate-cell descendants, increasing from *light blue* to *green*, to *yellow*, to *red* in this representation. (Adapted from C.-P. Liao et al., *Cancer Res.* 67:7525–7533, 2007. With permission from the American Association for Cancer Research.)

gene, one can make a transgenic mouse that overexpresses it or a knockout mouse that lacks it. Using the techniques described in Chapter 8, one can engineer mice in which the misexpression or deletion of the gene is restricted to a specific set of cells, or in which expression of the gene can be switched on at will at a chosen point in time, or both, to see whether and how tumors develop. Moreover, to follow the growth of tumors from day to day in the living mouse, the cells of interest can be genetically marked and made visible by expression of a fluorescent or luminescent reporter (Figure 20–32). In these ways, one can begin to clarify the part that each cancer-critical gene plays in cancer initiation or progression.

Transgenic mouse studies confirm, for example, that a single oncogene is generally not enough to turn a normal cell into a cancer cell. Thus, in mice engineered to express a *Myc* or *Ras* oncogenic transgene, some of the tissues that express the oncogene may show enhanced cell proliferation, and, over time, occasional cells will undergo further changes to give rise to cancers. Most cells expressing the oncogene, however, do not give rise to cancers. Nevertheless, from the point of view of the whole animal, the inherited oncogene is a serious menace because it creates a high risk that a cancer will arise somewhere in the body. Mice that express both *Myc* and *Ras* oncogenes develop cancers earlier and at a much higher rate than mice that express either gene alone (Figure 20–33); but, again, the cancers originate as scattered, isolated tumors among noncancerous

Figure 20–33 Oncogene collaboration in transgenic mice. The graphs show the incidence of tumors in three types of transgenic mouse strains, one carrying a *Myc* oncogene, one carrying a *Ras* oncogene, and one carrying both oncogenes. For these experiments, two lines of transgenic mice were first generated. One carries an inserted copy of an oncogene created by fusing the proto-oncogene *Myc* with the mouse mammary tumor virus regulatory DNA (which then drives *Myc* overexpression in the mammary gland). The other line carries an inserted copy of the *Ras* oncogene under the control of the same regulatory element. Both strains of mice develop tumors much more frequently than normal, most often in the mammary or salivary glands. Mice that carry both oncogenes together are obtained by crossing the two strains. These hybrids develop tumors at a far higher rate still, much greater than the sum of the rates for the two oncogenes separately. Nevertheless, the tumors arise only after a delay and only from a small proportion of the cells in the tissues where the two genes are expressed. Further accidental changes, in addition to the two oncogenes, are apparently required for the development of cancer. (After E. Sinn et al., *Cell* 49:465–475, 1987.)

MBOC7_ptr_ch20_1163-1216.indd 1191 02/12/21 12:24 PM

cells. Thus, even cells expressing these two oncogenes must undergo further, randomly generated changes to become cancerous. This strongly suggests that multiple mutations are required for tumorigenesis, as supported by a great deal of other evidence discussed earlier. Experiments using mice with deletions of tumor suppressor genes lead to similar conclusions.

Cancers Become More and More Heterogeneous as They Progress

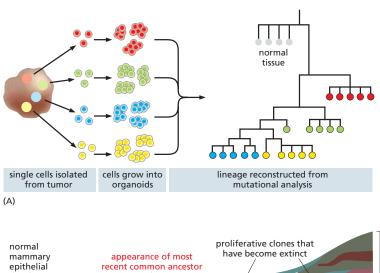

Although useful to study the function and interaction of cancer driver genes *in vivo*, there are important limitations to mouse models of human cancer. Whereas a mouse tumor is small and arises over a period of months or even days, a human tumor may be the size of a mouse or larger and will often have been growing for decades. From simple histology looking at stained tissue sections, it is clear that some tumors contain distinct sectors, all clearly cancerous, but differing in appearance because they differ genetically or epigenetically: the cancer cell population is heterogeneous. Evidently, within the initial clone of cancerous cells, additional mutations have arisen and conferred selective advantages, such as increased growth rates, creating diverse subclones. Today, the ability to analyze cancer genomes lets us look much deeper into the process. Comparison of samples from different regions of a tumor and the metastases it has spawned reveal a classic picture of Darwinian evolution, occurring on a time scale of months or years rather than millions of years, but governed by the same rules of natural selection.

One approach to examine the development of tumor heterogeneity takes advantage of human cells grown outside the body, termed "organoids" (described in Chapter 22). Unlike the immortalized cancer cell lines described previously that have adapted to an artificial, two-dimensional lifestyle (see Figure 20-15), organoids are grown from adult stem cells under more physiological conditions within a three-dimensional matrix. In this environment, a single stem cell can proliferate and differentiate into a self-organizing structure that resembles a miniature, simplified version of the organ from which it was taken, with realistic microanatomy. One study applied this organoid system to examine the genetic heterogeneity within individual colorectal tumors (Figure 20-34A). Organoids were grown from single cells isolated from different regions of a tumor as well as from neighboring, normal tissue. Genome analysis revealed detailed patterns of mutations in each organoid that indicated how closely it was related to the others, and from these data one could draw up a family tree. Those organoids derived from the same tumor site bore the most similarities, and all possessed the same set of cancer-driving mutations that arose in their common ancestor within the trunk of the tree, corresponding to the early stages of tumor growth.

Clearly, cancer cells are constantly mutating, multiplying, competing, evolving, and diversifying as they exploit new ecological niches and react to the treatments that are used against them (Figure 20–34B). Diversification accelerates as they metastasize and colonize new territories, where they encounter new selection pressures. The longer the evolutionary process continues, the harder it becomes to catch them all in the same net and kill them.

Colorectal Cancers Evolve Slowly Via a Succession of Visible Changes

At the beginning of this chapter, we saw that most cancers develop gradually from a single aberrant cell, progressing from benign to malignant tumors by the accumulation of a number of independent genetic and epigenetic changes. We have discussed what some of these changes are in molecular terms and have seen how they contribute to cancerous behavior. We now examine one of the common human cancers more closely, using it to illustrate and enlarge upon some of the general principles and molecular mechanisms we have introduced. We take **colorectal cancer** as our example.

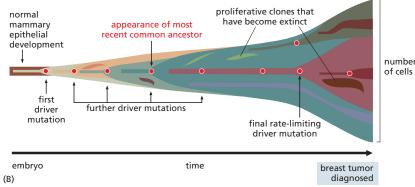

Figure 20–34 How cancers progress as a series of subclones. (A) Cancer analysis using organoids. Single cells were isolated from four different regions of a human colorectal tumor (color coded) as well as from nearby healthy tissue (not shown). These cells were then used to produce organoids, allowing large amounts of material to be obtained for analysis. DNA sequencing was used to determine the mutations in each organoid. These data then enabled construction of a phylogenetic tree that reveals the order in which the mutations emerged in the original tumor. (B) A depiction of how driver mutations are thought to cause cancer progression over long periods of time, before producing a large enough clone of proliferating cells to be detected as a tumor. The data indicate that driver mutations occur only rarely in a background of long-lived subclones of cells that continually accumulate passenger mutations without gaining a growth advantage. (A, adapted from C.J. Kuo and C. Curtis, Nature 556:441–442, 2016. With permission from Springer Nature. B, adapted from S. Nik-Zainal et al., Cell 149:994–1007, 2012. This article is distributed under the terms of the Creative Commons Attribution License.)

Colorectal cancers arise from the epithelium lining the colon (the large intestine) and rectum (the terminal segment of the gut). The organization of this tissue is broadly similar to that of the small intestine, discussed in Chapter 22 (pp. 1281–1282). For both the small and large intestine, the epithelium is renewed at an extraordinarily rapid rate, taking about a week to completely replace most of the epithelial sheet. In both regions, the renewal depends on stem cells that lie in deep pockets of the epithelium, called intestinal crypts. The signals that maintain the stem cells and control the normal organization and renewal of the epithelium are beginning to be quite well understood, as explained in Chapter 22. Mutations that disrupt these signals begin the process of tumor progression for most colorectal cancers (Movie 20.7).

Colorectal cancers are common, currently causing nearly 60,000 deaths a year in the United States, or about 10% of total deaths from cancer. Like most cancers, they are not usually diagnosed until late in life (90% occur after the age of 55). However, routine examination of normal adults with a colonoscope (a fiberoptic device for viewing the interior of the colon and rectum) often reveals a small benign tumor, or adenoma, of the gut epithelium in the form of a protruding mass of tissue called a *polyp*. These adenomatous polyps are believed to be the

^{1,2}The genes with the same superscript numeral act in the same pathway, and therefore only one of the components is mutated in an individual cancer.

precursors of a large proportion of colorectal cancers. Because the progression of the disease is usually very slow, there is typically a period of about 10 years in which the slowly growing tumor is detectable but has not yet turned malignant. Thus, when people are screened by colonoscopy in their fifties and the polyps are removed through the colonoscope—a quick and easy procedure—the subsequent incidence of colorectal cancer is much lower: according to some studies, less than a quarter of what it would be otherwise.

In microscopic sections of polyps smaller than 1 cm in diameter, the cells and their arrangement in the epithelium usually appear almost normal. The larger the polyp, the more likely it is to contain cells that look aberrant and are abnormally organized. Sometimes, two or more distinct areas can be distinguished within a single polyp, with the cells in one area appearing relatively normal and those in the other appearing clearly cancerous, as though they have arisen as a mutant subclone within the original clone of adenomatous cells. At later stages in the disease, some tumor cells become invasive in a small fraction of the polyps, first breaking through the epithelial basal lamina, then spreading through the layer of muscle that surrounds the gut, and finally metastasizing to lymph nodes via lymphatic vessels and to liver, lung, and other organs via blood vessels.

A Few Key Genetic Lesions Are Common to a Large Fraction of Colorectal Cancers

What are the mutations that accumulate with time to produce this chain of events? Of those genes so far discovered to be involved in colorectal cancer, three stand out as most frequently mutated: the proto-oncogene *K-Ras* (a member of the *Ras* gene family), in about 40% of cases; *p53*, in about 60% of cases; and the tumor suppressor gene *Apc* (discussed below), in more than 80% of cases. Others are involved in smaller numbers of colon cancers, and some of these are listed in Table 20–1.

The role of *Apc* first came to light through study of certain families showing a rare type of hereditary predisposition to colorectal cancer, called *familial adenomatous polyposis coli* (*FAP*). In this syndrome, hundreds or thousands of polyps develop along the length of the colon (**Figure 20–35**). These polyps start

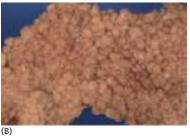

Figure 20–35 Colon of individual with familial adenomatous polyposis coli compared to normal colon. (A) The normal colon wall is a gently undulating but smooth surface. (B) The polyposis colon is completely covered by hundreds of projecting polyps, each resembling a tiny cauliflower when viewed with the naked eye. (Courtesy of Mark Arends.)

to appear in early adult life, and if they are not removed, one or more will almost always progress to become malignant; the average time from the first detection of polyps to the diagnosis of cancer is 12 years. The disease can be traced to a deletion or inactivation of the tumor suppressor gene Apc, named after the syndrome. Individuals with FAP have inactivating mutations or deletions of one copy of the Apc gene in all their cells and show loss of heterozygosity in tumors, meaning that both copies have been lost or inactivated, even in the benign polyps. Most individuals with colorectal cancer do not have the hereditary condition. Nevertheless, in more than 80% of the cases, their cancer cells (but not their normal cells) have inactivated both copies of the Apc gene through mutations acquired during the individual's lifetime. Thus, by a route similar to what we discussed for retinoblastoma, mutation of the Apc gene was identified as one of the central ingredients of colorectal cancer.

The APC protein is an inhibitory component of the *Wnt signaling pathway* (discussed in Chapter 15). It binds to the β -catenin protein, another component of the Wnt pathway, and helps to induce the protein's degradation. By inhibiting β -catenin in this way, APC prevents it from localizing to the nucleus, where it would act as a transcriptional regulator to drive cell proliferation and maintain the stem-cell state (see Figure 15–61). Loss of APC results in an excess of free β -catenin and thus leads to an uncontrolled expansion of the stem-cell population. This causes massive increase in the number and size of the intestinal crypts (see Figure 22–4).

When the β -catenin gene was sequenced in a collection of colorectal tumors, it was discovered that many of the tumors that did not have Apc mutations had activating mutations in the β -catenin protein instead. Thus, it is excessive activity in the Wnt signaling pathway that is critical for the initiation of this cancer, rather than any single oncogene or tumor suppressor gene that the pathway contains.

This being so, why is the Apc gene in particular so often the most common culprit in colorectal cancer? The APC protein is large and it interacts not only with β -catenin but also with various other cell components, including microtubules. Loss of APC appears to increase the frequency of mitotic spindle defects, leading to chromosome abnormalities when cells divide. This additional, independent cancer-promoting effect could explain why Apc mutations feature so prominently in the causation of colorectal cancer.

Some Colorectal Cancers Have Defects in DNA Mismatch Repair

In addition to the hereditary disease (FAP) associated with *Apc* mutations, there is a second, more common kind of hereditary predisposition to colon carcinoma in which the course of events differs from the one we have described for FAP. In this more common condition, called *hereditary nonpolyposis colorectal cancer* (*HNPCC*), or *Lynch syndrome*, the probability of colon cancer is increased without any increase in the number of colorectal polyps (adenomas). Moreover, the cancer cells are unusual, in that they have a normal (or almost normal) karyotype. The majority of colorectal tumors in non-HNPCC individuals, in contrast, have gross chromosomal abnormalities, with multiple translocations, deletions, and other aberrations, and have many more chromosomes than normal (see Figure 20–10).

The mutations that predispose HNPCC individuals to colorectal cancer occur in one of several genes that code for central components of the DNA *mismatch repair system*. These genes are homologous in structure and function to the *MutL* and *MutS* genes in bacteria and yeast (see Figure 5–20). Only one of the two copies of the involved gene is defective, so the repair system is still able to remove the inevitable DNA replication errors that occur in the individual's cells. However, as discussed previously, these individuals are at risk because the accidental loss or inactivation of the remaining good gene copy will immediately elevate the spontaneous mutation rate by a hundredfold or more (discussed in

MBOC7_ptr_ch20_1163-1216.indd 1195 02/12/21 12:24 PM

Chapter 5). These genetically unstable cells can then speed through the standard processes of mutation and natural selection that allow clones of cells to progress to malignancy.

This particular type of genetic instability produces invisible changes in the chromosomes—most notably changes in individual nucleotides and short expansions and contractions of mononucleotide and dinucleotide repeats such as AAAA... or CACACA.... Once the defect in HNPCC individuals was recognized, the epigenetic silencing or mutation of mismatch repair genes was found in about 15% of the colorectal cancers occurring in people with no inherited predisposing mutation.

Thus, the genetic instability found in many colorectal cancers can be acquired in at least two ways. The majority of the cancers display a form of chromosomal instability that leads to visibly altered chromosomes, whereas in the others the instability occurs on a much smaller scale and reflects a defect in DNA mismatch repair. Indeed, many carcinomas show either chromosomal instability or defective mismatch repair—but rarely both. These findings clearly demonstrate that genetic instability is not an accidental by-product of malignant behavior but a contributory cause—and that cancer cells can acquire this instability in multiple ways.

The Steps of Tumor Progression Can Often Be Correlated with Specific Mutations

In what order do *K-Ras*, *p53*, *Apc*, and the other identified colorectal cancer-critical genes mutate, and what contribution does each of them make to the asocial behavior of the cancer cell? There is no single answer because colorectal cancer can arise by more than one route: thus, we know that in some cases, the first mutation can be in a DNA mismatch repair gene; in others, it can be in a gene regulating cell proliferation. Moreover, as previously discussed, a general feature such as genetic instability or a tendency to proliferate abnormally can arise in a variety of ways, through mutations in different genes.

Nevertheless, certain sets of mutations are particularly common in colorectal cancer, and they occur in a characteristic order. Thus, in most cases, mutations inactivating the *Apc* gene appear to be the first or, at least, a very early step, as they are detected at the same high frequency in small benign polyps as in large malignant tumors. Changes that lead to genetic and epigenetic instability are likely also to arise early in tumor progression, as they are needed to drive the later steps.

Activating mutations in the *K-Ras* gene occur later, as they are rare in small polyps but common in larger ones that show disturbances in cell differentiation and histological pattern.

Inactivating mutations in p53 are thought to come later still, as they are rare in polyps but common in carcinomas (Figure 20–36). We have seen that loss of p53 function allows cancer cells to endure stress and to avoid apoptosis and cell-cycle arrest. Additionally, loss of p53 is related to the heightened activation of oncogenes such as Ras. Experiments in mice show that an initial low level of oncogene

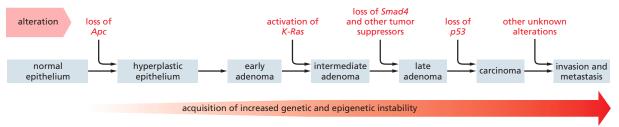

Figure 20–36 Suggested typical sequence of genetic changes underlying the development of a colorectal carcinoma. This oversimplified diagram provides a general idea of the way mutation and tumor development are related. But many other mutations are generally involved, and different colon cancers can progress through different sequences of mutations (and/or epigenetic changes).

activation can give rise to a slowly growing tumor even while p53 is functional: genes such as Ras are, after all, part of the normal machinery of growth control, and moderate activation is not stressful for a cell and does not call the p53 protein into play. Progression of a tumor from slow to rapid, malignant growth, however, involves activation of oncogenes beyond normal physiological limits to a higher, stressful level. If the p53 protein is present and functional, this should lead to cell-cycle arrest or death. Only by losing p53 function can the cancer cells with hyperactive oncogenes survive and progress.

The steps we have just described are only part of the picture. It is important to emphasize that each case of colorectal cancer is different, with its own detailed combination of mutations, and that even for the mutations that are commonly shared, the sequence of occurrence may vary.

The Changes in Tumor Cells That Lead to Metastasis Are Still Largely a Mystery

Perhaps the most significant gap in our understanding of cancer concerns invasiveness and metastasis (see Figure 20-20). More than 25 years after the multistep progression of colorectal cancer was first described, no genetic mutations have been identified that are characteristically associated with metastatic disease. To date, even large-scale genomic sequencing efforts have yet to uncover recurrent mutations that adequately explain the escape of cancer cells from a primary tumor and their dissemination and colonization of a distant tissue. One possibility is that metastasis can be initiated by epigenetic changes that alter patterns of gene expression. These changes could allow cancer cells to take on new traits in the absence of further genetic changes, thereby reprogramming their behavior to promote invasiveness and motility or to generate cancer stem cells. Importantly, changes in cellular programming and behavior operate normally in a variety of contexts during cellular differentiation. The example most relevant to metastasis is the epithelial-to-mesenchymal transition (EMT), a highly regulated and poorly understood process that allows epithelial cells to lose their characteristic polarity and adhesiveness and take on a mesenchymal phenotype, which includes enhanced migratory behavior. An EMT program operates at several stages of embryogenesis as well as during wound healing, and its activation in cancer cells could explain how they escape from a primary tumor and invade a new tissue. However, EMT is unlikely to explain the major puzzle of how disseminated cells acquire the ability to survive in the microenvironment of that new tissue, with its unfamiliar mix of growth factors and extracellular matrix components. Because the EMT program (like almost all cellular differentiation programs) involves changes in gene expression, it does not alter DNA sequences and would not be detected by sequencing the genomes of metastasized cancer cells.

Observations of the many stages and varied features of tumorigenesis highlight that cancer cells do not invent new biological phenomena, but instead deploy existing mechanisms and pathways at inappropriate times and places. A better understanding of the normal, underlying cell biology, and of the molecular changes that act to subvert it in cancer, will provide promising leads for cancer treatment, as we discuss in the final section of this chapter.

Summary

The molecular analysis of cancer cells reveals two classes of cancer-critical genes: oncogenes and tumor suppressor genes. A set of these genes becomes altered by a combination of genetic and epigenetic accidents to drive tumor progression. Many cancer-critical genes code for components of the social control pathways that regulate when cells grow, divide, differentiate, or die. In addition, a subclass of tumor suppressors can be categorized as genome maintenance genes, because their normal role is to help maintain genome integrity.

The inactivation of the p53 pathway, which occurs in nearly all human cancers, allows genetically damaged cells to escape apoptosis and continue to proliferate.

MBOC7_ptr_ch20_1163-1216.indd 1197 02/12/21 12:24 PM

Inactivation of the Rb pathway also occurs in most human cancers, illustrating how fundamental each of these pathways is for protecting us against cancer. More generally, the extensive sequencing of cancer cell genomes reveals that the development of a cancer requires the acquisition of heritable disturbances in each of three types of normal controls—those in the cell cycle, cell proliferation, and cell survival pathways.

The sequencing of cancer cell genomes indicates that—except for the cancers of childhood—many cancers acquire multiple driver mutations over the long course of tumor progression, along with a considerably larger number of passenger mutations of no consequence. The same methods reveal how subclones of cells arise and die out as a tumor ages. Tumors thus contain a heterogeneous mixture of cells, some—the so-called cancer stem cells—being much more dangerous than others.

We can often correlate the steps of tumor progression with mutations that activate specific oncogenes and inactivate specific tumor suppressor genes, and colon cancer provides a good example. But different combinations of mutations and epigenetic changes are found in different types of cancer, and even in different individuals with the same type of cancer, reflecting the random way in which these inherited changes arise. Nevertheless, many of the same changes are encountered repeatedly, suggesting that there are a limited number of ways to breach our defenses against cancer. However, the molecular basis of the final and most deadly step in cancer, metastasis, remains poorly understood.

CANCER PREVENTION AND TREATMENT: PRESENT AND FUTURE

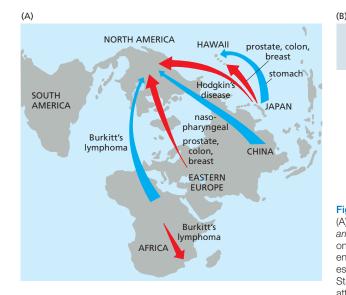

We can apply the growing understanding of the molecular biology of cancer to sharpen our attack on the disease at three levels: prevention, diagnosis, and treatment. Prevention is always better than cure, and indeed many cancers can be prevented, especially by avoiding smoking. Highly sensitive molecular assays promise new opportunities for earlier and more precise diagnosis, with the aim of detecting primary tumors while they are still small and have not yet metastasized. Cancers caught at these early stages can often be nipped in the bud by surgery or radiotherapy, as we saw for colorectal polyps. Nevertheless, full-blown malignant disease will continue to be common for many years to come, and cancer treatments will continue to be needed.

In this section, we first examine the preventable causes of cancer and then consider how advances in our understanding at a molecular level are beginning to transform the treatment of the disease.

Epidemiology Reveals That Many Cases of Cancer Are Preventable

A certain irreducible background incidence of cancer is to be expected regardless of circumstances. As discussed in Chapter 5, mutations can never be absolutely avoided because they are an inescapable consequence of fundamental limitations on the accuracy of DNA replication and repair. If a person could live long enough, it is inevitable that at least one of his or her cells would eventually accumulate a set of mutations sufficient for cancer to develop.

Nevertheless, environmental factors seem to play a large part in determining the risk for cancer. This is demonstrated most clearly by a comparison of cancer incidence in different countries: for almost every cancer that is common in one country, there is another country where the incidence is much lower. Because migrant populations tend to adopt the pattern of cancer incidence typical of their new host country, the differences are thought to be due mostly to environmental, not genetic, factors (Figure 20–37A). From epidemiologic studies compiled by the American Cancer Society, it is estimated that at least 45% of cancer deaths can be attributed to modifiable risk factors, indicating that more than half of all cancers should be avoidable (Figure 20–37B).

в)			
cause	deaths (percent of total)	number of deaths in US (2018)	estimated reduction possible (percent)
all risk factors	45%	265,150	50%
cigarette smoke	29%	169,180	75%
excess body weight	6.6%	38,230	50%
diet	4.9%	28,630	50%
alcohol	4.0%	23,510	50%
viruses	2.7%	16,100	100%
physical inactivity	2.2%	12,800	85%
UV radiation	1.5%	8,750	50%

Figure 20–37 Cancer incidence is related to environmental influences. (A) This map of the world shows the rates of cancer increasing (red arrows) or decreasing (blue arrows) when specific populations move from one location to another. Such observations suggest the importance of environmental factors, including diet, in dictating cancer risk. (B) Some estimated effects of environment and lifestyle on cancer in the United States (US). The table shows both the yearly deaths in the United States attributable to each factor and the estimated percentage of deaths that could be eliminated through prevention. (B, data from F. Islami et al., CA Cancer J. Clin. 68:31–54, 2018; and G.A. Colditz et al., Sci. Transl. Med. 4:127rv4, 2012.)

Unfortunately, different cancers have different environmental risk factors, and a population that escapes one such danger is usually exposed to another. This is not, however, inevitable. There are some human subgroups whose way of life substantially reduces the total cancer death rate among individuals of a given age. Under the current conditions in the United States and Europe, approximately one in five people will die of cancer. But the incidence of cancer among strict Mormons in Utah—who avoid alcohol, coffee, cigarettes, drugs, and unsafe sex—is only about half the incidence for nonpracticing members of the same family or for Americans in general.

Although such observations on human populations indicate that cancer can often be avoided, it has been difficult in most cases—with cigarette smoking as a striking exception—to pinpoint the specific environmental factors responsible for these large population differences or to establish how they act. Nevertheless, several important classes of environmental cancer risk factors have been identified (Figure 20–37B). But there are also many other influences—including the chemicals in our environment, the hormones that circulate in our bodies, and the irritations, infections, and damage to which we expose our tissues—that are no less important and favor development of the disease in other ways.

Sensitive Assays Can Detect Those Cancer-causing Agents That Damage DNA

Many quite disparate chemicals are carcinogenic when they are fed to experimental animals or painted repeatedly on their skin. Examples include a range of aromatic hydrocarbons and derivatives of them such as aromatic amines, nitrosamines, and alkylating agents such as mustard gas. Although these **chemical carcinogens** are diverse in structure, a large proportion of them have at least one shared property—they cause mutations. In one common test for mutagenicity (the *Ames test*), the carcinogen is mixed with an activating extract prepared from rat liver cells (to mimic the biochemical processing that occurs in an intact animal). The mixture is then added to a culture of specially designed test bacteria and the bacterial mutation rate measured. Most of the compounds scored as mutagenic by this rapid and convenient assay in bacteria also cause mutations or chromosome aberrations when tested on mammalian cells.

MBOC7_ptr_ch20_1163-1216.indd 1199 02/12/21 12:24 PM

(A) AFLATOXIN B1

AFLATOXIN-2,3-EPOXIDE

CARCINOGEN BOUND TO GUANINE IN DNA

Figure 20–38 Some known carcinogens. (A) Carcinogen activation. A metabolic transformation that occurs in the liver must activate many chemical carcinogens before they will cause mutations by reacting with DNA (labeled *orange*). The compound illustrated here is *aflatoxin B1*, a toxin from a mold (*Aspergillus flavus*) that grows on grain and peanuts when they are stored under humid tropical conditions. Aflatoxin is an important cause of liver cancer in the tropics. (B) Different carcinogens cause different types of cancer. (B, data from Institute of Medicine, Cancer and the Environment: Gene-Environment Interactions. Washington, DC: National Academies Press, 2002.)

A few of these carcinogens act directly on DNA. But generally the more potent ones are relatively inert chemically; these chemicals become damaging only after they have been converted to a more reactive molecule by metabolic processes in the liver, catalyzed by a set of intracellular enzymes known as the *cytochrome P-450 oxidases*. These enzymes normally help to convert ingested toxins into harmless and easily excreted compounds. Unhappily, their activity on certain chemicals generates products that are highly mutagenic. Examples of carcinogens activated in this way include *benzo[a]pyrene*, a cancer-causing polycyclic aromatic hydrocarbon present in coal tar, tobacco smoke, and the fungal toxin *aflatoxin B1* (Figure 20–38).

Fifty Percent of Cancers Could Be Prevented by Changes in Lifestyle

Tobacco smoke is the most important carcinogen in the world today. Even though many other risk factors have been identified, none of these appear to be responsible for anything like the same numbers of human cancer deaths attributable to tobacco smoke. It is sometimes thought that the main environmental causes of cancer are the products of a highly industrialized way of life—the rise in pollution, the enhanced use of food additives, and so on—but there is little evidence to support this view. The idea may have come in part from the identification of some highly carcinogenic materials used in industry, such as 2-naphthylamine and asbestos. Except for the increase in cancers caused by smoking, however, age-adjusted death rates for most common human cancers have stayed much the same over the past half-century or, in some cases, have declined significantly (Figure 20–39).

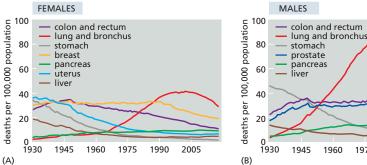

Most of the carcinogenic factors that are known to be significant are by no means specific to the modern world. The most potent known carcinogen, by certain assays at least, is aflatoxin B1 (see Figure 20–38). It is produced by fungi that naturally contaminate foods such as tropical peanuts and is an important cause of liver cancer in Africa and Asia.

Except for tobacco, chemical toxins and mutagens are of lesser importance as contributory causes of cancer than other factors that are a matter of human behavior. For example, currently nearly three-fourths of adults and one-third of children and adolescents in the United States are overweight or obese. The combination of four risk factors—excess body weight, alcohol intake, poor diet, and physical inactivity—now accounts for the highest proportion of all cancer cases in women and is second only to smoking in men. Thus, it is estimated that as many

Viruses and Other Infections Contribute to a Significant Proportion of Human Cancers

Human cancers are not contagious, but a significant minority of cancers are related directly or indirectly to infections with viruses and, less frequently, bacteria or parasites. Such infections account for approximately 15% of cancers worldwide and are more common in developing countries. Evidence for their involvement comes partly from the detection of viruses in individuals with cancer and partly from epidemiology. Thus, cancer of the uterine cervix is associated with infection with a papillomavirus, while liver cancer is very common in parts of the world (Africa and Southeast Asia) where hepatitis-B viral infections are common. Chronic infection with hepatitis-C virus, which has infected 170 million people worldwide, is also clearly associated with the development of liver cancer.

The main culprits, as shown in Table 20-2, are the DNA viruses. The DNA tumor viruses cause cancer by the most direct route—by interfering with controls of the cell cycle and apoptosis. To understand this type of viral carcinogenesis, it is important to review the life history of viruses. Many DNA viruses use the host cell's DNA replication machinery to replicate their own genomes. However, to produce a large number of infectious virus particles within a single host cell, the DNA virus has to commandeer this machinery and drive it hard, breaking through the normal constraints on DNA replication and usually killing the host cell in the process. Many DNA viruses reproduce only in this way. But some have a second option: they can propagate their genome as a quiet, well-behaved passenger in the host cell, replicating in parallel with the host cell's DNA (either integrated into the host genome or as an extrachromosomal plasmid) in the course of ordinary cell-division cycles. These viruses will switch between two modes of existence according to circumstances, remaining latent and harmless for a long time, but then proliferating in occasional cells in a process that kills the host cell and generates large numbers of infectious particles.

Neither of these conditions converts the host cell to a cancerous character, nor is it in the interest of the virus to do so. But for viruses with a latent phase, accidents can occur that prematurely activate some of the viral proteins that the

virus would normally use in its replicative phase to allow the viral DNA to replicate independently of the cell cycle. As in the case of papillomavirus described below, this type of accident can switch on the persistent proliferation of the host cell itself, leading to cancer.

Cancers of the Uterine Cervix Can Be Prevented by Vaccination Against Human Papillomavirus

The **papillomaviruses** are a prime example of DNA tumor viruses. They are responsible for human warts and are especially important as a cause of carcinoma of the uterine cervix: this is the second most common cancer of women in the world as a whole, representing about 6% of all human cancers. Human papillomaviruses (**HPVs**) infect the cervical epithelium and maintain themselves in a latent phase in the basal layer of cells as extrachromosomal plasmids, which replicate in step with the chromosomes. Infectious virus particles are generated through a switch to a replicative phase in the outer epithelial layers, as progeny of these cells begin to differentiate before being sloughed from the surface. Here, cell division should normally stop, but the virus interferes with this cell-cycle arrest so

MBOC7_ptr_ch20_1163-1216.indd 1202 02/12/21 12:24 PM

Figure 20–40 How certain papillomaviruses are thought to give rise to cancer of the uterine cervix. Papillomaviruses have double-stranded circular DNA chromosomes of about 8000 nucleotide pairs. These chromosomes are normally stably maintained in the basal cells of the epithelium as plasmids (red circles), whose replication is regulated so as to keep step with the chromosomes of the host. (A) Normally, the virus perturbs the host cell cycle only when the virus is programmed to produce infectious progeny, in the outer layers of an epithelium. This is relatively harmless. (B) Rare accidents can cause the integration of a fragment of such a plasmid into a chromosome of the host, altering the environment of the viral genes in the basal cells of an epithelium. This can disrupt the normal control of viral gene expression. The unregulated production of certain viral proteins (named E6 and E7) interferes with the control of cell division in the basal cells, thereby helping to generate a cancer (bottom).

as to allow replication of its own genome. Usually, the effect is restricted to the outer layers of cells and is relatively harmless, as in a wart. Occasionally, however, a genetic accident causes the viral genes that encode the proteins that prevent cell-cycle arrest to integrate into the host chromosome and become active in the basal layer, where the stem cells of the epithelium reside (see Figure 22–6). This can lead to cancer, with the viral genes acting as oncogenes (Figure 20–40).

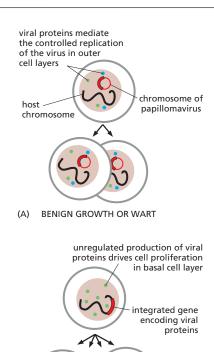

The whole process, from initial infection to invasive cancer, is slow, taking many years. It involves a long intermediate stage when the affected patch of cervical epithelium is visibly disordered but the cells have not yet begun to invade the underlying connective tissue—a phenomenon called *intraepithelial neoplasia*. Many such lesions regress spontaneously. Moreover, at this stage, it is still easy to cure the condition by destroying or surgically removing the abnormal tissue. Fortunately, the presence of such lesions can be detected by scraping off a sample of cells from the surface of the cervix and viewing it under the microscope (the *Pap smear* technique).

Better still, a vaccine has now been developed that protects against infection with the relevant strains of human papillomavirus. This vaccine, if given to girls before puberty and thus before they become sexually active, has been shown to greatly reduce their risk of ever developing cervical cancer. Because the virus spreads through sexual activity, it is now recommended that both young males and young females be routinely vaccinated. Mass immunization programs have begun in several countries.

Infectious Agents Can Cause Cancer in a Variety of Ways

In papillomaviruses, the viral genes that are mainly to blame are called *E6* and *E7*. The protein products of these viral oncogenes interact with many host-cell proteins, but, in particular, they bind to two key tumor suppressor proteins of the host cell, putting them both out of action and so permitting the cell to replicate its DNA and divide in an uncontrolled way. One of these host proteins is Rb; the other is p53. Other DNA tumor viruses use similar mechanisms to inhibit Rb and p53, underlining the central importance of altering both the cell-cycle control pathway and the cell survival pathway if a cell is to escape the normal constraints on proliferation, as we have previously discussed.

In other cancers, viruses have indirect tumor-promoting actions. The hepatitis-B and hepatitis-C viruses, for example, favor the development of liver cancer by causing chronic inflammation (hepatitis), which stimulates extensive cell division in the liver that promotes the eventual evolution of tumor cells. In AIDS, the human immunodeficiency virus (HIV) promotes development of an otherwise rare cancer called Kaposi's sarcoma by destroying the immune system, thereby permitting a secondary infection with a human herpesvirus (HHV-8) that has a direct carcinogenic action. By causing severe inflammation, chronic infection with parasites and bacteria can also promote the development of some cancers. For example, chronic infection of the stomach with the bacterium *Helicobacter pylori*, which causes ulcers, appears to be a major cause of stomach cancer; dramatic falls in the incidence of stomach cancer over the past half-century (see Figure 20–39) correlate with a decline in the incidence of *Helicobacter* infections.

(B) EVOLUTION OF MALIGNANT TUMOR

MBOC7_ptr_ch20_1163-1216.indd 1203 02/12/21 12:24 PM

The Search for Cancer Cures Is Difficult but Not Hopeless

The difficulty of curing a cancer is similar to the difficulty of getting rid of weeds. Cancer cells can be removed surgically or destroyed with toxic chemicals or radiation, but it is hard to eradicate every single one of them. Surgery can rarely ferret out every metastasis, and treatments that kill cancer cells are generally toxic to normal cells as well. Moreover, unlike normal cells, cancer cells can mutate rapidly and will often evolve resistance to the poisons and irradiation used against them.

In spite of these difficulties, effective cures using anticancer drugs (alone or in combination with other treatments) have already been found for some formerly highly lethal cancers, including Hodgkin's lymphoma, testicular cancer, choriocarcinoma, and some leukemias and other cancers of childhood. Even for types of cancer where a cure at present seems beyond our reach, there are treatments that will prolong life or at least relieve distress. But what prospect is there of doing better and finding cures for the most common forms of cancer, which still cause great suffering and so many deaths?

Traditional Therapies Exploit the Genetic Instability and Loss of Cell-Cycle Checkpoint Responses in Cancer Cells

Anticancer therapies need to take advantage of some molecular peculiarity of cancer cells that distinguishes them from normal cells. One such property is genetic instability, reflecting deficiencies in chromosome maintenance, cellcycle checkpoints, and/or DNA repair. Remarkably, the most widely used cancer therapies seem to work by exploiting these abnormalities, although this was not known by the scientists who first developed the treatments. Ionizing radiation and most anticancer drugs damage DNA or interfere with chromosome segregation at mitosis, and they preferentially kill cancer cells because cancer cells have a diminished ability to survive the damage. Normal cells treated with radiation, for example, arrest their cell cycle until they have repaired the damage to their DNA, thanks to the cell-cycle checkpoint responses discussed in Chapter 17. Because cancer cells generally have defects in their checkpoint responses, they may continue to divide after irradiation, only to die after a few days because the genetic damage remains unrepaired. More generally, most cancer cells are physiologically deranged to a stressful degree: they live dangerously. Even though the cells in a tumor have evolved to be unusually tolerant of minor DNA damage, they are hypersensitive to the much greater amount of damage that can be created by radiation and by DNA-damaging drugs. A small increase of genetic damage can be enough to tip the balance between proliferation and death. Unfortunately, however, DNA-damaging therapies typically cause terrible side effects on normal, rapidly dividing cells in the digestive system, bone marrow, and mucous membranes. Furthermore, these treatments are themselves carcinogenic and can lead to second cancers.

Furthermore, while the molecular abnormalities present in cancer cells often enhance their sensitivity to cytotoxic agents, they can also increase their resistance. For example, where a normal cell might die by apoptosis in response to DNA damage, thanks to the stress response mediated by p53, a cancer cell may escape apoptosis because it lacks p53. Cancers vary widely in their sensitivity to cytotoxic treatments, some responding to one drug, some to another, probably reflecting the particular kinds of defects that a particular cancer has in its DNA repair processes, cell-cycle checkpoints, and control of apoptosis.

New Drugs Can Kill Cancer Cells Selectively by Targeting Specific Mutations

Radiotherapy and traditional cytotoxic drugs are rather weakly selective: they hurt normal cells as well as the cancer cells, and the safety margin is narrow. The dose often cannot be raised high enough to kill all the cancer cells, because

this would kill the patient, and curative treatments, where achievable, generally require a combination of several cytotoxic agents. The side effects can be harsh and hard to endure. How can we do better?

An ideal treatment is one that is cell-lethal in combination with some lesion that is present in the cancer cells, but harmless to cells where this lesion is absent. Such a treatment is said to be *synthetic-lethal* (from the original sense of the word *synthesis*, meaning "putting together"): it kills only in partnership with the cancer-specific mutation. As we become increasingly able to pinpoint the specific molecular alterations in cancer cells that make them different from their normal neighbors, new opportunities for such precisely targeted treatments are coming into view. We end this chapter with some examples of new treatments that are already being put into practice.

PARP Inhibitors Kill Cancer Cells That Have Defects in *Brca1* or *Brca2* Genes

As we have emphasized, the genetic instability of cancer cells makes the cells both dangerous and vulnerable—dangerous because of their enhanced ability to evolve and proliferate, and vulnerable because treatment that leads to still more extreme genetic disruption can take them over the brink and kill them. In some cancers, genetic instability results from an identified fault in one of the many devices on which normal cells depend for DNA repair and maintenance. In this case, a drug tailored to block a complementary part of the DNA repair machinery can lead to such severe genetic damage that the cancer cells die.

Detailed studies of the mechanisms for DNA maintenance discussed in Chapter 5 reveal a surprising amount of apparent redundancy. Thus, knocking out a particular pathway for DNA repair is generally less disastrous than one might expect, because alternate repair pathways exist. For example, stalled DNA replication forks can arise when the fork encounters a single-strand break in a template strand, but cells can avoid the disaster that would otherwise result either by directly repairing these single-strand breaks or, if that fails, by using homologous recombination to repair the broken fork (see Figure 5–49). Suppose that the cells in a particular cancer have become genetically unstable by acquiring a mutation that reduces their ability to repair broken replication forks by homologous recombination. Might it be possible to eradicate that cancer by treating it with a drug that inhibits the repair of single-strand breaks, thereby greatly increasing the number of forks that break? The consequences of such drug treatment might be expected to be relatively harmless for normal cells, but lethal for the cancer.

This strategy appears to work to kill the cells in at least one class of cancers—those that have inactivated both copies of either their *Brca1* or their *Brca2* tumor suppressor genes. As described in Chapter 5, Brca2 is an accessory protein that interacts with the Rad51 protein (the RecA analog in humans) in the repair of DNA double-strand breaks by homologous recombination. Brca1 is another protein that is also required for this repair process. Like *Rb*, the *Brca1* and *Brca2* genes were discovered as mutations that predispose humans to cancer—in this case, chiefly cancers of the breast and ovaries (though unlike *Rb*, they seem to be involved in only a small proportion of such cancers). Individuals who inherit one mutant copy of *Brca1* or *Brca2* develop tumors that have inactivated the second copy of the same gene, presumably because this change makes the cells genetically unstable and speeds tumor progression.

While Brca1 and Brca2 are needed for the repair of DNA double-strand breaks, single-strand breaks are repaired by other machinery, involving an enzyme called PARP (polyADP-ribose polymerase). This understanding of the basic mechanisms of DNA repair led to a striking discovery: drugs that block PARP activity kill *Brca*-deficient cells with extraordinary selectivity. At the same time, PARP inhibition has very little effect on normal cells; in fact, mice that have been engineered to lack PARP1—the major PARP family member involved in DNA repair—remain healthy under laboratory conditions. This result suggests that,

MBOC7_ptr_ch20_1163-1216.indd 1205 02/12/21 12:24 PM

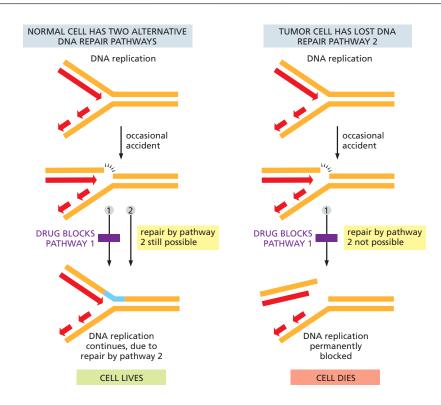

Figure 20–41 How a tumor's genetic instability can be exploited for cancer therapy. As explained in Chapter 5, the maintenance of DNA sequences is so critical for life that cells have evolved multiple pathways for repairing DNA damage and reducing DNA replication errors. As illustrated, a DNA replication fork will stall whenever it encounters a break in a DNA template strand. In this example, normal cells have two different repair pathways that help them to avoid the problem, pathways 1 and 2. They are therefore not harmed by treatment with a drug that blocks repair pathway 1. But, because the inactivation of repair pathway 2 was selected for during the evolution of the tumor cell, the tumor cells are killed by the same drug treatment.

In the actual case that underlies this example, the function of repair pathway 1 (requiring the PARP protein discussed in the text) is to remove persistent, accidental breaks in a DNA single strand before they are encountered by a moving replication fork. Pathway 2 is the recombination-dependent process (requiring the Brca2 and Brca1 proteins) for repairing stalled replication forks illustrated in Figure 5–49. PARP inhibitors are often used for treating cancers with defective *Brca2* or *Brca1* tumor suppressor genes.

while the repair pathway requiring PARP provides a first line of defense against persistent breaks in a DNA strand, these breaks can be repaired efficiently by a genetic recombination pathway in normal cells. In contrast, tumor cells that have acquired their genetic instability by the loss of Brca1 or Brca2 have lost this second line of defense, and they are therefore uniquely sensitive to PARP inhibitors (Figure 20–41).

PARP inhibitors have produced some striking results, causing tumors to regress in many Brca-deficient patients and delaying progression of their disease, with relatively few disagreeable side effects. These drugs also appear to be applicable to cancers with other mutations that cause defects in the cell's homologous recombination machinery—a small, though significant, proportion of cancer cases.

PARP inhibition provides an example of the type of rational, highly selective approach to cancer therapy that is beginning to be possible. Along with other new treatments to be discussed below, it raises high hopes for treating many other cancers.

Small Molecules Can Be Designed to Inhibit Specific Oncogenic Proteins

An obvious tactic for treating cancer is to attack a tumor expressing an oncogene with a drug designed to specifically block the function of the protein that the oncogene produces. But how can such a treatment avoid hurting the normal cells that depend on the function of the proto-oncogene from which the oncogene has evolved, and why should the drug kill the cancer cells, rather than simply calm them down? One answer may lie in the phenomenon of *oncogene dependence*. Once a cancer cell has undergone an oncogenic mutation, it will often undergo further mutations, epigenetic changes, or physiological adaptations that make it reliant on the hyperactivity of the initial oncogene, just as drug addicts become reliant on high doses of their drug. Blocking the activity of the oncogenic protein may then kill the cancer cell without significantly harming its normal neighbors. Some remarkable successes have been achieved in this way.

As we saw earlier, chronic myelogenous leukemia (CML) is usually associated with a particular chromosomal translocation, visible as the Philadelphia chromosome (see Figure 20–5). This results from chromosome breakage and rejoining at the sites of two specific genes, *Abl* and *Bcr*. The fusion of these genes creates a hybrid gene, called *Bcr-Abl*, that codes for a chimeric protein consisting of the N-terminal fragment of Bcr fused to the C-terminal portion of Abl (Figure 20–42). Abl is a tyrosine kinase involved in cell signaling. The substitution of the Bcr fragment for the normal N-terminus of Abl makes it hyperactive, so that it stimulates inappropriate proliferation of the hemopoietic precursor cells that contain it and prevents these cells from dying by apoptosis—which many of them would normally do. As a result, excessive numbers of white blood cells accumulate in the bloodstream, producing CML.

The chimeric Bcr-Abl protein is an obvious target for therapeutic attack. Searches for synthetic drug molecules that can inhibit the activity of tyrosine kinases discovered one, called *imatinib* (trade name Gleevec), that blocks Bcr-Abl (Figure 20-43). When the drug was first given to patients with CML, nearly

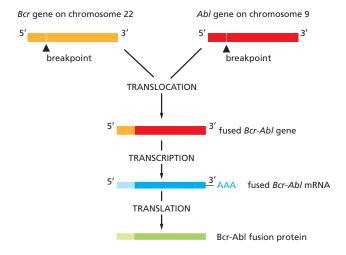

Figure 20–42 The conversion of the *AbI* proto-oncogene into an oncogene in individuals with chronic myelogenous leukemia. The chromosome translocation responsible joins the *Bcr* gene on chromosome 22 to the *AbI* gene from chromosome 9, thereby generating a Philadelphia chromosome (see Figure 20–5). The resulting fusion protein has the N-terminus of the Bcr protein joined to the C-terminus of the *AbI* tyrosine protein kinase; in consequence, the *AbI* kinase domain becomes inappropriately active, driving excessive proliferation of a clone of hemopoietic cells in the hope marrow.

MBOC7_ptr_ch20_1163-1216.indd 1207 02/12/21 12:24 PM

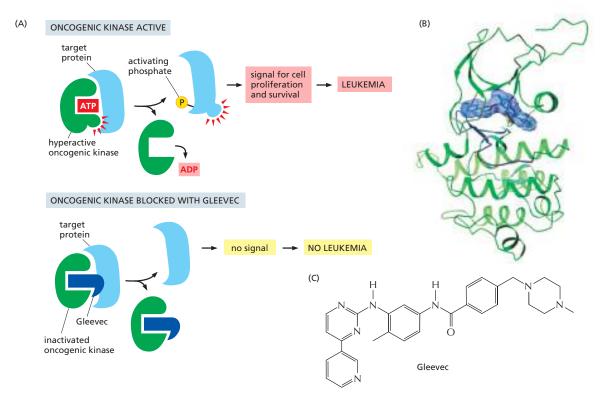

Figure 20–43 How imatinib (Gleevec) blocks the activity of Bcr-Abl protein and halts chronic myelogenous leukemia. (A) Imatinib sits in the ATP-binding pocket of the tyrosine kinase domain of Bcr-Abl and thereby prevents Bcr-Abl from transferring a phosphate group from ATP onto a tyrosine residue in a substrate protein. This blocks transmission of a signal for cell proliferation and survival. (B) The structure of the complex of imatinib (solid *blue* object) with the tyrosine kinase domain of the Abl protein (ribbon diagram), as determined by x-ray crystallography. (C) The chemical structure of the drug. It can be administered orally; it has side effects, but they are usually quite tolerable. (B, from T. Schindler et al., *Science* 289:1938–1942, 2000. With permission from AAAS. PDB code: 3K5V.)

all of them showed a dramatic response, with an apparent disappearance of the cells carrying the Philadelphia chromosome in more than 80% of patients. The response appears relatively durable: after years of continual treatment, many patients have not progressed to later stages of the disease—although imatinibresistant cancers emerge with a probability of about 5% per year during the early years.

Results are not so good for those patients who have already progressed to the more acute phase of myeloid leukemia, known as blast crisis, where genetic instability has set in and the march of the disease is far more rapid. These patients show a response at first and then relapse because the cancer cells develop a resistance to imatinib. This resistance is usually associated with secondary mutations in the part of the *Bcr-Abl* gene that encodes the kinase domain, disrupting the ability of imatinib to bind to Bcr-Abl kinase. Second-generation inhibitors that function effectively against a whole range of imatinib-resistant mutants have now been developed. By combining one or more of these new inhibitors with imatinib as the initial therapy, it seems that CML—at least in the chronic (early) stage—may be on its way to becoming a curable disease.

Despite the complications with resistance, the extraordinary success of imatinib is enough to drive home an important principle: once we understand precisely what genetic lesions have occurred in a cancer, we can begin to design effective rational methods to treat it. This success story has fueled efforts to identify small-molecule inhibitors for other oncogenic protein kinases and to use them to attack the appropriate cancer cells. Increasing numbers are being developed. These include molecules that target the EGF receptor and are currently approved

MBOC7_ptr_ch20_1163-1216.indd 1208 02/12/21 12:24 PM

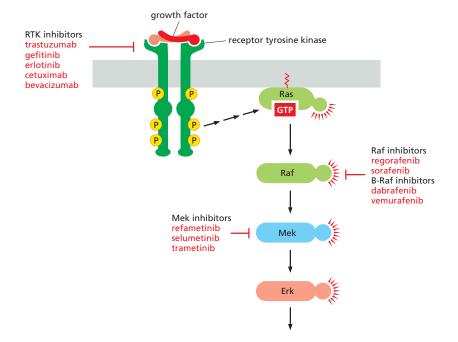

Figure 20–44 Some anticancer drugs and drug targets in the Ras–MAP-kinase signaling pathway. This Ras–MAP-kinase signaling pathway is triggered by a variety of receptor tyrosine kinases (RTKs), including the EGF receptor (see Figures 15–48 and 15–50. Raf kinase inhibitors include several that specifically target the oncoprotein B-Raf. By convention, those drugs that are antibodies end in "mab," while those that are small molecules end in "nib." (Adapted from B. Vogelstein et al., Science 339:1546–1558, 2013.)

for the treatment of some lung cancers, as well as drugs that specifically target the B-Raf oncoprotein in melanomas.

Protein kinases have been relatively easy to inhibit with small molecules such as imatinib, and many kinase inhibitors are being produced by pharmaceutical companies in the hope that they can be effective as drugs for some forms of cancer. Many cancers lack an oncogenic mutation in a protein kinase. But most tumors contain inappropriately activated signaling pathways, for which a target somewhere in the pathway can hopefully be found (Movie 20.8). As an example, Figure 20–44 displays some of the anticancer drugs and drug targets that are currently being tested for a pathway frequently activated in cancers.

Many Cancers May Be Treatable by Enhancing Immune Responses

Cancers have complex interactions with the immune system, and its various components may sometimes help as well as hinder tumor progression. But for more than a century it has been a dream of cancer researchers to somehow harness our immune systems in a controlled and efficient way to exterminate cancer cells, just as it exterminates pathogenic microorganisms. There are finally signs that this dream may one day be realized, at least for some forms of cancer.

The simplest type of immunological therapy, conceptually at least, is to inject the patient with antibodies that target the cancer cells. This approach has had some successes. About 25% of breast cancers, for example, express unusually high levels of the Her2 (human epidermal growth factor receptor 2) protein, a receptor tyrosine kinase related to the EGF receptor that plays a part in the normal development of mammary epithelium. A monoclonal antibody called *trastuzumab* (trade name Herceptin), which binds to Her2 and inhibits its function, slows the growth of human breast cancers that overexpress Her2, and it is now a standard therapy for these cancers (see Figure 20–44). A related approach uses antibodies to deliver poisons to the cancer cells. Antibodies against proteins that are abundant on the surface of a particular type of cancer cell but rare on normal cells can be coupled to a toxin that kills the cells that the antibody binds to.

A great deal of current excitement centers around a different type of immunological approach, which is based on a class of lymphocytes called T cells. As

MBOC7_ptr_ch20_1163-1216.indd 1209 02/12/21 12:24 PM

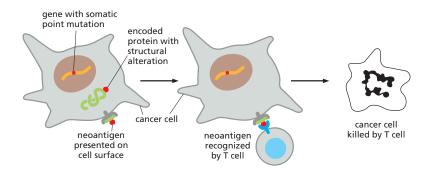

Figure 20–45 Tumor-specific antigens are recognized by the immune system. Due to somatic mutation, cells in tumors will produce many different mutant proteins. As described in Chapter 24, peptides from these proteins will be displayed as neoantigens on the tumor cell surface and have the potential to activate a T cell response that kills the cell (see Figure 24–42).

described in detail in Chapter 24, cytotoxic T cells can kill a host cell that displays foreign peptide antigens on its surface. Because the peptide is usually derived from an invading pathogen, the response helps terminate the infection. The challenge is to find ways of recruiting cytotoxic T cells to attack cancers with similar efficiency and specificity, presuming that the cancer cells express tumorspecific antigens. Recall that, from the thousands of tumor genome sequences thus far determined, we know that a typical cancer cell contains approximately 50 proteins with a mutation that alters an amino acid sequence, most of these being passenger mutations, as previously explained (see p. 1186). The amino acid changes resulting from either passenger or driver mutations have the potential to produce cell-surface neoantigens that can be recognized as foreign by T cells, resulting in cancer cell death (Figure 20-45). However, because cytotoxic T cells kill infected host cells, they are under tight control to keep their activity within safe bounds. Furthermore, cancer cells typically lack some of the components present in pathogen-infected cells that are necessary to initiate a robust T cell response. Thus, very few tumor-reactive T cells exist, and therapies to boost their numbers are at the forefront of immunotherapy.

One approach to augment the T cell response to cancer cells is to collect a patient's own T cells from his or her blood, expand the cancer-reactive population, and then re-infuse them into the patient. This method of introducing a large number of T cells that already recognize the tumor cells bearing cancer-specific antigens has been very effective in metastatic melanoma patients, achieving complete remission rates as high as 20%. In an even more elaborate variation of this strategy, the patient's T cells can be genetically engineered before their numbers are increased, in a procedure called chimeric antigen receptor T cell (CAR T) therapy (Movie 20.9). The engineered CAR T cells not only recognize the patient's tumor-specific antigen but also possess co-stimulatory activities that boost the response of the T cells. This therapy is extremely effective against certain blood cancers, but, unfortunately, it also has severe side effects due to immune system hyperactivation.

Immunosuppression Is a Major Hurdle for Cancer Immunotherapy

If cancer cell neoantigens are recognized as foreign, why doesn't the immune system work better to eliminate the cancer in the first place? As discussed previously (see pp. 1175–1176), cancer cells manipulate their surrounding stroma, including immune cells, to create a microenvironment that simultaneously promotes tumor growth and suppresses immune responses. Investigation of how tumors escape immune destruction led to the discovery of crucial immunosuppressive mechanisms—the expression on the cancer cell surface of one or more proteins that bind to inhibitory receptors on various immune cells, including activated T cells. As a result, even if cytotoxic T cells recognize tumor antigens, they are prevented from killing the tumor cells. The inhibitory receptors expressed on the surface of T cells are part of the *immune checkpoint* that plays an important normal function in preventing excessive, tissue-damaging immune responses during infections. But, in the context of cancer, immune

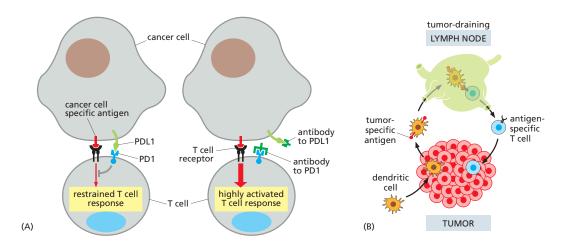

Figure 20–46 How the immune system interacts with cancer. (A) An antibody therapy for overcoming the immunosuppressive microenvironment in tumors. Cancer cells often protect themselves from immune attack by expressing proteins on their surface that bind to inhibitory receptors on T cells. In the example shown, the cancer cell expresses PDL1, which binds the PD1 receptor on a T cell and interferes with T cell activation. This makes the tumor susceptible to antibodies that unleash T cell attack. (B) Dendritic cells play a key role in activating T cells by acquiring tumor cell antigens from tumors and presenting them in lymph nodes, as illustrated, and some cancers have evolved mechanisms that interfere with this process (not shown).

checkpoint mechanisms can prevent an individual from killing the cancer cells that are threatening his or her survival.

To overcome the immunosuppressive environment and provide a strong T cell activating signal, a promising new type of anticancer therapy focuses on developing *immune checkpoint inhibitors* such as antibodies that prevent the tumor cells from engaging with the inhibitory receptors on T cells. As illustrated in **Figure 20–46A**, targeting inhibitory receptors or their ligands with antibodies can unleash an immune attack on the cancer cells. Importantly, multiple neoantigens are recognized as foreign, so that cancer cells cannot escape an immune attack through the mutational loss of a single neoantigen, making it difficult for the tumor to become resistant to the antibody treatment. A substantial fraction of metastatic melanoma patients injected repeatedly with monoclonal antibodies that bind to either one such receptor, PD1 (programmed cell death 1), or its ligand on the surface of cancer cells, PDL1, respond in a dramatic way, with their cancer being driven into remission for years. Unfortunately, the treatment fails to help others with the same type of cancer.

An important clue as to why immunotherapies are effective in some patients but not others comes from the extensive analysis of cancer genomes described in the second part of this chapter. A fortuitous property of tumor samples is that they contain not only the cancer cells but also the cells of the associated stroma, including fibroblasts and endothelial and various immune cells. Because each cell type expresses a signature set of RNAs, the presence and proportion of each cell type in the tumor can be assessed, including the T cells. A comparison of the immune cell profiles of thousands of different tumors has revealed interesting correlations. For example, as one might predict, cancers with genomes that contain large numbers of point mutations are frequently found to possess a higher proportion of T cells compared to cancers with genomes that contain fewer mutations, presumably due to an increase in neoantigens. In turn, this tumor profile correlates with better treatment outcomes after treatment with immune checkpoint inhibitors.

Some cancers appear to avoid immune destruction by preventing T cells from infiltrating the tumor in the first place. The cellular basis of this phenomenon is poorly understood and is an important ongoing area of investigation. It is known that T cell activation requires that T cells physically interact with antigenpresenting cells called dendritic cells. Dendritic cells are highly migratory and pick up pathogens or their products at sites of infection and deliver them to lymph

MBOC7_ptr_ch20_1163-1216.indd 1211 02/12/21 12:24 PM

nodes or other lymphoid organs, where they present them to T cells. In the case of cancer, dendritic cells present neoantigens to T cells, so that they can track down the cells expressing the antigens and destroy them (Figure 20–46B). Some cancer cells inhibit this process by preventing the dendritic cells from interacting with them and acquiring their neoantigens.

These observations illustrate how the immune system is subject to many levels of control and how cancer cells have been selected to take advantage of them. Importantly, research into the cell biological mechanisms behind these phenomena not only helps to develop new cancer treatments but will also teach us basic principles of how the system operates in the first place, as described in Chapter 24.

Cancers Evolve Resistance to Therapies

High hopes have to be tempered with sobering realities. We have seen that genetic instability can provide an Achilles' heel that cancer therapies can exploit, but at the same time it can make eradicating the disease more difficult by allowing the cancer cells to evolve resistance to therapeutic drugs, often at an alarming rate. This applies even to the drugs that target genetic instability itself. Thus, PARP inhibitors give valuable remission of illness, but in the long term the disease generally comes back. For example, *Brca*-deficient cancers can sometimes develop resistance to PARP inhibitors by undergoing a second mutation in an affected *Brca* gene that restores its function. By then, the cancer is already out of control and it may be too late to affect the course of the disease with additional treatments.

There are many different strategies by which cancers can evolve resistance to anticancer drugs. Often, a cancer will be dramatically reduced in size by an initial drug treatment, with all of the detectable tumor cells seeming to disappear. But months or years later the cancer will reappear in an altered form that is resistant to the drug that was at first so successful. In such cases, the initial drug treatment has evidently failed to destroy some tiny fraction of cells in the original tumor-cell population. These cells may have escaped death because they carry a protective mutation or epigenetic change or perhaps simply because they were lurking in a protected environment. Alternatively, and most insidiously, a phenotypically distinct subpopulation of tumor cells may function as cancer stem cells. The surviving cells eventually regenerate the cancer by continuing to proliferate, mutating and evolving still further as they do so. Combination therapies, in which the right two agents are used simultaneously to target the same cancer cells, should in principle help greatly with such problems.

However, in some cases, cells that are exposed to one anticancer drug evolve a resistance not only to that drug but also to other drugs to which they have never been exposed. This phenomenon of **multidrug resistance** frequently correlates with amplification of a part of the genome that contains a gene called *Mdr1* or *Abcb1*. This gene encodes a plasma membrane-bound transport ATPase of the ABC transporter superfamily (discussed in Chapter 11), which pumps lipophilic drugs out of the cell (see Movie 11.5). The overproduction of this protein (or some of its other family members) by a cancer cell can prevent the intracellular accumulation of many cytotoxic drugs, making the cell insensitive to them.

In the to-and-fro struggle between advanced metastatic cancer and the therapist, as current practice stands, the cancer usually wins in the end. Does it have to be so? As we discuss below, there is reason to think that by attacking a cancer with many weapons at once—instead of using them one after another, each until it fails—it may be possible to do much better.

We Now Have the Tools to Devise Combination Therapies Tailored to the Individual

Nowadays, cancers caught at an early stage can often be cured by surgery, radiation, or drugs. For most cancers that have progressed and metastasized widely, however, cure is still frequently beyond us. Treatments such as those described

earlier can give valuable remissions, but sooner or later these are typically followed by relapse.

Nevertheless, for some forms of advanced cancer, curative therapies are being developed that utilize multiple strategies; for example, combining chemotherapy and radiation therapy with immunotherapy. Ideally, the choice of drugs to be given in combination should be tailored to the individual patient. Cancers evolve by a fundamentally random process, and each individual is different, but modern methods of genome analysis now let us characterize the cells from a tumor biopsy in exhaustive detail so as to discover which cancer-critical genes are affected in a particular case. Admittedly, this is not straightforward: the tumor cells in an individual are heterogeneous and do not all contain the same genetic lesions. With increased understanding of the pathways of cancer evolution, however, and with the experience gained from many different cases, it should become possible to make informed decisions about the optimal therapies to use.

Improvements in tissue sampling, genomics, and biostatistics have enabled the direct characterization of primary human tumors. However, these analyses do not take into account the contributions of the entire body. Advances in cancer therapy are also coming from the development of more sophisticated models of the disease, which can be used to investigate the factors involved in tumor growth and metastasis, as well as to examine response to therapy. In one approach, mice can be genetically engineered to introduce particular combinations of human mutations (see Figure 20–33). A second approach is the human tumor xenograft. In this model, human cancer cells are transplanted—either under the skin or into the organ type in which the cancer originated—into immunocompromised mice that do not reject human cells. In an approach that bypasses the use of mice, organoids can be grown in 3D culture from patient-derived healthy and tumor tissues (see Figure 20–34A). These systems facilitate patient-specific drug testing and the development of individualized treatment regimens.

From the perspective of the patient, the pace of advance in cancer research can seem frustratingly slow. Each new drug has to be tested in the clinic, first for safety and then for efficacy, before it can be released for general use. And if the drug is to be used in combination with others, the combination therapy must then go through the same long process. Strict ethical rules constrain the conduct of trials, which means that they take time—typically several years. But slow and cautious steps, taken systematically in the right direction, can lead to great advances. There is still far to go, but the examples that we have discussed provide proof of principle and grounds for optimism.

From the cancer research effort, we have learned a great deal of what we know about the molecular biology of the normal cell. Now, more and more, we are discovering how to put that knowledge to use in the battle with cancer itself.

Summary

Our growing understanding of the cell biology of cancers has already begun to lead to better ways of preventing, diagnosing, and treating these diseases. Anticancer therapies can be designed to destroy cancer cells preferentially by exploiting the properties that distinguish cancer cells from normal cells, including the cancer cells' dependence on oncogenic proteins and the defects they harbor in their DNA repair mechanisms. We now have good evidence that, by increasing our understanding of normal cell control mechanisms and exactly how they are subverted in specific cancers, we can eventually devise drugs to kill cancers precisely by attacking specific molecules critical for the proliferation and survival of the cancer cells. In addition, great progress has recently been made through sophisticated immunological approaches to cancer therapy. And, as we become better able to determine which genes are altered in the cells of any given tumor, we can begin to tailor treatments more accurately to each individual.

MBOC7_ptr_ch20_1163-1216.indd 1213 02/12/21 12:24 PM

PROBLEMS

Which statements are true? Explain why or why not.

20–1 Cancer therapies directed solely at killing the rapidly dividing cells that make up the bulk of a tumor are unlikely to eliminate the cancer from many patients.

20–2 In the regulatory pathways that control cell growth and proliferation, the products of oncogenes are stimulatory components and the products of tumor suppressor genes are inhibitory components.

20–3 The chemical carcinogen dimethylbenz[*a*]anthracene (DMBA) must be an extraordinarily specific mutagen because 90% of the skin tumors it causes have an A-to-T alteration at exactly the same site in the mutant *Ras* gene.

20–4 The main environmental causes of cancer are the products of our highly industrialized way of life such as pollution and food additives.

Discuss the following problems.

20–5 What is the term for a cancer arising from epithelial cells?

20–6 In contrast to colon cancer, the incidence of which increases dramatically with age, the incidence of osteosarcoma—a tumor that occurs most commonly in the long bones—peaks during adolescence. Osteosarcomas are relatively rare in young children (up to age 9) and in adults (over age 20). Why do you suppose that the incidence of osteosarcoma does not show the same sort of age dependence as colon cancer?

20–7 Mortality due to lung cancer was followed in groups of males in the United Kingdom for 50 years. Figure Q20–1 shows the cumulative risk of dying from lung cancer as a function of age and smoking habits for four groups of males: those who never smoked, those who stopped at age 30, those who stopped at age 50, and those who continued to smoke. These data show clearly that individuals can substantially reduce their cumulative risk of dying from lung cancer by stopping smoking. What do you suppose is the biological basis for this observation?

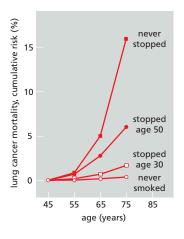

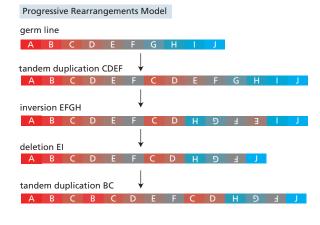

Figure Q20-1 Cumulative risk of lung cancer mortality for nonsmokers, smokers, and former smokers (Problem 20-7). Cumulative risk is the running total of deaths, as a percentage. for each group. Thus, for continuing smokers, 1% died of lung cancer between ages 45 and 55; an additional 4% died between 55 and 65 (giving a cumulative risk of 5%); and 11% more died between 65 and 75 (for a cumulative risk of 16%).

20–8 A small fraction—2 to 3%—of all cancers, across many subtypes, displays a quite remarkable phenomenon: tens to hundreds of rearrangements that primarily involve a single chromosome or chromosomal region. The breakpoints can be tightly clustered, with several in a few kilobases, and the junctions of the rearrangements often involve segments of DNA that were not originally close together on the chromosome. The copy number of various segments within the rearranged chromosome is found to be 0, indicating deletion, or 1, indicating retention.

You can imagine two ways in which such multiple, localized rearrangements might happen: a progressive rearrangements model with ongoing inversions, deletions, and duplications involving a localized area, or a catastrophic model in which the chromosome is shattered into fragments that are stitched back together in random order by a double-strand break repair process such as nonhomologous end joining (Figure Q20–2).

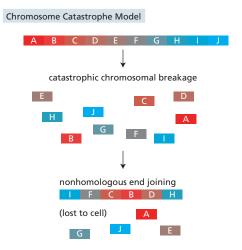

Figure Q20–2 Two models to explain the multiple, localized chromosome rearrangements found in some cancers (Problem 20–8). The progressive rearrangements model shows a sequence of rearrangements that disrupts the chromosome, generating increasingly complex chromosomal configurations. The chromosome catastrophe model shows the chromosome being fragmented and then reassembled randomly, with some pieces left out.

PROBLEMS 1215

Which of the two models in Figure Q20-2 accounts more readily for the features of these highly rearranged chromosomes? Explain your reasoning.

The Tasmanian devil (Figure Q20-3A) is a carnivorous Australian marsupial that is threatened with extinction by the spread of a fatal disease in which a malignant oral-facial tumor interferes with the animal's ability to feed. You have been called in to analyze the source of this unusual cancer. It seems clear to you that the cancer is somehow spread from animal to animal, very likely by their frequent fighting, which is accompanied by biting around the face and mouth. To uncover the source of the cancer, you isolate tumors from 11 Tasmanian devils captured in widely separated regions and examine them. The karyotypes of nontumor cells from these Tasmanian devils are normal (Figure Q20-3B). As expected, the tumor cells are highly rearranged relative to the normal karyotype, but, surprisingly, the karyotypes from all 11 tumor samples are very similar (Figure Q20-3C). Moreover, one of the Tasmanian devils has an inversion on chromosome 5 that is not present in its facial tumor. How do you suppose this cancer is transmitted from animal to animal? Is it likely to arise as a consequence of an infection by a virus or microorganism? Explain your reasoning.

(A) Tasmanian devil (Sarcophilus harrisii)

(B) normal karyotype

1 2 3 4 5 6 XY

(C) tumor karyotype

Figure Q20–3 Karyotypes of cells from Tasmanian devils (Problem 20–9). (A) A Tasmanian devil. (B) Normal karyotype for a male Tasmanian devil. The karyotype has 14 chromosomes, including XY. (C) Karyotype of cancer cells found in each of the 11 facial tumors studied. The karyotype has 13 chromosomes, no sex chromosomes, no chromosome 2 pair, one chromosome 6, two chromosomes 1 with deleted long arms, and four highly rearranged marker chromosomes (M1–M4). (A, reproduced courtesy of Museum Victoria; B and C, from A.-M. Pearse and K. Swift, *Nature* 439:549, 2006. Reproduced with permission from SNCSC.)

20–10 Virtually all cancer treatments are designed to kill cancer cells. However, one particular cancer—acute promyelocytic leukemia (APL), which is caused by too many immature blood-forming cells (promyelocytes) in the blood—has been successfully treated with all-*trans*-retinoic acid, which causes the promyelocytes to differentiate into neutrophils. How might a change in the state of differentiation of APL cancer cells help the patient?

20–11 PolyADP-ribose polymerase (PARP) plays a key role in the repair of DNA single-strand breaks. In the presence of the PARP inhibitor olaparib, single-strand breaks accumulate. When a replication fork encounters a single-strand break, it converts it to a double-strand break, which in normal cells is then repaired by homologous recombination. In cells defective for homologous recombination, however, inhibition of PARP triggers cell death.

Individuals who have only one functional copy of the *Brca1* gene, which is required for homologous recombination, are at much higher risk for cancer of the breast and ovary. Cancers that arise in these tissues in these individuals can be treated successfully with olaparib. Explain how it is that treatment with olaparib kills the cancer cells in these individuals but does not harm their normal cells.

20–12 One major goal of modern cancer therapy is to identify small molecules—anticancer drugs—that can be used to inhibit the products of specific cancer-critical genes. If you were searching for such molecules, would you design inhibitors for the products of oncogenes or the products of tumor suppressor genes? Explain why you would (or would not) select each type of gene.

Development of Multicellular Organisms

CHAPTER

21

Every multicellular organism, be it animal or plant, starts its life as a single cell—a fertilized egg, or **zygote**. During development, this cell divides repeatedly to produce many different kinds of cells, arranged in a final pattern of spectacular complexity and precision. The goal of developmental cell biology is to understand the cellular and molecular mechanisms that direct this amazing transformation (Movie 21.1).

Plants and animals have very different ways of life, and they use different developmental strategies. In this chapter, we focus mainly on animals. Three processes are fundamental to animal development: (1) cell proliferation, which produces many cells from one; (2) cell specialization, or **differentiation**, by which cells take on different characteristics and functions; and (3) morphogenesis, in which cells rearrange themselves to form structured tissues and organs (Figure 21–1).

Development of the zygote begins with multiple rounds of cell division, generating a large population of cells that can then be specialized for different functions. At each subsequent stage in its development, a cell is presented with a limited set of options, so that its developmental pathway branches repeatedly, reflecting a large set of sequential choices. Like the decisions we make in our own lives, the choices made by the cell are based on its internal state—which largely reflects its history—and on current influences from other cells, especially its close neighbors. To understand development, we need to know how each choice is controlled and how it depends on previous choices. Beyond that, we need to understand how the choices, once made, influence the cell's chemistry and behavior, and how cell behaviors act synergistically to determine the structure and function of the body.

As cells become specialized, they change not only their biochemistry but also their shape and their attachments to other cells and to the extracellular matrix. They move and rearrange themselves to create the complex architecture of the body, with all its tissues and organs, each structured precisely and defined in size. To understand this process of form generation, or **morphogenesis**, we will need to take account of the mechanical, as well as the biochemical, interactions between the cells.

At first glance, one would no more expect the worm, the flea, the eagle, and the giant squid to be generated by the same developmental mechanisms than one would suppose that the same methods were used to make a shoe and an airplane. Remarkably, however, research has revealed that much of the basic machinery of development is essentially the same in all animals—not just in all vertebrates, but in all invertebrates too. Recognizably similar, evolutionarily related molecules

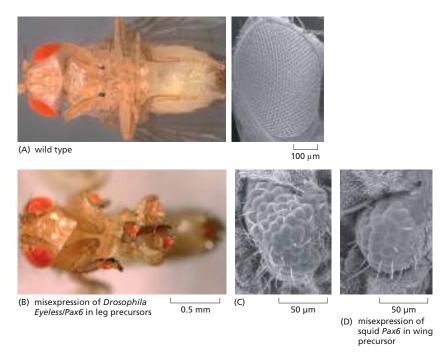

Figure 21–2 Homologous proteins often have conserved functions.

(A) The Eyeless protein (also called Pax6) controls eye development in Drosophila. In a wild-type fly (top row), the Eyeless/ Pax6 gene is expressed in the developing eye and directs formation of the eye structure shown in the scanning electron micrograph at right. Misexpression of Eyeless/Pax6 in the legs (bottom row) results in the formation of eye tissue on leg precursor (B) (see Figure 7-38) or wing precursor (C). The homologous Pax6 from a squid, when misexpressed in developing Drosophila legs, has the same effect (D). (Fly images courtesy of Katy Ong and Justin Kumar; electron micrographs from S.I. Tomarev et al., Proc. Natl. Acad. Sci. USA 94:2421-2426. Copyright 1997 National Academy of Sciences, USA. With permission from National Academy of Sciences.)

define the specialized animal cell types, mark the differences between body regions, and help create the animal body pattern. Homologous proteins often perform the same role in different species and are functionally interchangeable. Thus, a mouse or squid protein produced artificially in a fly, for example, can perform the same function as the fly's own version of that protein (Figure 21–2). Thanks to an underlying unity of mechanisms, developmental biologists have been making great strides toward a coherent understanding of animal development.

We begin this chapter with an overview of some of the basic mechanisms that operate in animal development, focusing on those that are best understood and generate differences between cells. We then discuss, in sequence, how cells in the embryo diversify to form patterns in space, how the timing of developmental events is controlled, how changing cell behaviors drive morphogenesis, and how the size of an animal is regulated.

OVERVIEW OF DEVELOPMENT

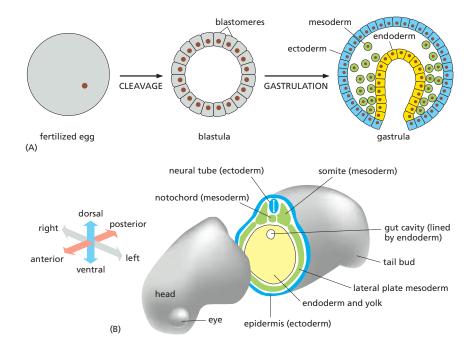

Animals live by eating other organisms. Thus, despite their remarkable diversity, animals as different as worms, mollusks, insects, and vertebrates share anatomical features that are fundamental to this way of life. Epidermal cells form a protective outer layer; gut cells absorb nutrients from ingested food; muscle cells allow movement toward food sources; and neurons and sensory cells control behavior. These various cell types are organized into tissues and organs, forming a sheet of skin covering the exterior, a mouth for feeding, and an internal gut tube for digestion—with muscles, nerves, and other tissues arranged in the space between the skin and the gut. Many animals have clearly defined axes—an anteroposterior axis, with mouth and brain anterior and anus posterior; a dorsoventral axis, with back dorsal and belly ventral; and a left-right axis. In this section, we discuss some fundamental mechanisms underlying how the basic animal body plan is established and how this diversity of cell types is created.

Conserved Mechanisms Establish the Core Tissues of Animals

The shared anatomical features of animals develop through conserved mechanisms. After fertilization, the zygote usually divides rapidly, or **cleaves**, to form many smaller cells called **blastomeres**. During this cleavage phase, the embryo, which cannot yet feed, does not grow. This step of development is initially driven

MBOC7_ptr_ch21_1217-1278.indd 1218 02/12/21 12:24 PM

OVERVIEW OF DEVELOPMENT 1219

and controlled entirely by the material deposited in the egg by the mother. The embryonic genome remains largely inactive until a point is reached when maternal mRNAs and proteins are used up or abruptly degraded. The embryo's genome is then activated—the maternal–zygotic transition that we will discuss later—and the cells cohere to form a **blastula**, typically a solid or a hollow fluid-filled ball of cells.

Even in these early stages of embryogenesis, genetic programs are under way that give rise to the basic tissue types. Complex cell rearrangements called **gastrulation** (from the Greek *gaster*, meaning "belly") soon transform the blastula into a multilayered structure containing a rudimentary internal gut (**Figure 21–3**). Some cells of the blastula remain external, constituting the **ectoderm**, which will give rise to the epidermis and the nervous system; other cells invaginate, forming the **endoderm**, which will give rise to the gut tube and its appendages, such as lung, pancreas, and liver. In most animals, another group of cells moves into the space between ectoderm and endoderm and forms the **mesoderm**, which will give rise to muscles, connective tissues, blood, kidneys, and various other components. Further cell movements and accompanying cell differentiation create and refine the embryo's architecture.

The ectoderm, mesoderm, and endoderm formed during gastrulation constitute the three **germ layers** of the early embryo. This initial subdivision is the first step in defining the multitude of cell fates that will emerge in development. Many later developmental transformations will produce the elaborately structured organs. But the basic body plan and axes set up in miniature during gastrulation are preserved into adult life, when the organism may be billions of times larger (Movie 21.2).

The Developmental Potential of Cells Becomes Progressively Restricted

Concomitant with the refinement of the body plan, the individual cells within a *lineage*—that is, the progeny of a particular proliferating mother cell—become more and more restricted in their developmental potential. During the blastula stages, cells are often **totipotent** or **pluripotent**—they have the potential to give rise to all or almost all of the cell types of the adult body. The pluripotency is lost as gastrulation proceeds: a cell located in the endodermal germ layer, for

Figure 21-3 The early stages of development, as exemplified by a frog. (A) A fertilized egg divides to produce many blastomere cells that form an epithelial sheet often surrounding a cavity. During gastrulation, some of the cells tuck into the interior to form the mesoderm (green) and endoderm (vellow). Ectodermal cells (blue) remain on the outside. (B) A cross section through the trunk of an amphibian embryo shows the basic animal body plan, with a sheet of ectoderm on the outside, a tube of endoderm on the inside, and mesoderm sandwiched between them. The endoderm forms the epithelial lining of the gut, from the mouth to the anus. It gives rise not only to the pharynx, esophagus, stomach, and intestines, but also to many associated structures. The salivary glands, liver, pancreas, trachea, and lungs, for example, all develop from the wall of the digestive tract and grow to become systems of branching tubes that open into the gut or pharvnx. The endoderm forms only the epithelial components of these structuresthe lining of the gut and the secretory cells of the pancreas, for example. The supporting muscular and fibrous elements arise from the mesoderm.

The mesoderm gives rise to the connective tissues—at first, to the loose mesh of cells in the embryo known as mesenchyme, and ultimately to cartilage, bone, and fibrous tissue, including the dermis (the inner layer of the skin). The mesoderm also forms the muscles, the entire vascular system—including the heart, blood vessels, and blood cells—and the tubules, ducts, and supporting tissues of the kidneys and gonads. The notochord forms from the mesoderm and serves as the core of the future backbone and the source of signals that coordinate the development of surrounding tissues.

The ectoderm will form the epidermis (the outer, epithelial layer of the skin) and epidermal appendages such as hair, sweat glands, and mammary glands. It will also give rise to the whole of the nervous system, central and peripheral, including not only neurons and glia but also the sensory cells of the nose, the ear, the eye, and other sense organs. (B, after T. Mohun et al., Cell 22:9–15, 1980.)

example, can give rise to the cell types that will line the gut or form gut-derived organs such as the liver or pancreas, but it no longer has the potential to form mesoderm-derived structures such as skeleton, heart, or kidney. Such a cell is said to be *determined* for an endodermal fate. Thus, **cell determination** starts early and progressively narrows the options as the cell steps through a programmed series of intermediate states—guided at each step by its genome, its history, and its interactions with neighbors. The process reaches its limit when a cell undergoes **terminal differentiation** to form one of the highly specialized cell types of the adult body (**Figure 21-4**). Some cell types in the adult, which maintain the ability to divide, also retain a degree of pluripotency, albeit with a generally narrow range of options. These adult stem cells are discussed in Chapter 22.

Cell Memory Underlies Cell Decision-Making

Underlying the richness and astonishingly complex outcomes of development is **cell memory** (see p. 435). Both the genes a cell expresses and the way it behaves depend on the cell's past, as well as on its present circumstances. The cells of our body—the muscle cells, the neurons, the skin cells, the gut cells, and so on—maintain their specialized characters largely because they retain a record of the extracellular signals their ancestors received during development, rather than because they continually receive such instructions from their surroundings. Despite their radically different phenotypes, almost all cells retain the same complete genome that was present in the zygote. Their differences arise instead from differential gene expression, which can lead to the stable inheritance of a particular cellular program. We have discussed the molecular mechanisms of gene regulation, cell memory, cell division, cell signaling, and cell movement in previous chapters. In this chapter, we shall see how these basic processes are collectively deployed as the developing animal self-assembles.

Several Model Organisms Have Been Crucial for Understanding Development

The anatomical features that animals share have undergone many extreme modifications in the course of evolution. As a result, the differences between species are usually more striking to our human eye than the similarities. But at the level of the underlying molecular mechanisms and the particular macromolecules involved, the reverse is true: the similarities among all animals are profound and extensive. Through more than half a billion years of evolutionary divergence, all animals have retained unmistakably similar sets of genes and proteins that are responsible for generating their body plans and for forming their specialized cells and organs.

This astonishing degree of evolutionary conservation was discovered not by broad surveys of animal diversity, but through intensive study of a small number of experimentally convenient species—the model organisms discussed in Chapter 1. For animal developmental biology, the most important have been the fly *Drosophila melanogaster*, the frog *Xenopus laevis*, the roundworm *Caenorhabditis elegans*, the mouse *Mus musculus*, and the zebrafish *Danio rerio*. In discussing the mechanisms of development, we shall draw our examples mainly from these few species, keeping in mind that they represent only a portion of the tree of animal life.

Regulatory DNA Seems Largely Responsible for the Differences Between Animal Species

Although many developmental mechanisms are conserved, they nevertheless produce animals that can be quite different. These differences arise primarily from variation in the activity of key development-controlling genes. As discussed in Chapter 7, each gene in a multicellular organism is associated with many thousands of nucleotides of noncoding DNA that contains regulatory elements. These

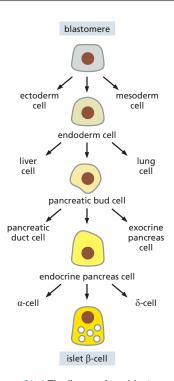

Figure 21–4 The lineage from blastomere to a terminally differentiated cell type. As development proceeds, cells become more and more specialized. Blastomeres have the potential to give rise to most or all cell types. Under the influence of signaling molecules and gene regulatory factors, cells acquire more restricted fates until they differentiate into highly specialized cell types, such as the pancreatic β cells that secrete the hormone insulin.

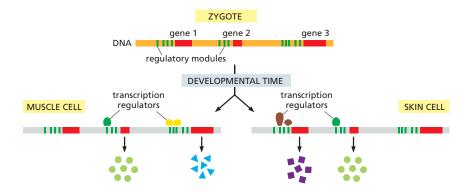

Figure 21–5 Regulatory DNA defines the gene expression patterns in development. The genome is the same in a muscle cell as in a skin cell, but different genes are active because these cells express different transcription regulators that bind to gene regulatory elements. For example, transcription regulators in skin cells recognize a regulatory element in gene 1, leading to its activation, whereas a different set of regulators is present in muscle cells, binding to and activating gene 3. Transcriptional regulators that activate the expression of gene 2 are present in both cell types.

regulatory elements determine when, where, and how strongly the gene product is expressed, according to the transcription regulators and chromatin structures that are present in the particular cell (Figure 21–5). Consequently, a change in sequence of the regulatory DNA that arises in evolution, even without any change in the coding DNA, can alter the logic of the gene regulatory network and change the outcome of development.

As discussed in Chapter 4, when we compare the genomes of different animal species, we find that evolution has altered the coding and regulatory DNA to different extents. The coding DNA can be quite conserved, but the noncoding regulatory DNA is usually much less so. It seems that changes in regulatory DNA are largely responsible for the dramatic differences between one class of animals and another (see p. 239). We can view the protein products of the conserved coding sequences as a kit of common molecular parts and the regulatory DNA as instructions for assembly: with different instructions, the same kit of parts can be used to make a whole variety of different body structures. We will return to this important concept later.

Small Numbers of Conserved Cell–Cell Signaling Pathways Coordinate Spatial Patterning

Spatial patterning of a developing animal requires that cells become different according to their positions in the embryo, which means that cells must respond to extracellular signals produced by other cells, especially their neighbors. In the most common mode of spatial patterning, a group of cells starts out with the same developmental potential, and a signal from cells outside the group then induces one or more members of the group to change their character. This process is called *inductive signaling*. Generally, the inductive signal is limited in time and space so that only a subset of the cells capable of responding—the cells close to the source of the signal—take on the induced character (Figure 21–6). Some inductive signals depend on cell-cell contact; others act over a longer range and are mediated by molecules that diffuse through the extracellular medium or are transported in the bloodstream (see Figure 15–2).

Most of the known inductive events in animal development are governed by a small number of highly conserved signaling pathways, including transforming growth factor- β (TGF β), Wnt, Hedgehog, Notch, and receptor tyrosine kinase (RTK) pathways (discussed in Chapter 15). The discovery of the limited vocabulary that developing cells use for intercellular communication has emerged as one of the great simplifying features of developmental biology.

Through Combinatorial Control and Cell Memory, Simple Signals Can Generate Complex Patterns

How can a small number of signaling pathways generate the huge diversity of cells and patterns? Several kinds of mechanisms are responsible. First, the effect of activating a signaling pathway depends on the previous experiences of the

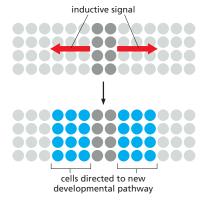

Figure 21–6 Inductive signaling. Cells (gray) expressing an extracellular signaling molecule direct a new cell fate in nearby neighbors (blue).

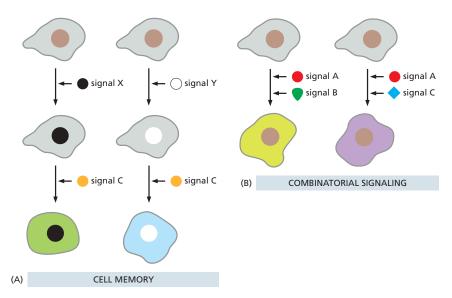

Figure 21–7 Two mechanisms for generating different responses to the same inductive signal. (A) Through cell memory, previous signals (or other events) can leave a lasting trace that alters the response to the current signal (see Figure 7–56). The memory trace is represented here in the coloring of the cell nucleus. (B) In combinatorial signaling, the effect of a signal depends on the presence of other signals received at the same time.

responding cell: past influences leave a lasting mark, registered in the state of the cell's chromatin and the selection of transcription regulators and RNA molecules that the cell contains. This cell memory enables cells with different histories to respond to the same signals differently (Figure 21–7A). Second, the response of a cell to a given signal depends on the other signals that the cell is receiving concurrently (Figure 21–7B). As a result, different combinations of signals can generate a large variety of different responses.

Alongside these two mechanisms, some components of a signaling pathway, such as ligands or receptors, are encoded by genes that have undergone duplication followed by functional divergence during evolution. These closely homologous genes can then be expressed in distinct cell types, where they can direct different signaling outcomes. Notch signaling, for example, may be mediated by Notch1 in one tissue, but by Notch4 in another, with each homolog inducing transcription of different target genes. Thus, the same few signaling pathways can be used repeatedly at different times and places with different outcomes, so as to generate patterns of unlimited complexity.

Morphogens Are Diffusible Inductive Signals That Exert Graded Effects

Signal molecules often govern simple yes-no choices—one outcome when their concentration is high, another when it is low or absent. In other cases, however, the responses are more finely graded: a high concentration of a signal molecule may, for example, direct cells into one developmental pathway, an intermediate concentration into another, and a low concentration into yet another.

One common way to generate such different concentrations of a signal molecule is for the molecule to diffuse out from a localized signaling source, creating a concentration gradient. Cells at different distances from the source are driven to behave in a variety of different ways, according to the signal concentration that they experience (Figure 21–8). A signal molecule that imposes a pattern on a whole field of cells in this way is called a **morphogen**. In the simplest case, a specialized group of cells produces a morphogen at a steady rate, and the morphogen is then degraded as it diffuses away from this source. The speed of diffusion and

MBOC7_ptr_ch21_1217-1278.indd 1222 02/12/21 12:24 PM

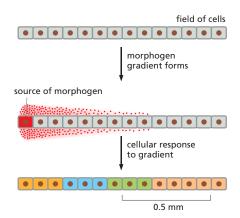

Figure 21–8 Gradient formation and interpretation. A gradient forms by the localized production of an inducer—a morphogen—that diffuses away from its source. Different concentrations of morphogen (or different durations of exposure) induce different gene expression patterns and cell fates in responding cells. Diffusive transport can generate steep gradients only over short distances, and morphogens generally act over distances of 1 mm or less.

the half-life of the morphogen will together determine the range and steepness of its resulting gradient (Figure 21–9).

Nearby cells then interpret their distance from the morphogen source according to how much signal they are exposed to, detected by binding to cell-surface receptors. After signal transduction from these receptors, target genes will become transcribed only if the morphogen concentration exceeds a specific threshold; low concentrations that fall beneath this threshold will not activate the target. In this manner, a graded signal can be converted into multiple discrete, on-or-off changes in gene activity. Thus, a single secreted protein, in combination with the physical properties of diffusion and the ability of cells to interpret the information, can generate several distinct fates within a field of cells.

This simple mechanism can be modified in various ways. For example, cell-surface receptors may trap the diffusing morphogen and cause it to be endocy-tosed and degraded, shortening its effective half-life. Alternatively, the morphogen may bind to molecules in the extracellular matrix such as heparan sulfate proteoglycan (discussed in Chapter 19), thereby greatly reducing its diffusion rate.

Lateral Inhibition Can Generate Patterns of Different Cell Types

Morphogen gradients, and other types of inductive signals, exploit an existing asymmetry in the embryo to create further asymmetries and differences between cells: already, at the outset, some cells are specialized to produce the morphogen and thereby impose a pattern on another class of cells that are sensitive to it. But what if there is no clear initial asymmetry? Can a regular pattern arise spontaneously within a set of cells that are initially all alike?

The answer is yes. The fundamental principle underlying such *de novo* pattern formation is positive feedback: cells can exchange signals in such a way that any small initial discrepancy between cells at different sites becomes self-amplifying, driving the cells toward different fates. This is most clearly illustrated in the phenomenon of *lateral inhibition*, a form of cell-cell interaction that forces close neighbors to become different and thereby generates fine-grained patterns of different cell types.

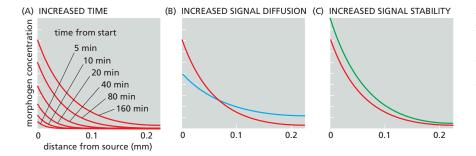

Figure 21-9 Setting up a signal gradient by diffusion. Each graph shows the concentration of a morphogen signal molecule that is produced at a steady rate at the origin. In all cases, the molecule undergoes degradation as it diffuses away from the source, and the graphs are calculated on the assumption that diffusion is occurring along two axes in space (for example, radially from a source in an epithelial sheet). (A) The pattern of the morphogen assuming that production starts at time 0, the molecule has a half-life of 170 minutes, and that it diffuses with an effective diffusion constant of D = 1 μm² sec⁻¹, typical of a small protein molecule in extracellular tissues. Red lines show six successive stages in the buildup of the morphogen, which falls off exponentially with distance from the source. Panels B and C show how simple changes in the properties of the system alter the gradient at the 160-minute time point. (B) A threefold increase in the diffusion constant of the morphogen extends its range (blue line) but lowers its concentration next to the source. (C) A threefold increase in morphogen half-life (green line) increases its concentration throughout the tissue. Effects of the morphogen will depend not just on its concentration at some critical moment, but also on how each target cell integrates its response over time. (Courtesy of Patrick

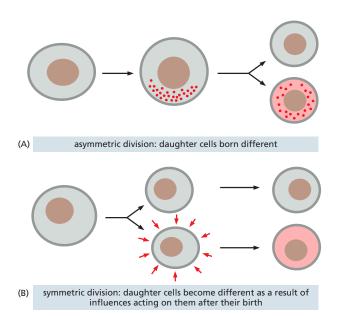

MBOC7_ptr_ch21_1217-1278.indd 1223 02/12/21 12:24 PM

Consider a pair of adjacent cells that start off in a similar state. Each of these cells can both produce and respond to a certain signal molecule X, with the added rule that the stronger the signal a cell receives, the weaker the signal it generates itself (Figure 21–10). If one cell produces more X, the other is thus forced to produce less, for instance by reducing transcription of the X-encoding gene. This gives rise to a positive feedback loop that tends to amplify any initial difference between the two adjacent cells. Such a difference may arise from a bias imposed by some present or past external factor or it may simply originate from spontaneous random fluctuations, or "noise"—an inevitable feature of the genetic control circuitry in cells (discussed in Chapter 7). In either case, lateral inhibition means that if cell 1 makes a little more of X, it will thereby cause cell 2 to make less; and because cell 2 makes less X, it delivers less inhibition to cell 1 and so allows the production of X in cell 1 to rise higher still; and so on, until a stable state is reached where cell 1 produces a lot of X and cell 2 produces very little. The result is that the two cells are driven along different pathways of differentiation.

In almost all tissues, a balanced mixture and distribution of different cell types are required. Lateral inhibition provides a common way to generate the mixture. As we shall see, lateral inhibition is very often mediated by exchange of signals at cell-cell contacts via the Notch signaling pathway, driving cell diversification by enabling individual cells that express one set of genes to direct their immediate neighbors to express a different set, in exactly the way we have described (see also Figure 15–60).

Asymmetric Cell Division Can Also Generate Diversity

Cell diversification does not always depend on extracellular signals: in some cases, cells are born different as a result of an asymmetric cell division, in which some important molecule or molecules present in the mother cell are distributed unequally between the two daughters. This asymmetric inheritance during mitosis ensures that the two daughter cells develop differently (Figure 21–11). The mechanism here is intrinsic to the dividing cell, although daughter cells can also become asymmetric after division as a result of the extrinsic, inductive signals discussed earlier. Intrinsically asymmetric division is a common feature of early development. The fertilized egg may already possess an internal pattern, and cleavage of this large cell segregates different fate determinants into separate blastomeres. We shall see later that asymmetric division also plays a part in later developmental processes, as well as in stem cells (see Chapter 22).

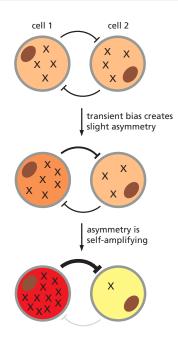

Figure 21-10 Genesis of asymmetry through lateral inhibition and positive feedback. In this example, two cells interact, each producing a substance X that acts on the other cell to inhibit its production of X, an effect known as lateral inhibition. An increase of X in one of the cells leads to a positive feedback that tends to increase X in that cell still further, while decreasing X in its neighbor. This can create an accelerating instability, making the two cells become radically different. Ultimately, the system comes to rest in one or the other of two opposite stable states. The final choice of state represents a form of memory: the small influence that initially directed the choice is no longer required to maintain it.

Figure 21–11 Two ways of making daughter cells different. Daughters can assume different fates either through (A) an intrinsically asymmetric division in which there is differential inheritance of cytoplasmic molecules or through (B) a symmetric division followed by signaling to only one daughter.

OVERVIEW OF DEVELOPMENT 1225

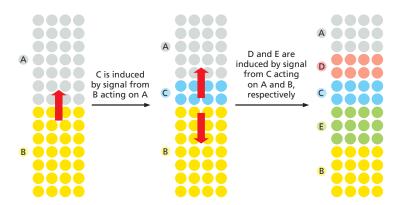

Figure 21–12 Patterning by sequential induction. A series of inductive interactions can generate many types of cells, starting from only a few.

Initial Patterns Are Established in Small Fields of Cells and Refined by Sequential Induction as the Embryo Grows

The signals that organize the spatial pattern of cells in an embryo generally act over short distances and govern relatively simple choices. A morphogen, for example, typically acts over a distance of less than 1 mm—an effective range for diffusion—and directs choices between several developmental options for the cells on which it acts. Yet the organs that eventually develop are much larger and more complex than this.

As the organ grows via cell proliferation, the refinement of its initial pattern is explained by a series of successive interactions that add increasing levels of detail to an initially simple sketch. For example, as soon as two types of cells are present in a developing tissue, one of them can produce a signal that induces a subset of neighboring cells to specialize in a third way. The third cell type can in turn signal back to the other two cell types nearby, generating a fourth and a fifth cell type, and so on (Figure 21–12).

This strategy for generating a progressively more complicated pattern is called **sequential induction**. It is chiefly through sequential inductions that the body plan of a developing animal, after being first roughed out in miniature, becomes elaborated with finer and finer details as development proceeds.

Developmental Biology Provides Insights into Disease and Tissue Maintenance

The rapid progress in understanding animal development has been one of the great success stories in biology, and it has important practical implications. Some 2–5% of all human babies are born with anatomical abnormalities, such as heart malformations, truncated limbs, cleft palate, or spina bifida. Advances in developmental biology help us understand how these defects arise, even if we cannot yet prevent or cure most of them.

Less obvious, but even more important from a practical point of view, is that developmental biology also provides insights into the workings of cells and tissues in the adult body. Developmental processes do not halt at birth; they continue throughout life, as tissues are maintained and repaired. The fundamental mechanisms of cell growth and division, cell-cell signaling, cell memory, cell adhesion, and cell movement are all involved in adult tissue maintenance and repair—just as they are in embryo development. These are also the main mechanisms perturbed in tumor cells, as we saw in Chapter 20.

Embryos are simpler than adults, and they allow us to analyze such basic processes more easily. Studies of the early *Drosophila* embryo, for example, were crucial to the discovery of several conserved signaling pathways, including the Wnt, Hedgehog, and Notch pathways. They also provided the key to understanding the central role of these pathways in the maintenance of normal adult human tissues and laid the foundation for manipulating the pathways in the cause of regenerative medicine. Finally, they have identified both targets and rational mechanisms for therapies to fight cancer and other diseases.

In Chapter 22, we shall consider how these and other core developmental mechanisms operate in the normal adult body, especially in tissues that are continually renewed by means of stem cells—including the gut, skin, and the hematopoietic system. But now, we must look more closely at the way in which an early embryo generates its spatial pattern of specialized cells, beginning with the transformations that create the adult body plan.

Summary

Animal development is an amazing self-assembly process, in which the initially similar cells of the embryo become different from one another and organize themselves into increasingly complex structures. The process begins with a single large cell, the fertilized egg, which cleaves to produce a blastula that undergoes gastrulation to generate the three germ layers of the embryo—ectoderm, mesoderm, and endoderm. As development continues, the cells become more and more narrowly specialized according to their locations and their interactions with one another, eventually forming one of the differentiated cell types of the adult body.

Differences between developing cells arise in various ways and have to be properly coordinated in space. In one common strategy, initially similar cells within a group become different by exposure to different levels of an inductive signal or morphogen emanating from a source outside the group. Neighboring cells can also become different by lateral inhibition, in which a cell signals to its neighbors not to follow the same fate. These cell-cell interactions are mediated by a small number of highly conserved signaling pathways, which are used repeatedly in different organisms and at different times during development. Not all cell diversification arises by cell-cell interactions, however: daughter cells can be born different as a result of asymmetric cell division.

Regulators of transcription and chromatin structure bind to regulatory DNA and determine the fate of each cell. Differences of body plan seem to arise to a large extent from differences in the regulatory DNA associated with each gene. This DNA has a central role in defining the sequential program of development, calling genes into action at specific times and places according to the pattern of gene expression that was present in each cell at the previous developmental stage.

Development has been most thoroughly studied in a handful of model organisms. But most of the genes and mechanisms thereby identified are used in all animals and repeatedly at different stages of development. Thus, insights from worms, flies, fish, frogs, and mice deeply inform our understanding of embryology and adult tissue maintenance in humans, as well as how aberrations in these processes cause birth defects and cancer.

MECHANISMS OF PATTERN FORMATION

A developing multicellular organism has to create different cell fates in fields of cells that were nearly indistinguishable and accomplish this task in a spatially ordered manner so that functional tissues are formed. Some of the early microscopists imagined the entire shape and structure of the human body to be already present in the sperm as a "homunculus," a miniature human; after fertilization, the homunculus would simply grow and generate a full-sized person. We now know that this view is incorrect, and that development is a progression from simple to complex, through a gradual refinement of an animal's anatomy. To see how the whole sequence of events of spatial patterning and cell determination is set in motion, we must return to the egg and the early embryo.

Different Animals Use Different Mechanisms to Establish Their Primary Axes of Polarization

Surprisingly, the earliest steps of animal development are among the most variable, even within a phylum. A frog, a chicken, and a mammal, for example, even though they develop in similar ways later, make eggs that differ radically in size and structure, and they begin their development with different sequences of cell

MBOC7_ptr_ch21_1217-1278.indd 1226 02/12/21 12:24 PM

divisions and cell specializations. Likewise, there is great variation in the time and manner in which the primary axes of the body become marked out. However, this *polarization* of the embryo usually becomes discernible very early, before gastrulation begins—it is the first step of spatial patterning.

Two axes have to be established. The *anteroposterior* (*A-P*) axis specifies the locations of future head and tail. The *dorsoventral* (*D-V*) axis specifies the future back and belly. For species that show bilateral asymmetry, creation of an additional *left-right* (*L-R*) axis is also important. Finally, the eggs of many animals have an *animal-vegetal* (*A-V*) axis that is not evident in the adult, but defines which parts are to become internal (through the movements of gastrulation) and which are to remain external. (The bizarre name dates from a century ago and has nothing to do with vegetables.)

At one extreme within animal diversity, the egg is spherically symmetrical, and the axes only become defined during embryogenesis. The mouse is one example, with little obvious sign of polarity in the egg. Correspondingly, the blastomeres produced by the first few cell divisions all seem to be alike and are remarkably adaptable. If the early mouse embryo is split in two, a pair of identical twins can be produced—two complete, normal individuals from a single cell. Similarly, if one of the cells in a two-cell mouse embryo is destroyed by pricking it with a needle and the resulting "half-embryo" is placed in the uterus of a foster mother to develop, in many cases a perfectly normal mouse will emerge.

At the opposite extreme, an egg is built with an asymmetric structure that itself defines the future axes of the body. This is the case for most species, including insects such as *Drosophila*, as we shall see shortly. Other organisms lie somewhere in between. The egg of the frog *Xenopus*, for example, has a clearly defined A-V axis before fertilization: the pronucleus near the top defines the animal pole, while the mass of yolk (the embryo's food supply, destined to be incorporated in the gut) toward the bottom defines the vegetal pole. Several types of mRNA molecules are already localized in the vegetal cytoplasm of the egg, where they produce their protein products. After fertilization, these mRNAs and proteins act in and on the cells in the lower and middle part of the embryo, giving the cells their specialized characters.

Formation of the D-V axis of the *Xenopus* embryo is triggered by fertilization. At the site where the sperm enters, which is only permitted in the region of the animal pole, the sperm centrosome nucleates a microtubule aster. This reorganization of the microtubule cytoskeleton causes the outer cortex of the egg to rotate relative to the central core of the egg cytoplasm, so that the animal pole of the cortex becomes slightly shifted to one side (Figure 21-13). Cortical rotation

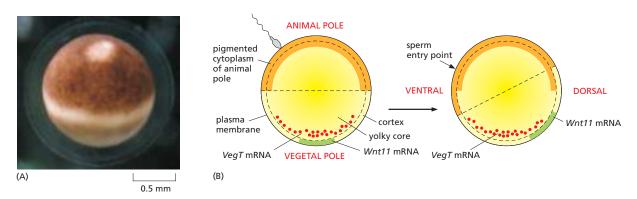

Figure 21–13 The frog egg and its asymmetries. (A) Side view of a *Xenopus* egg photographed just before fertilization. (B) The asymmetric distribution of molecules inside the egg along the animal–vegetal axis, and how fertilization activates dorsoventral asymmetry. Vegetally localized *VegT* in the unfertilized egg defines the vegetal source of signals that will induce endoderm and mesoderm. Sperm entry initiates a reorganization of the microtubule cytoskeleton that triggers a rotation of the egg cortex (a layer a few micrometers deep) through about 30° relative to the core of the egg. Cortical rotation relocalizes Wnt signaling components including *Wnt11* mRNA to the future dorsal side, which sets up the dorsoventral axis of the embryo. (A, courtesy of Tony Mills.)

MBOC7_ptr_ch21_1217-1278.indd 1227 02/12/21 12:24 PM

relocalizes signaling molecules and initiates a cascade of events that will organize the dorsoventral axis of the body. (The A-P axis of the embryo will only become clear later, in the process of gastrulation.) This general process, by which a cue creates a new axis in the embryo, is known as *symmetry breaking*.

Although different animal species use a variety of different mechanisms to specify their overall organization, the outcome has been relatively well conserved in evolution: head is distinguished from tail, back from belly, and gut from skin. It seems that it does not much matter what tricks the embryo uses, it always manages to break the initial symmetry and set up its basic body plan.

Studies in *Drosophila* Have Revealed Many Genetic Control Mechanisms Underlying Development

It is the fly *Drosophila*, more than any other organism, that has provided the key to our present understanding of how genes govern early development. Decades of study culminated in a large-scale genetic screen, focusing on the early embryo and searching for mutations that disrupt its pattern. This revealed a group of key developmental genes that act in a relatively small set of regulatory pathways. The discovery of these genes and the subsequent analysis of their functions is a famous *tour de force* that has had a revolutionary impact on all of biology, earning its discoverers a Nobel Prize. Some parts of the machinery revealed in this way are conserved between flies and vertebrates, some parts not. But the logic of the experimental approach and the general strategies of genetic control that it revealed have transformed our understanding of multicellular development in general.

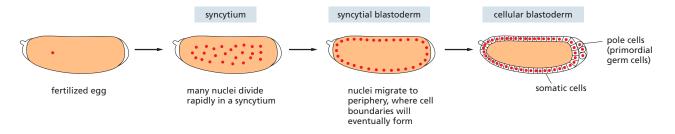

To understand how the early developmental machinery operates in *Drosophila*, it is important to note a peculiarity of fly development. Like the eggs of other insects, but unlike most vertebrates, the *Drosophila* egg—shaped like a cucumber—begins its development with an extraordinarily rapid series of nuclear divisions without cell division, producing multiple nuclei in a common cytoplasm—a **syncytium**. The nuclei then migrate to the cell cortex, forming a structure called the *syncytial blastoderm*. After about 6000 nuclei have been produced, the plasma membrane folds inward between them and partitions them into separate cells, converting the syncytial blastoderm into the *cellular blastoderm* (Figure 21–14).

We shall see that the initial patterning of the *Drosophila* embryo depends on molecules that diffuse through the cytoplasm at the syncytial stage and exert their actions on genes in the rapidly dividing nuclei, before the partitioning of the egg into separate cells. Here, there is no need for the usual forms of cell-cell signaling; neighboring regions of the syncytial blastoderm can communicate by means of transcription regulators that move through the cytoplasm of the giant multinuclear cell.

Gene Products Deposited in the Egg Organize the Axes of the Early *Drosophila* Embryo

As in most insects, the main axes of the future body of *Drosophila* are defined before fertilization by a complex exchange of signals between the developing egg, or *oocyte*, and the mother's somatic cells that surround it in the ovary.

Figure 21–14 Development of the *Drosophila* egg from fertilization to the cellular blastoderm stage.

MBOC7_ptr_ch21_1217-1278.indd 1228 02/12/21 12:24 PM

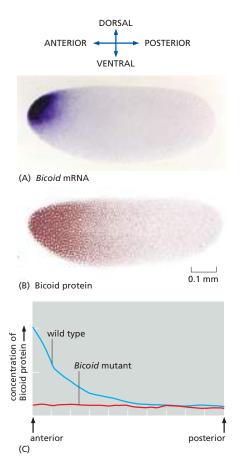

Figure 21–15 The Bicoid protein gradient. (A) Bicoid mRNA is deposited at the anterior pole during oogenesis. (B) Local translation followed by diffusion generates the Bicoid protein gradient. (C) Absence of the Bicoid protein gradient in embryos from Bicoid homozygous mutant mothers. (A and B, courtesy of Stephen Small.)

These signals can be described as **maternal effect**, because it is the genome of the mother rather than the zygote that produces them. Before fertilization, the anteroposterior and dorsoventral axes of the future embryo become defined by systems of **egg-polarity genes** that create landmarks—either mRNA or protein—in the oocyte. After fertilization, each landmark serves as a beacon, providing a signal that organizes the developmental process in its neighborhood.

The nature of the egg-polarity genes emerged from studies of mutants in which the patterning of the embryo was altered. Some of these mutations gave embryos with disrupted polarity; for example, one caused tail-end structures at both ends of the body, with no head-end structures. This particular mutation allowed the identification of the landmark that organizes the anterior end of the embryo, called *Bicoid*. A deposit of *Bicoid* mRNA molecules is localized, before fertilization, at the anterior end of the egg. Upon fertilization, the mRNA is translated to produce Bicoid protein. This protein is an intracellular morphogen and transcription regulator that diffuses away from its source to form a concentration gradient within the syncytial cytoplasm, with its maximum at the head end of the embryo (Figure 21–15). The different concentrations of Bicoid along the A-P axis help determine different cell fates by directly regulating the transcription of genes in the nuclei of the syncytial blastoderm (discussed in Chapter 7).

There are three other egg-polarity gene systems that pattern the syncytial nuclei; two act along the A-P axis and one acts along the D-V axis. Together with the *Bicoid* group of genes, and acting in a broadly similar way, their gene products mark out three fundamental partitions of body regions—head versus rear,

MBOC7_ptr_ch21_1217-1278.indd 1229 02/12/21 12:24 PM

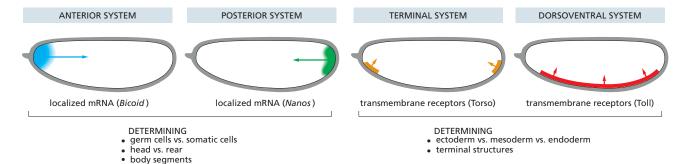

Figure 21–16 The organization of the four egg-polarity gradient systems in *Drosophila*. *Bicoid* mRNA encodes a transcriptional activator that determines the head and thoracic regions. Nanos is a translational repressor that governs the formation of the abdomen. Localized *Nanos* mRNA is also incorporated into the germ cells as they form at the posterior of the embryo, and Nanos protein is necessary for germ-line development. Toll and Torso are receptor proteins that are distributed all over the membrane but are activated only at the sites indicated by the coloring, through localized exposure to the extracellular ligands Spaetzle (the ligand for Toll) and Trunk (the ligand for Torso). Toll activity determines the mesoderm and Torso activity determines the formation of terminal structures at the head and tail.

dorsal versus ventral, and endoderm versus mesoderm and ectoderm—as well as a fourth partition, no less fundamental to the body plan of animals: the distinction between germ cells and somatic cells (Figure 21–16).

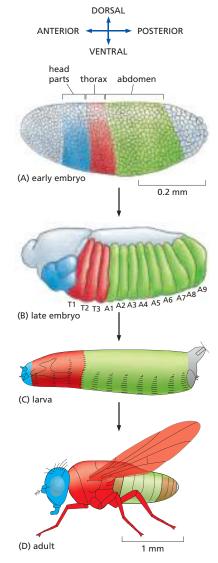

The egg-polarity genes act first in a hierarchy of gene systems that define a progressively more detailed pattern of body parts. In the next few pages, we begin with the molecular mechanisms that pattern the developing *Drosophila* embryo and larva along the A-P axis, before considering the patterning along the D-V axis.

Three Groups of Genes Control *Drosophila* Segmentation Along the A-P Axis

The body of an insect is divided along its A-P axis into a series of **segments**. The segments are repetitions of a theme with variations: each segment forms highly specialized structures, all built according to a similar fundamental plan (Figure 21–17). The gradients of transcription regulators set up along the A-P axis in the early embryo by the egg-polarity genes are the prelude to the creation of the segments. These regulators initiate the orderly transcription of *segmentation genes*, which refine the pattern of gene expression to define the boundaries and ground plan of the individual segments. Segmentation genes are expressed by subsets of cells in the embryo, and their products are among the first components that the embryo's own genome contributes to embryonic development; they are therefore called *zygotic-effect genes*, to distinguish them from the earlier-acting maternal-effect genes. Mutations in segmentation genes can alter either the number of segments or their basic internal organization.

The **segmentation genes** fall into three groups according to their mutant phenotypes (**Figure 21–18**). It is convenient to think of the three groups as acting in sequence, although in reality their functions overlap in time. First to be expressed is a set of at least six **gap genes**, whose products mark out coarse A-P subdivisions of the embryo. Mutations in a gap gene eliminate one or more groups of adjacent segments: in the mutant *Krüppel*, for example, the larva lacks eight segments. Next comes a set of eight **pair-rule genes**. Mutations in these genes

Figure 21–17 The origins of the *Drosophila* body segments. (A) At 3 hours, the embryo (shown in side view) is at the blastoderm stage and no segmentation is visible, although a fate map can be drawn showing the future segmented regions (color). (B) At 10 hours, all the segments are clearly defined (T1: first thoracic segment; A1: first abdominal segment). See Movie 21.3. (C) The segments of the *Drosophila* larva and their correspondence with regions in the embryo. (D) The segments of the *Drosophila* adult and their correspondence with regions in the embryo.

MBOC7_ptr_ch21_1217-1278.indd 1230 02/12/21 12:24 PM

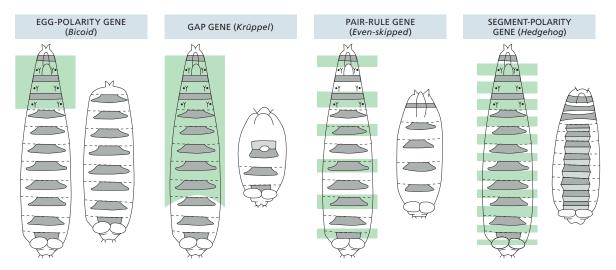

Figure 21–18 Examples of the phenotypes of mutations affecting egg-polarity genes and the three types of segmentation genes. In each case, the areas shaded in *green* on the normal larva (*left*) are deleted in the mutant (*right*) or are replaced by mirror-image duplicates of the unaffected regions. (Modified from C. Nüsslein-Volhard and E. Wieschaus, *Nature* 287:795–801, 1980.)

cause a series of deletions affecting alternate segments, leaving the embryo with only half as many segments as usual; although all the mutants display this two-segment periodicity, they differ in the precise pattern. Finally, there are at least 10 **segment-polarity genes**, in which mutations produce a normal number of segments but with a part of each segment deleted and replaced by a mirrorimage duplicate of all or part of the rest of the segment.

The phenotypes of the various segmentation mutants suggest that the segmentation genes form a coordinated system that subdivides the embryo progressively into smaller and smaller domains along the A-P axis, each distinguished by a different pattern of gene expression. Molecular genetics has helped to reveal how this system works.

A Hierarchy of Gene Regulatory Interactions Subdivides the *Drosophila* Embryo

Like *Bicoid*, most of the segmentation genes encode transcription regulators. Their control by the egg-polarity genes and their actions on one another and on still other genes can be deciphered by comparing gene expression in normal and mutant embryos. By using appropriate probes to detect RNA transcripts or their protein products, one can observe genes switch on and off in changing patterns. These patterns reveal the wealth of spatial information created within the morphologically uniform embryo by the egg-polarity gene network. By comparing these patterns in different mutants, one can begin to discern the logic of the entire gene control system.

The products of the egg-polarity genes provide the global positional signals in the early embryo (see Figure 21–16). The Bicoid protein, as we have seen, acts as a morphogen and activates different sets of genes at different positions along the A-P axis: some gap genes are only activated in regions with high levels of Bicoid, others only where levels of Bicoid are lower. There are only six gap genes, but a combination of overlapping expression as well as different levels within their domains provides each cell along the A-P axis with a rich variety of positional identities. After the gap-gene products refine their positions by repressing each other's expression, they provide a second tier of positional signals that act more locally to regulate finer details of patterning. They control the expression of the pair-rule genes, through combinatorial effects as discussed in Chapter 7 for the pair-rule gene *Even-skipped* (see pp. 423–424). The pair-rule genes demarcate

MBOC7_ptr_ch21_1217-1278.indd 1231 02/12/21 12:24 PM

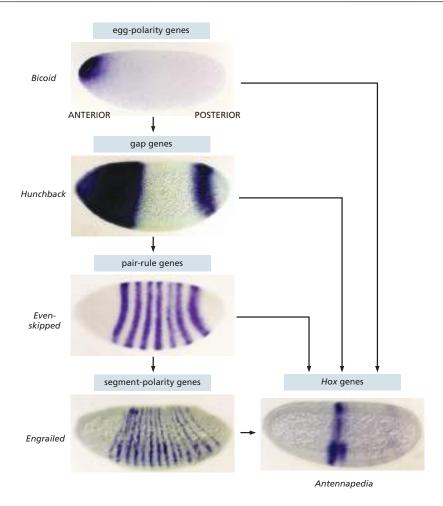

Figure 21–19 The regulatory hierarchy of A-P patterning in the *Drosophila* embryo. Egg-polarity genes define the A-P axis and also initiate expression of three groups of genes (gap, pair-rule, and segment polarity) that create segments. The identity of each segment is specified by *Hox* genes (discussed shortly), whose expression is controlled by input from both egg-polarity and segmentation genes. The photographs show mRNA expression patterns of representative examples of genes of each type. (Courtesy of Stephen Small.)

the repeated groups of cells that will later become segments and, in turn, collaborate with one another and with the gap genes to set up a regular, periodic pattern of expression of the segment-polarity genes, which define the internal pattern of each individual segment (Figure 21–19).

A large subset of the segment-polarity genes codes for components of two signaling pathways—the Wnt pathway and the Hedgehog pathway, including the secreted signal proteins Wingless (the first-named member of the Wnt family) and Hedgehog. (The Hedgehog pathway was first discovered through study of *Drosophila* segmentation, and it takes its name from the prickly appearance of the surface of the *Hedgehog* mutant embryo.) Wingless and Hedgehog are synthesized in different bands of cells that serve as signaling centers within each segment. The two proteins mutually maintain each other's expression while regulating the expression of genes such as *Engrailed* in neighboring cells (**Figure 21–20**). In such a manner, a series of sequential inductions creates a fine-grained pattern of gene expression within each segment.

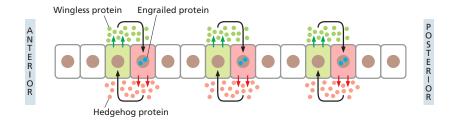

Figure 21-20 Mutual maintenance of Hedgehog and Wingless expression. Engrailed is a transcription regulator (blue) that drives the expression of Hedgehog. Hedgehog encodes a secreted protein (red) that activates a signaling pathway in neighboring cells and thereby drives them to express the Wingless gene. In turn, Wingless encodes a secreted protein (green) that acts back on neighbors of the Wingless-expressing cell to maintain their expression of Engrailed. Engrailed then maintains Hedgehog expression to complete the loop. As indicated, the same network repeats along the A-P axis of the flv. (Based on S. DiNardo et al., Curr. Opin. Genet. Dev. 4:529-534, 1994.)

MBOC7_ptr_ch21_1217-1278.indd 1232 02/12/21 12:24 PM

Egg-Polarity, Gap, and Pair-Rule Genes Create a Transient Pattern That Is Remembered by Segment-Polarity and *Hox* Genes

The gap genes and pair-rule genes are activated within the first few hours after fertilization. Their mRNA products initially appear in patterns that only approximate the final picture; then, within a short time, this fuzzy initial pattern resolves itself into a regular, crisply defined system of stripes. But this pattern itself is unstable and transient: as the embryo proceeds through gastrulation and beyond, the pattern disintegrates. The genes' actions, however, have passed on an enduring memory of their patterns of expression by inducing the expression of certain segment-polarity genes along with another class of genes called *Hox* genes (discussed shortly). After a period of pattern refinement mediated by cell-cell interactions, the expression patterns of these new groups of patterning genes are stabilized to provide positional labels that serve to maintain the segmental organization of the larva and adult fly.

The segment-polarity gene *Engrailed* provides a good example. Its RNA transcripts form a series of 14 bands in the cellular blastoderm, each approximately one cell wide. These stripes lie immediately anterior to similar stripes of expression of another segment-polarity gene, *Wingless*. As the cells in the developing embryo continue to divide and move, signaling between the Wingless-expressing cells and the Engrailed-expressing cells maintains narrow stripes of their expression (see Figure 21–20). This interaction triggers a stable Engrailed expression pattern that will last throughout the life of the fly, long after the signals that induced and refined it have disappeared. The segment borders in embryo, larva, and adult will all form at the posterior edge of each such Engrailed stripe (Figure 21–21).

In addition to regulating the segment-polarity genes, the products of pair-rule genes collaborate with those of gap genes to induce the precisely localized activation of a further set of genes—the *Hox genes* (see Figure 21–19). It is the *Hox* genes that first define and then permanently distinguish one segment from another. In the next section, we examine these important genes in detail; we shall see that this role is critical in a wide range of animals, including ourselves.

Hox Genes Permanently Pattern the A-P Axis

As animal development proceeds, the body becomes more and more complex. But again and again, in every species and at every level of organization, we find that complex structures are made by repeating a few elementary themes, with variations. Thus, a subset of basic differentiated cell types, such as muscle cells or fibroblasts, recur at different sites and are organized into tissues such as muscle or tendon. Subtle variations in how and where patterning mechanisms are deployed determines how structures such as teeth or digits are built, giving rise to molars and incisors, fingers and thumbs and toes.

Wherever we find this phenomenon of *modulated repetition*, we can break down the developmental biologist's problem into two kinds of questions: What is the basic construction mechanism common to all the objects of the given class, and how is this mechanism modified to give the observed variations in different animals? The segments of the insect body provide a good example. We have thus far sketched the way in which the rudiment of a single body segment is constructed and how cells within each segment become different from one another. We now consider how one segment becomes determined, or *specified*, to be different from another.

The first glimpse of the answer to this problem came more than 80 years ago, with the discovery of a set of mutations in *Drosophila* that cause bizarre disturbances in the organization of the adult fly. In the *Antennapedia* mutant, for example, legs sprout from the head in place of antennae, whereas in the *Bithorax* mutant, portions of an extra pair of wings appear where normally there should be the much smaller appendages called halteres (Figure 21–22). These mutations transform parts of the body into structures appropriate to other positions, and

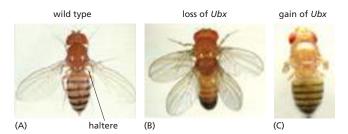

A THE STATE OF THE PARTY OF THE

adult

Figure 21-21 The pattern of expression of Engrailed, a segment-polarity gene. The Engrailed pattern is shown in a 10-hour embryo and an adult (whose wings have been removed in this preparation). The pattern is revealed by constructing a strain of Drosophila containing the control sequences of the Engrailed gene coupled to the coding sequence of the reporter LacZ, whose product is detected histochemically through the brown product generated by immunohistochemistry against LacZ itself (10-hour embryo) or through the blue product generated by a reaction that LacZ catalyzes (adult). Note that the Engrailed pattern marks segment boundaries and, once established, is preserved throughout the animal's life. (Courtesy of Tom Kornberg.)

MBOC7_ptr_ch21_1217-1278.indd 1233 02/12/21 12:24 PM

they are called *homeotic* mutations (from the Greek *homoios*, meaning "similar") because the transformation is between structures of a recognizably similar general type, changing one kind of limb or one kind of segment into another. It was eventually discovered that a whole set of genes, the **homeotic selector genes** or **Hox genes**, serve to permanently specify the A-P characters of the whole set of animal segments. These genes are all related to one another as members of a multigene family.

There are eight *Hox* genes in the fly, and they all lie in one or the other of two gene clusters known as the *Bithorax* complex and the *Antennapedia* complex. The genes in the *Bithorax* complex control the differences among the abdominal and thoracic segments of the body, while those in the *Antennapedia* complex control the differences among thoracic and head segments. Comparisons with other species show that the same genes are present in essentially all animals, including humans. These comparisons also reveal that the *Antennapedia* and *Bithorax* complexes are two halves of a single entity, called the *Hox* complex, that has become split in the course of the fly's evolution, and whose members operate in a coordinated way to exert their control over the head-to-tail pattern of the body.

The products of the *Hox* genes, the **Hox proteins**, are transcription regulators, all of which possess a highly conserved, 60-amino-acid-long DNA-binding *home-odomain* (see p. 404). The homeodomain-encoding DNA sequence is called a "homeobox," from which, by abbreviation, the *Hox* complex takes its name. There are many homeobox-containing genes, but only those located in a *Hox* complex are *Hox* genes.

Hox Proteins Give Each Segment Its Individuality

The Hox proteins can be viewed as molecular address labels possessed by the cells of each segment: these labels give the cells in each region a **positional value**; that is, an intrinsic character that differs according to a cell's location. If the address labels in a developing *Drosophila* segment are changed, the segment behaves as though it were located somewhere else; if all the *Hox* genes in an embryo are deleted, the body segments in the larva will all be alike.

To a first approximation, each *Hox* gene is normally expressed in those regions that develop abnormally when that gene is mutated or absent. How does each Hox protein give a segment its permanent identity? Recall that the Hox proteins are transcription regulators, which can bind to gene regulatory DNA; each Hox protein targets a different set of genes for activation or repression. Hundreds of genes are under this type of Hox-modulated control, including genes that control cell-cell signaling, transcriptional regulation, cell polarity, cell adhesion, cytoskeletal function, cell growth, and cell death, all conspiring to give each segment its distinctive Hox-dependent character.

Hox Genes Are Expressed According to Their Order in the Hox Complex

How, then, is the expression of the *Hox* genes themselves regulated? The coding sequences of the eight *Hox* genes in *Drosophila* are interspersed amid a much larger quantity of regulatory DNA. This DNA includes binding sites for the

Figure 21-22 Homeotic mutations. Ultrabithorax, or Ubx, is one of three genes in the Bithorax gene complex (a Hox gene cluster). Ubx is responsible for all of the differences between the second (wing-bearing) and third (haltere-bearing) thoracic segments. (A and B) Ubx loss-offunction mutations transform the halterebearing segment (A) into a wing-bearing segment, resulting in four-winged flies (B). (C) Ubx gain-of-function in the second thoracic segment transforms this wingbearing segment into a haltere-bearing segment, resulting in wingless flies. (A, courtesy of the Archives, California Institute of Technology; C, courtesy of L.S. Shashidhara.)

MBOC7_ptr_ch21_1217-1278.indd 1234 02/12/21 12:24 PM

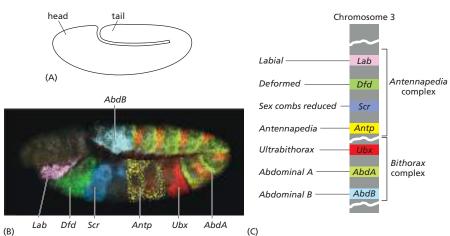

Figure 21-23 The patterns of expression compared to the chromosomal locations of the genes of the Hox complex. (A) Diagram of a Drosophila embryo at the so-called germ band retraction stage, about 10 hours after fertilization when the developing body axis is folded over on itself. (B) An embryo at this stage has been stained by in situ hybridization using differently labeled probes to detect the mRNA products of different Hox genes in different colors. (C) The spatial pattern in the photograph corresponds, with minor deviations, to the sequence of genes in each of the two subdivisions of the chromosomal complex. (B, courtesy of William McGinnis, adapted from D. Kosman et al., Science 305:846, 2004. With permission from AAAS.)

products of the egg-polarity and segmentation genes, thereby serving as an interpreter of the detailed spatial information supplied to it by all of these transcription regulators. The net result is that a particular set of *Hox* genes is transcribed in a specific region along the A-P body axis.

The pattern of *Hox* gene expression exhibits a remarkable regularity that suggests an additional form of control. The sequence in which the genes are ordered along the chromosome, in both the *Antennapedia* and the *Bithorax* complexes, corresponds almost exactly to the order in which they are expressed along the A-P axis of the body (Figure 21–23). This hints at some process of gene activation, perhaps dependent on chromatin structures that propagate along the *Hox* complexes, switching on one *Hox* gene after another according to their order along the chromosome. The most "posterior" of the *Hox* genes that are expressed in a cell generally dominates, driving down expression and activity of the "anterior" genes and dictating the character of the segment. The gene regulatory mechanisms underlying these phenomena are still not well understood, but their consequences are profound. We shall see that the serial organization of gene expression in the *Hox* complex is a fundamental feature that has been highly conserved in the course of animal evolution.

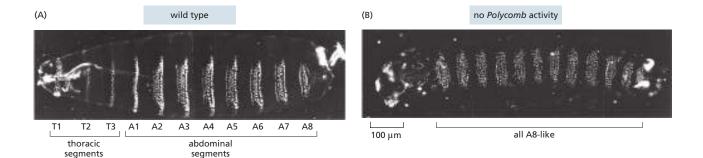

Trithorax and Polycomb Group Proteins Regulate *Hox* Expression to Maintain a Permanent Record of Positional Information

The spatial pattern of expression of the genes in the *Hox* complex is set up by signals acting early in development, but the effects are long lasting. Although the pattern of expression undergoes complex adjustments as development proceeds, the *Hox* pattern stamps each cell and all of its progeny with a permanent record of the A-P position that the cell occupied in the early embryo. In this way, the cells of each segment maintain a memory of their location along the A-P axis of the body, which governs the segment-specific identity not only of the larval segments but also of the structures of the adult fly.

Two molecular mechanisms ensure that a cell remembers its positional information. One is from the *Hox* genes themselves: many of the Hox proteins autoactivate the transcription of their own genes, thereby helping to keep the genes on indefinitely. Another crucial input is from two large, complementary sets of proteins, called the **Trithorax group** and the **Polycomb group**, which imprint the chromatin of the *Hox* complex with a heritable record of its embryonic state of activation or repression. These are key general regulators of chromatin structure that are critical for cell memory: if genes of the *Trithorax* or *Polycomb* group are defective, the pattern of expression of the *Hox* genes is set up correctly at first, but it is not correctly maintained as cells divide and the embryo grows older.

The two sets of regulators act in opposite ways. Trithorax group proteins are needed to maintain the transcription of *Hox* genes in cells where their

MBOC7_ptr_ch21_1217-1278.indd 1235 02/12/21 12:24 PM

transcription has already been switched on. In contrast, Polycomb group proteins form stable complexes that bind to the chromatin of the *Hox* complex and maintain the repressed state in cells where *Hox* genes have not yet been activated (Figure 21–24). Although first discovered because of their influence on *Hox* genes in flies, Polycomb and Trithorax group proteins are general regulators of chromatin structure that control many genes in plants as well as animals. How such changes in chromatin can store developmental cell memory is discussed in Chapters 4 and 7.

The D-V Signaling Genes Create a Gradient of the Transcription Regulator Dorsal

We now turn to patterning of the second major axis of the *Drosophila* embryo. As with the patterning along the A-P axis just discussed, the patterning along the dorsoventral (D-V) axis begins with maternal gene products that define this axis in the egg (see Figure 21–16) and then progresses through zygotic gene products that further subdivide the D-V axis in the embryo.

Initially, a protein that is produced by the mother's somatic cells underneath the future ventral region of the embryo leads to the localized activation of a transmembrane receptor called Toll on the ventral side of the egg membrane. (Curiously, Drosophila Toll and vertebrate Toll-like proteins also operate in innate immune responses, as discussed in Chapter 24.) The localized activation of Toll controls the distribution of Dorsal, a transcription regulator of the NFkB family discussed in Chapter 15. The Toll-regulated activity of Dorsal, like that of NFkB, depends on the translocation of Dorsal protein from the cytosol, where it is held in an inactive form, to the nucleus, where it regulates gene expression (see Figure 15-63). In the newly laid egg, both Dorsal mRNA and protein are distributed uniformly in the cytosol. After the nuclei in the syncytial blastoderm have migrated to the surface of the embryo, but before cellularization (see Figure 21-14), Toll receptor activation on the ventral side induces a remarkable redistribution of the Dorsal protein. On the dorsal side, the protein remains in the cytosol, but ventrally it becomes concentrated in the nuclei, with a smooth gradient of nuclear localization between these two extremes (Figure 21-25).

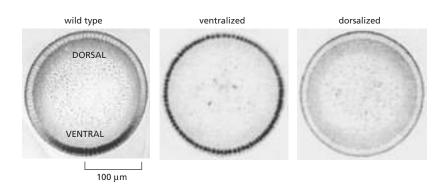

Figure 21-24 The role of genes of the Polycomb group. (A) Photograph of a wild-type Drosophila embryo, imaged by dark-field microscopy. (B) Photograph of a mutant embryo defective for the gene Extra sex combs (Esc) and derived from a mother also lacking this gene. The gene belongs to the Polycomb group. Essentially all segments have been transformed to resemble the most posterior abdominal segment, A8. In the mutant, the pattern of expression of the homeotic selector genes, which is roughly normal initially, is unstable in such a way that all these genes soon become switched on all along the body axis. (From G. Struhl, Nature 293:36-41, published 1981 by Nature Publishing Group. Reproduced with permission of SNCSC.)

Figure 21-25 The concentration gradient of Dorsal protein in the nuclei of the blastoderm. In wild-type Drosophila embryos, the protein is present in the dorsal cytoplasm and absent from the dorsal nuclei; ventrally, it is depleted in the cytoplasm and concentrated in the nuclei. In a mutant in which the Toll pathway is activated everywhere and not just ventrally, Dorsal protein is everywhere concentrated in the nuclei: the result is a ventralized embryo. Conversely, in a mutant in which the Toll signaling pathway is inactivated, Dorsal protein everywhere remains in the cytoplasm and is absent from the nuclei: the result is a dorsalized embryo. (From S. Roth et al., Cell 59:1189-1202, 1989. With permission from Elsevier.)

MBOC7_ptr_ch21_1217-1278.indd 1236 02/12/21 12:24 PM

Similar to Bicoid along the A-P axis, Dorsal acts as a morphogen along the D-V axis. Once inside the nucleus, the Dorsal protein turns on or off the expression of different sets of genes depending on Dorsal's concentration. The expression of each responding gene depends on its regulatory DNA—specifically, on the number and affinity of the binding sites that this DNA contains for Dorsal and other transcription regulators. In this way, the regulatory DNA interprets the positional signal provided by the nuclear Dorsal protein gradient, so as to define a distinct D-V series of territories—complementary bands of cells that run the length of the embryo. Most ventrally—where the nuclear concentration of Dorsal protein is highest—it switches on, for example, the expression of a gene called *Twist*, which directs mesodermal fate. Most dorsally, where the nuclear concentration of Dorsal protein is lowest, the cells switch on a gene called *Decapentaplegic* (*Dpp*). And in an intermediate region, where the nuclear concentration of Dorsal protein is high enough to repress *Dpp* but too low to activate *Twist*, the cells switch on another set of genes, including one called *Short gastrulation* (*Sog*) (Figure 21–26A).

Products of the genes directly regulated by the Dorsal protein generate in turn more local signals, which define finer subdivisions along the D-V axis. These signals act after cellularization and take the form of conventional extracellular diffusible proteins. In particular, Dpp codes for a secreted TGF β family protein, which forms a local morphogen gradient in the dorsal part of the embryo. Sog, produced ventrally to Dpp, encodes another secreted protein that acts as an antagonist of Dpp protein, by binding to it and preventing Dpp from activating its receptor. The opposing diffusion gradients of these two signal proteins create a steep gradient of Dpp activity: the highest Dpp activity levels, in combination with certain other factors, cause development of the most dorsal tissue of all—an

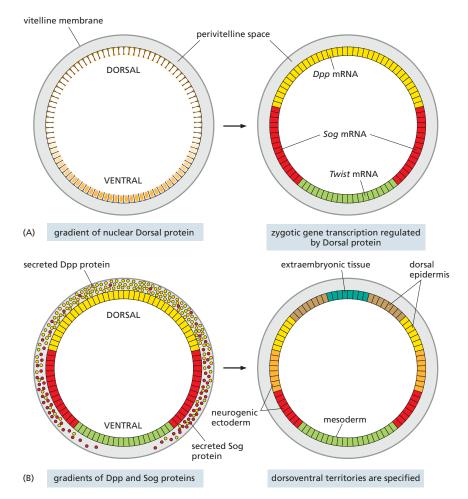

Figure 21–26 How morphogen gradients guide a patterning process along the dorsoventral axis of the *Drosophila* embryo. (A) Initially, a gradient of Dorsal protein defines three broad territories of gene expression, marked here by the expression of three representative genes: Dpp, Sog, and Twist. (B) Slightly later, the cells expressing Dpp and Sog secrete, respectively, the signal proteins Dpp (a TGF β family member) and Sog (an antagonist of Dpp). These two proteins then diffuse and interact with one another (and with certain other factors) to create the dorsoventral (D-V) territories shown.

MBOC7_ptr_ch21_1217-1278.indd 1237 02/12/21 12:24 PM

extraembryonic membrane. Intermediate levels cause development of dorsal epidermis; and the absence of Dpp activity in cells expressing Sog allows the development of neurogenic ectoderm, which will give rise to the nervous system (Figure 21–26B).

A Hierarchy of Inductive Interactions Subdivides the Vertebrate Embryo

The molecular genetic analysis of *Drosophila* development has uncovered how a cascade of transcription regulators and signaling pathways sequentially subdivides the embryo. The same principle of progressive pattern refinement is used during the development of all animal embryos, including vertebrates. Remarkably, conservation is not restricted to the general strategy of pattern formation, but also extends to many of the molecules involved.

As mentioned previously, the earliest phases of vertebrate development are surprisingly variable, even between closely related species, and it is even hard to say precisely how the A-P and D-V axes of an early fly embryo correspond to those of an early frog or mouse embryo. Nevertheless, we shall see that amid this display of evolutionary plasticity, some features of early development turn out to be highly conserved. The same is true of later developmental stages also, often to an astonishing degree. From our own anatomy, it is obvious that we are cousins to birds and fish. But looking at molecular mechanisms, we see that we are related to flies and worms too.

In the following pages, we discuss how vertebrate embryos are patterned by the interplay of signaling molecules and transcription regulators. We begin by discussing the formation and patterning of the embryonic axes in amphibians, taking the frog *Xenopus* as our example. We have already broached this topic earlier in the chapter. Here, we pick up the thread and draw comparisons with the fly.

As noted earlier, the origins of the embryonic axes and the three germ layers in the frog can be traced back to the blastula (see Figure 21-3A). By labeling individual blastomeres, we can track cells through all their divisions, transformations, and migrations and see what they become and where they come from. The precursors of ectoderm, mesoderm, and endoderm are arranged in order along the animal-vegetal axis of the blastula: the endoderm derives from the most vegetal blastomeres, the ectoderm from the most animal, and the mesoderm from a middle set. Within each of these territories, the cells have diverse fates according to their positions along the D-V axis of the later embryo. For ectoderm, epidermal precursors are located ventrally, and future neurons are found dorsally; for mesoderm, precursors for notochord, muscle, kidney, and blood are arranged from dorsal to ventral. All this can be represented by a fate map that shows which later cell types derive from which regions of the early embryo (Figure 21-27). The fate map confronts us with the central question: How are the cells in different positions driven toward their different fates? We have already explained how maternal factors deposited in the developing frog egg define its animal-vegetal axis, and how cortical rotation triggered by fertilization defines the orientation of the dorsoventral axis (see Figure 21-13). But how does the establishment of axes lead on to the subdivision of the embryo into the future body parts?

The answer is that the maternal gene products lead to the formation of *signaling centers* on the vegetal and dorsal sides of the embryo. The dorsal signaling center in particular has a special place in the history of developmental biology. Experiments in the early twentieth century identified it as a small cluster of cells with an extraordinary property: when the cells were transplanted to an opposite site, they could trigger a radical reorganization of the neighboring tissue, causing it to form a second whole-body axis (Figure 21–28). The discovery of this signaling center, called the Organizer, led the way to a pioneering analysis of the chain of inductive interactions that establish the framework of the vertebrate body.

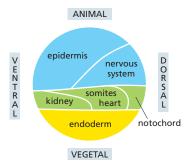

Figure 21–27 Blastula fate map in a frog embryo. The endoderm derives from the most vegetal blastomeres (yellow), the ectoderm from the most animal (blue), and the mesoderm from a middle set (green) that contributes also to endoderm and ectoderm. Different cell types derive from different positions along the dorsoventral axis.

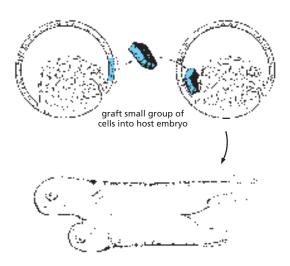

Figure 21–28 Induction of a secondary axis by the Organizer. An amphibian embryo receives a graft of a small cluster of cells taken from a specific site, called the Organizer region, on the dorsal side of another embryo at the same stage. Signals from the graft organize the behavior of neighboring cells of the host embryo, causing development of a pair of conjoined (Siamese) twins. See Movie 21.4. [After J. Holtfreter and V. Hamburger, in Analysis of Development (B.H. Willier, P.A. Weiss, and V. Hamburger, eds.), pp. 230–296. Philadelphia: Saunders, 1955.]

In contrast to the *Drosophila* syncytial embryo, the fertilized frog egg undergoes conventional cleavage divisions that result in an embryo consisting of thousands of cells. Patterning must therefore be mediated by extracellular signal molecules that diffuse through the embryo from cell to cell, not by transcription regulators that move through the cytoplasm of a syncytium. Not surprisingly, the Organizer is now known to be a major source of secreted signals. As we shall see, this includes not only ligands that bind and activate transmembrane receptors (see Chapter 15), but also secreted proteins that inhibit the activity of these ligands.

A Competition Between Secreted Signaling Proteins Patterns the Vertebrate Embryonic Axes

The signal molecules that pattern the frog embryo along the animal-vegetal (A-V) axis belong to the TGF β family: they are secreted by a signaling center at the vegetal pole and form concentration gradients along the A-V axis. These *Nodal* proteins act over a relatively short range: cells closest to the vegetal pole are exposed to high levels and respond by switching on genes that promote the development of endoderm; cells farther away are exposed to lower levels and activate genes that promote the formation of mesoderm. The cells at the vegetal pole that produce Nodal also produce a second, more rapidly diffusing protein called *Lefty*, which antagonizes Nodal. The high ratio of Lefty to Nodal at the animal pole allows Lefty to block Nodal signaling; this causes the cells there to develop as ectoderm (Figure 21–29A). Thus, a mid-range activation by Nodal, combined with a long-range inhibition by Lefty, sets up the pattern of progenitors along the A-V axis for the three germ layers—endoderm, mesoderm, and ectoderm.

The frog uses a somewhat related strategy to subdivide the germ-layer territories along the D-V axis of the embryo. It relies on patterned inhibition of otherwise uniform signaling by the *bone morphogenetic proteins* (BMPs; members of yet another subclass of the TGF β family), which are secreted throughout the embryo. The dorsal signaling system exerts its influence by secreting several proteins, including *Chordin* and *Noggin*, that block BMP signaling when their own concentrations are high. In this way, Chordin and Noggin create a dorsal-to-ventral gradient of BMP, with low activity on the dorsal side and high activity on the ventral side (**Figure 21–29B**). Ectodermal cells that experience high levels of BMP signaling are driven to epidermal fates, whereas cells that experience little or no BMP signaling remain neural. We can note that this strategy for patterning the D-V axis by opposing gradients of BMP family signals and diffusible inhibitors is similar to that used in *Drosophila*, and indeed the particular molecules used are homologous.

MBOC7_ptr_ch21_1217-1278.indd 1239 02/12/21 12:24 PM

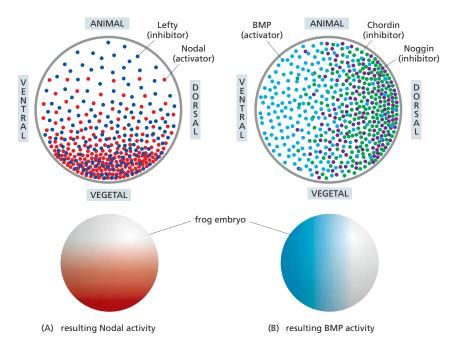

Figure 21-29 How Nodal and bone morphogenic protein (BMP) signaling pattern the embryonic axes. Nodal and its antagonist Lefty pattern the animal-vegetal axis, while BMP and its antagonists Chordin and Noggin pattern the dorsoventral axis. (A) In the animal-pole region, where Nodal levels are low relative to Lefty, Lefty blocks Nodal from binding to its receptors. In the vegetal region, there is an excess of Nodal, resulting in Nodal pathway activation. (B) Along the dorsoventral axis. BMP is widely present. but Chordin and Noggin are concentrated at the dorsal side: there, they bind to BMP and block its binding to receptors The resulting patterns of Nodal and BMP activity are illustrated at the bottom of the figure.

Knowing the signals that specify the three germ layers and various tissue types of the vertebrate body, one can reproduce this specification in a culture dish. Frog cells taken from the animal-pole region of the embryo, for example, will differentiate into blood (a ventral mesodermal tissue) when diverted from their original fate by exposure to intermediate concentrations of Nodal and high concentrations of BMP. Similarly, mouse or human embryonic stem cells can be coaxed into generating specific cell types by exposing them in culture to appropriate combinations of signal molecules. In this way, the insights gained through studies of animal development can be used to generate the cell types needed for regenerative medicine, as we discuss in the next chapter.

Hox Genes Control the Vertebrate A-P Axis

The conservation of developmental mechanisms between *Drosophila* and vertebrates extends far beyond the D-V signaling system. *Hox* genes are found in almost every animal species studied, where they are often grouped in complexes similar to the insect *Hox* complex. In mice and humans, for example, there are four such complexes—called the *HoxA*, *HoxB*, *HoxC*, and *HoxD* complexes—each on a different chromosome. Individual genes in each complex can be recognized by their sequences as counterparts of specific members of the *Drosophila* set. Indeed, mammalian *Hox* genes can function in *Drosophila* as partial replacements for the corresponding *Drosophila Hox* genes. It appears that each of the four mammalian *Hox* complexes is, roughly speaking, the equivalent of one complete insect *Hox* complex (that is, an *Antennapedia* complex plus a *Bithorax* complex) (Figure 21–30).

The ordering of the genes within each vertebrate *Hox* complex is essentially the same as in the insect *Hox* complex, suggesting that all four vertebrate complexes originated by duplications of a single primordial complex present in the common ancestor of vertebrates and insects, and have preserved its basic organization. Most tellingly, the members of each vertebrate *Hox* complex are expressed in a head-to-tail series along the axis of the embryo, just as they are in *Drosophila*. As in *Drosophila*, vertebrate *Hox* gene expression patterns are often aligned with vertebrate segments. This alignment is especially clear in the hindbrain (see Figure 21–30), where the segments are called *rhombomeres*.

The products of the vertebrate *Hox* genes, the Hox proteins, specify positional values that control the A-P pattern of parts in the hindbrain, neck, and trunk (as well as some other parts of the body). As in *Drosophila*, when a posterior *Hox*

MBOC7_ptr_ch21_1217-1278.indd 1240 02/12/21 12:24 PM

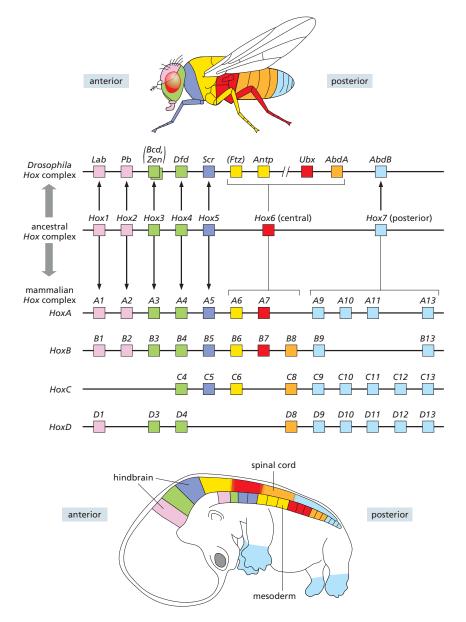

Figure 21-30 The Hox complexes of an insect and a mammal, compared and related to body regions. The genes of the Antennapedia and Bithorax complexes of Drosophila are shown in their chromosomal order in the top line (see Figure 21-23). The corresponding genes of the four mammalian Hox complexes are shown below, also in chromosomal order. The gene expression domains in fly and mammal are indicated in a simplified form by color in the diagrams of animals above and below. There is a remarkable parallelism. However, the details of the patterns depend on developmental stage and vary somewhat from one mammalian Hox complex to another. Also, in many cases, genes shown here as expressed in an anterior domain are also expressed more posteriorly, overlapping the domains of more posterior Hox genes.

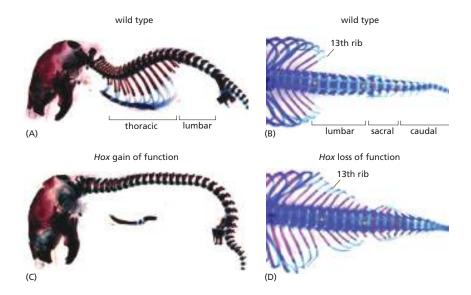

The complexes are thought to have evolved as follows: first, in some common ancestor of worms, flies, and vertebrates. a single primordial homeotic selector gene underwent repeated duplication to form a series of such genes in tandem—the ancestral Hox complex. In the Drosophila sublineage, this single complex became split into separate Antennapedia and Bithorax complexes. Meanwhile, in the lineage leading to the mammals, the whole complex was repeatedly duplicated to give four Hox complexes. The parallelism is not perfect because apparently some individual genes have been duplicated and others lost. Still others have been co-opted for different purposes (genes in parentheses in the top line) over the time that has elapsed since the complexes diverged. (Based on a diagram courtesy of William McGinnis.)

gene is artificially expressed in an anterior region, it can convert the anterior tissue to a posterior character. Conversely, loss of posterior Hox genes allows the posterior tissue where they are normally expressed to adopt an anterior character (Figure 21–31). Because of overlapping functions between genes in the four Hox gene clusters, the transformations observed in mouse Hox mutants are not always so straightforward as those in the fly, and they are often incomplete. Nonetheless, it seems clear that the fly and the mouse use essentially the same molecular machinery to impart individual characteristics to successive regions along at least a part of the A-P axis.

Some Transcription Regulators Can Activate a Program That Defines a Cell Type or Creates an Entire Organ

Just as there are single genes that specify the identity of a particular region of the body, there are also genes whose products act as triggers for the development of a specific cell type or even a specific organ, initiating and coordinating the whole complex program of gene expression that is required. An example is the MyoD

MBOC7_ptr_ch21_1217-1278.indd 1241 02/12/21 12:24 PM

family of transcription regulators that we encountered in Chapter 7. These proteins drive cells to differentiate into muscle, expressing muscle-specific actins and myosins and all the other specialized cytoskeletal, metabolic, and membrane proteins that a muscle cell needs. Analogously, members of the Achaete/Scute family of transcription regulators drive cells to become neural progenitors. In both these examples, the proteins belong to the helix-loop-helix (HLH) class of transcription regulators (see p. 405), and the same is true for several other proteins that induce the differentiation of particular cell types. These master transcription regulators exert their powerful differentiation-inducing activity by binding to many different regulatory sites in the genome and thereby controlling the expression of large numbers of downstream target genes. In one well-studied case, that of an Achaete/Scute family member called Atonal homolog 1 (Atoh1), the number of direct target genes in the mouse genome is more than 600. It is important to note, however, that even such powerful drivers of cell differentiation can have radically different effects according to the context and history of the cells in which they act: Atoh1, for example, drives differentiation of certain classes of neurons in the brain, of sensory hair cells in the inner ear, and of secretory cells in the lining of the gut.

Other genes encoding transcription regulators can drive the formation and assembly of the multiple cell types that constitute an entire organ. A famous example is the transcription regulator Eyeless (see Figure 21–2). When it is artificially expressed in a patch of cells in the leg precursors of *Drosophila*, a well-organized eye-like organ develops on the leg, with the various eye cell types correctly arranged; conversely, loss of the *Eyeless* gene results in flies that lack eyes. Moreover, loss of the *Eyeless* homolog *Pax6* in vertebrates likewise leads to loss of eye structures; humans with *Pax6* mutations display a condition called congenital aniridia (Figure 21–32). Similar organ-selector proteins are known for foregut, heart, pancreas, and other organs. They are all master transcription regulators that directly regulate hundreds of target genes, the products of which then specify and construct the different elements of the appropriate organ. However, as in the example of Atoh1, they usually exert their specific effect only in combination with the right partners, which are only expressed in cells that were appropriately primed during their earlier development.

Notch-mediated Lateral Inhibition Refines Cellular Spacing Patterns

After the establishment of the basic body plan and the generation of organ precursors, many further steps of pattern refinement are required to achieve the adult pattern of terminally differentiated cells in tissues and organs. Lateral

Figure 21-31 Control of anteroposterior pattern by Hox genes in the mouse. (A and B) A normal mouse (wild type) has about 65 vertebrae, differing in structure according to their position along the body axis: 7 cervical (neck), 13 thoracic (with ribs), 6 lumbar (bracketed by yellow asterisks in panel B), 4 sacral (bracketed by red asterisks in panel B), and about 35 caudal (tail). Panel A shows a side view, and panel B shows a dorsal view; for clarity, the limbs have been removed in each picture. (C) The HoxA10 gene is normally expressed in the lumbar region (together with its paralogs HoxC10 and HoxD10); here it has been artificially expressed in the developing vertebral tissue all along the body axis. As a result, the cervical and thoracic vertebrae are all converted to a ribless, lumbar character. (D) Conversely, when HoxA10 is removed along with HoxC10 and HoxD10, vertebrae that should normally have a lumbar or sacral character take on a thoracic, ribbearing character instead. inhibition (see Figure 21–10) mediated by Notch signaling is crucial for both cell diversification and fine-grained patterning in an enormous variety of tissues in all animals.

Certain tissues require the evenly spaced distribution of a specialized cell type, such as sensory cells, secretory cells, or stem cells, across their expanse. A good example is the development of **sensory bristles** in *Drosophila*, most easily seen on the fly's back, but also present on most of its other exposed surfaces. Each of these is a miniature sense organ, consisting of a sensory neuron and a small set of supporting cells. Some bristles respond to chemical stimuli and others to mechanical stimuli, but they are all constructed in a similar way (Figure 21–33).

The proneural genes *Achaete* and *Scute* mentioned earlier mark the clusters of epidermal cells within which bristles will form, but exactly which cells form a bristle depends on competitive interactions among them. Signaling within each cluster selects a single cell—called the *sensory organ precursor cell*—to serve as the bristle progenitor. The progenitor becomes distinct from surrounding cells through lateral inhibition (see Figure 21–10), which is mediated by the Notch signaling pathway. Binding of the transmembrane receptor *Notch* on the surface of a cell in the cluster by its transmembrane ligand *Delta* on a neighboring cell generates signals that inhibit differentiation to form a sensory organ precursor and also inhibit production of Delta in that same cell. At first, all cells in the cluster express both Notch and Delta and inhibit one another from differentiating.

Figure 21-33 Drosophila mechanosensory bristles. (A) The lineage of the four cells of the bristle-all descendants of a single sensory organ precursor cell—is shown on the left. The sensory organ precursor, once it is specified, generates this set of cells through a short program of division cycles. In each generation of the progeny, lateral inhibition operates again to drive the newborn cells toward different fates: one of the ultimate progeny cells will become the neuron; another, the shaft of the bristle; others, supporting cells of various sorts. (B) The distribution of sensory organ precursors in the pupal epidermis, seen using a fluorescent reporter for the senseless gene (pink). (C) The pattern of bristles on the thorax of an adult flv. MBOC7_ptr_ch21_1217-1278.indd 1243 02/12/21 12:24 PM

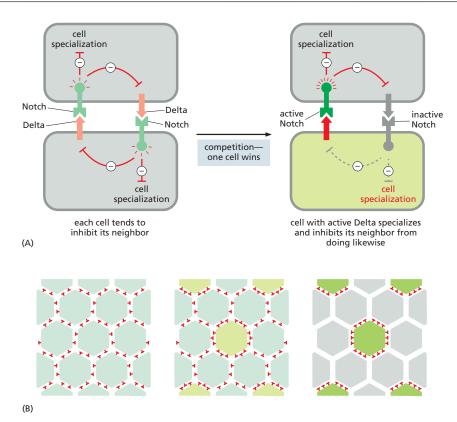

Figure 21-34 Lateral inhibition. (A) The basic mechanism of Notch-mediated competitive lateral inhibition, illustrated for just two interacting cells. Proteins or effector lines shown in gray indicate inactivity. (B) The outcome of the same process operating in a larger patch of cells. Initially, all cells in the patch are equivalent and signal through Delta-Notch interactions to discourage their neighbors from specializing as a sensory organ precursor. This balanced inhibition is disrupted when an individual cell generates a slightly stronger Delta signal than that of its neighbors: it then inhibits its neighbors more strongly while itself becoming more committed to the sensory organ precursor fate. As neighboring cells lose their capacity to differentiate, they also lose their capacity to inhibit other cells from doing so. Lateral inhibition thus makes adjacent cells follow different fates. Although the interaction is thought to be dependent primarily on cell-cell contacts, the sensory organ precursor can also deliver an inhibitory signal to cells that are more than one cell diameter away; for example, by sending out long protrusions to touch them.

Gradually, however, small signaling differences lead to a positive feedback loop in which a cell producing a slightly stronger Delta signal both discourages its neighbors from differentiating and reduces their production of Delta. The result is a competition, from which a single sensory organ precursor cell eventually emerges as winner, sending a strong inhibitory signal to its immediate neighbors but receiving no such signal in return (Figure 21–34).

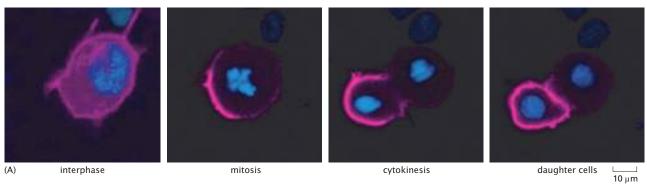

The sensory organ precursor goes through a short program of further divisions to generate the set of cells that form the final bristle (see Figure 21–33). Notch signaling acts repeatedly at successive stages in this program to drive the descendants of the sensory organ precursor along different pathways and assign them to their various specialized fates. However, it does so in conjunction with additional mechanisms that bias the outcome of the competition mediated by lateral inhibition. Determinants that are asymmetrically localized inside the dividing cells have this role in sensory bristle development, as we now discuss.

Cell-fate Determinants Can Be Asymmetrically Inherited

Cell diversification does not always depend on extracellular signals: in some cases, daughter cells are born different as a result of an intrinsically asymmetric cell division, during which some significant set of molecules is divided unequally between them. This asymmetrically segregated molecule (or set of molecules) then acts as a determinant for one of the cell fates by directly or indirectly altering the pattern of gene expression within the daughter cell that receives it (see Figure 21–11). A good example of the asymmetric segregation of molecules occurs in the early frog embryo: VegT RNA is localized specifically in the vegetal region of the fertilized egg. After the cleavage divisions, only vegetal cells will inherit VegT RNA.

Asymmetric divisions often occur at the beginning of development, but they are also encountered at some later stages. To return to our example of the adult *Drosophila* bristle (see Figure 21–33), the sensory organ precursor undergoes an

MBOC7_ptr_ch21_1217-1278.indd 1244 02/12/21 12:24 PM

asymmetric cell division to generate one daughter that will produce the outer shaft and socket cells and one daughter that will produce the inner neuron and sheath cell. Each fate is dictated by the differential inheritance of a protein called Numb, which influences a Notch-mediated lateral inhibition decision between the daughter cells. Numb is a cytosolic protein that inhibits Notch signaling, and its presence in a sensory organ precursor cell specifies the "inner" precursor fate. Prior to the division of this cell, Numb is associated uniformly with the cell cortex. As the mitotic spindle forms, Numb is displaced from the cortical region close to one spindle pole, restricting its localization to the cortex adjacent to the other pole (Figure 21–35). This restriction depends on the polarizing activity of the Par protein complex described in Chapter 16 (and see Figure 16–76). When cytokinesis is completed, Numb is present in only one of the two daughters, where it inhibits Notch signaling within that cell—thereby acting as an asymmetrically segregated fate determinant.

Numb operates in an analogous manner during asymmetric divisions of the *Drosophila* neural stem cell lineage to generate the large numbers and balanced proportions of neurons and glia. Asymmetric division of neural progenitors also drives neurogenesis in the cortex of the vertebrate brain. In both cases, Notch signaling determines the difference between a more progenitor-like and a more differentiated fate.

Evolution of Regulatory DNA Explains Many Morphological Differences

In the preceding sections, we have seen that animals contain the same essential cell types, have a similar collection of genes, and share many of the molecular mechanisms of pattern formation. But how can we reconcile these ideas with the radical differences that we see in the body structures of animals as diverse as a worm, a fly, a frog, and a mouse? We asserted earlier, in a general way, that these differences usually seem to reflect differences in the regulatory DNA that controls the conserved basic set of developmental regulatory proteins. We now examine the evidence more closely.

When we compare animal species with similar basic body plans—different vertebrates, for example, such as fish, birds, and mammals—we find that corresponding genes can have similar sets of regulatory elements that are conserved and recognizably homologous in the different animals. The same is true if we compare different species of nematode worms or insects. But, when we compare vertebrate regulatory regions with those of worms or flies, it is hard to see any such resemblance. The protein-coding sequences are unmistakably similar, but the corresponding regulatory DNA sequences appear very different, suggesting that the differences in body plans mainly reflect differences in regulatory DNA. Although variations in the proteins themselves also contribute, differences in regulatory DNA would be enough to generate extremely different tissues and body structures even if the proteins were the same.

It is not yet possible to trace all of the genetic steps that have led to the spectacular diversity of animals. Their lineages have diverged over hundreds of millions

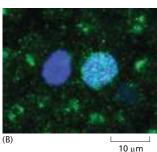

Figure 21-35 Asymmetric cell division creates different daughter-cell fates in the Drosophila bristle lineage. (A) Images of a dividing sensory organ precursor cell in the Drosophila pupa. Initially, the Numb protein (pink) is distributed uniformly around the cell cortex, but it partitions to one side of the cell during metaphase. Nuclear DNA is stained blue. Division results in the segregation of Numb into only one of the two daughter cells. (B) In this pair of daughter cells, asymmetrically inherited Numb (not shown) prevents Notch signaling in the daughter cell on the left; Notch activity is restricted to the daughter cell on the right, as shown by a reporter of the Notch target gene Enhancer of Split m8 (green), which appears as speckles in the cell nucleus (stained blue). pelvic spine enhancer deleted

of years, and in most cases too many changes have occurred for us to be able to say that this or that feature results from this or that mutation. The picture is clearer, however, for more recent evolutionary events. Studies of closely related animal populations and plant populations whose members have different morphologies have revealed that dramatic developmental effects can result from specific changes in regulatory DNA.

A well-studied example is the morphological diversity found in stickleback fish. Marine sticklebacks extend sharp spines from their pelvic skeleton. These spines are thought to help protect the fish from soft-mouthed fish predators that live in the ocean. After the last ice age ended about 10,000 years ago, some marine sticklebacks colonized newly formed freshwater streams and lakes, which often lacked such predators. Many of these populations of freshwater sticklebacks evolved to lose their pelvic spines. The development of this different morphology reflects differences in control of the expression of a transcription regulator called Pitx1. Whereas marine sticklebacks express the *Pitx1* gene in the hindlimb bud cells that will give rise to pelvic spikes, freshwater sticklebacks have lost this expression as a result of a change at the *Pitx1* locus. These changes do not lie in the coding sequence. Instead, each is a small deletion of a block of regulatory DNA that controls *Pitx1* expression specifically in the pelvic cells (Figure 21–36).

The Pitx1 protein has important functions elsewhere in the fish body, for example in the jaw and pituitary gland, and these functions must be retained. The DNA sequences that encode the Pitx1 protein, as well as the regulatory DNA responsible for tissue-specific *Pitx1* expression at these other body sites, is preserved in both marine and freshwater fish. The evolution of pelvic development

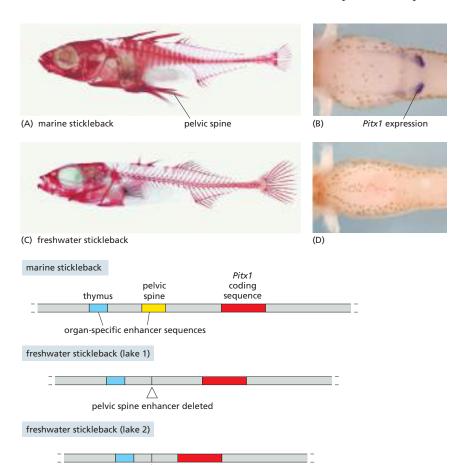

Figure 21-36 Morphological diversity in stickleback fish is caused by changes in regulatory elements. (A-D) Pelvic spines are present in marine (A) but missing in some freshwater (C) populations. Correspondingly, Pitx1 is expressed in the pelvic area in marine (B) but not in freshwater (D) fish. (E) The lack of expression in the pelvic area of freshwater populations is caused by regulatory deletions that removed pelvic-specific enhancer sequences; these deletions occurred independently in different populations and are of different sizes. The coding sequence and other enhancers and sites of expression for Pitx1 are conserved in marine and freshwater sticklebacks. (A-D, courtesy of Michael D. Shapiro.)

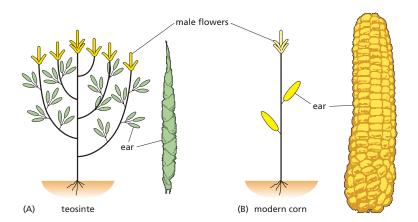

Figure 21–37 The insertion of a mobile genetic element helped produce modern corn. Today's corn plants were originally bred from a wild plant called teosinte (A). This wild ancestor produced numerous ears that contained small, hard seeds. (B) Modern corn, by contrast, produces fewer ears—but they contain numerous, plump, sweet seeds (kernels). The insertion of a mobile genetic element in the regulatory region of a gene involved in seed development helped drive the change. Here, the two plants are drawn to the same scale; for simplicity, the leaves are not shown.

in sticklebacks shows how the modular nature of regulatory DNA elements that we encountered in Chapter 7 (see Figure 7–31) allows independent modification of the different parts of the body, even when formation of multiple body parts depends on the same proteins.

In the recent evolution of plants, changes in their structure can be traced in a similar way to changes in regulatory DNA. In an important example for agriculture, such changes account for a large part of the dramatic difference between the wild teosinte plant and its modern descendant, maize, through some 10,000 years of selection upon natural genetic variation by Native Americans (Figure 21–37).

Summary

Drosophila has been the foremost model organism for the study of the genetics of animal development. Its embryonic pattern is initiated by the products of maternal-effect genes called egg-polarity genes, which operate by setting up graded distributions of transcription regulators in the egg and early embryo. The gradient of Bicoid protein along the anteroposterior (A-P) axis, for example, helps initiate the orderly expression of gap genes, pair-rule genes, and segment-polarity genes. These three classes of segmentation genes, through a hierarchy of interactions, become expressed in some regions of the embryo and not others, progressively subdividing an initially uniform field of cells along the A-P axis into a regular series of repeating modular units called segments.

Superimposed on the pattern of gene expression that repeats itself in every segment, there is a serial pattern of expression of Hox genes that confers on each segment a different identity. These genes are grouped in complexes and are arranged in a sequence that matches their sequence of expression along the A-P axis of the body.

Although Hox gene expression is initiated in the embryo, it is subsequently maintained by the action of chromatin-binding proteins of the Polycomb and Trithorax group, which stamp the chromatin of the Hox complex with a heritable record of its embryonic state of repression or activation, respectively. Hox complexes homologous to that of Drosophila are found in virtually every type of animal, where they help pattern the A-P axis of the body.

Signaling gradients are also set up along the dorsoventral (D-V) axis. Initially, Toll signaling generates a nuclear gradient of Dorsal protein, which induces an extracellular signaling gradient of the TGF β family protein Dpp and its antagonist, Sog. This creates a gradient of Dpp activity that helps refine the assignment of different characters to cells at different positions along the D-V axis.

In Xenopus, the polarity of the egg and the site of sperm entry set up the embryonic axes. A gradient generated by the $TGF\beta$ family protein Nodal induces different fates along the animal-vegetal axis, whereas BMP and Chordin—proteins homologous to Drosophila Dpp and Sog, respectively—control the patterning of the D-V axis.

MBOC7_ptr_ch21_1217-1278.indd 1247 02/12/21 12:24 PM

Transcription regulators control the formation of specific cell types. Members of the MyoD family drive the process of muscle-cell determination, coordinating the many components required, whereas Achaete/Scute transcription regulators control neural fate. Other genes encoding such master transcriptional regulators can regulate the formation of entire organs. Eyeless, for example, is both necessary and sufficient to generate eye structures in Drosophila.

To refine the anatomical pattern within such an organ, the cells interact locally, both by diffusible inductive signals and by short-range mechanisms. Often, the cells compete with one another by lateral inhibition. This process results in activation of the Notch signaling pathway in one cell and inhibition in its neighbors, generating two different cell types. Asymmetric cell divisions, in which daughter cells inherit different molecular determinants from the mother cell, provide an additional way to organize a fine-grained diversity of cell types.

Evidence from recent evolutionary events indicates that anatomical changes are mostly driven by changes in regulatory DNA sequences that determine when and where developmental genes are expressed. How the striking diversity in body structures has evolved over longer times remains largely unknown, although it seems likely that similar principles apply.

DEVELOPMENTAL TIMING

Developmental events unfold over minutes, hours, days, weeks, months, or even years, with each organism following its own strict timetable. The cascades of inductive interactions and transcriptional regulatory events described earlier take time, as signals are transmitted and transcription regulators are synthesized and then bind to DNA to activate or repress their target genes. So too do the changes in cell size, shape, and organization that result from changes in gene expression. All of these events require correct parameters of timing, including order (the sequence of events), interval (the time between events), and, in some cases, rhythm (repeated cycles of an event). Each developmental process must thus occur at an appropriate rate, tuned by evolution to fit with the timing of other processes in the embryo or in the environment. The control of timing is a compelling problem in developmental biology, but one of the least understood.

Molecular Lifetimes Play a Critical Part in Developmental Timing

Developmental processes are complex, but they are built up from simple steps. A first challenge is to understand the timing of these steps. How long does it take, for example, to switch the expression of a gene on or off? This is not like throwing a light switch: it involves delays. First, it takes time to make an mRNA molecule: the RNA polymerase must travel the length of the gene, the primary RNA transcript must be spliced and otherwise processed, and the resulting mRNA must be exported from the nucleus and delivered to the site where it will be translated. This adds up to what one might call the gestation time of the individual molecule. Second, it takes time for the individual mRNA molecules to accumulate to their fully effective concentration; as explained in Chapter 15, this accumulation time is dictated by the average lifetime of the molecules the longer they last, the higher their ultimate concentration, and the longer the time taken to attain it. Similar delays occur at the next step, where the mRNA is translated into protein: synthesis of each individual protein molecule involves a gestation delay, and attainment of an effective concentration of protein molecules involves an accumulation delay that depends on the time it takes for each protein to fold into its three-dimensional structure and its lifetime once produced. The time for the whole gene switching process is the sum of the gestation delays and the accumulation delays (basically, the molecular lifetimes) for both the mRNA and the protein molecules. Somewhat counterintuitively, it is the combined length of these delays, rather than the rate of molecular synthesis (the number of molecules synthesized per second), that chiefly determines the switching time.

MBOC7_ptr_ch21_1217-1278.indd 1248 02/12/21 12:24 PM

DEVELOPMENTAL TIMING 1249

The same additive principle applies to long cascades of gene switching, where gene A activates gene B, and gene B activates gene C, and so on. It also applies in other circumstances, such as in signaling pathways where one protein directly regulates the activation of the next. In all these cases, molecular lifetimes, along with gestation delays, play a key part in determining the pace of development. The lifetimes of mRNA and protein molecules are enormously variable, from a few minutes or hours to days or more, explaining much of the tempo of developmental events.

Gene switching delays, however, are not the be-all and end-all of developmental timing. Development involves many other kinds of delay that contribute to timing. Chromatin structure takes time to remodel. Inductive signals take time to diffuse across a field of cells (see Figure 21–9). Cells take time to move and rearrange themselves in space. Nevertheless, the timing of gene switching plays a fundamental part in developmental timing, as illustrated in an especially clear and striking way by a gene expression oscillator that controls the segmentation of the vertebrate body axis, as we now explain.

A Gene Expression Oscillator Acts as a Clock to Control Vertebrate Segmentation

The main body axis of all vertebrates has a repetitive, periodic structure, seen in the series of vertebrae, ribs, and segmental muscles of the neck, trunk, and tail. These segmental structures originate from the mesoderm that lies as a long slab on either side of the embryonic midline. This slab becomes broken up into a regular repetitive series of separate blocks, or **somites**—cohesive groups of cells, separated by clefts (**Figure 21–38A**). In contrast to the segments of a *Drosophila* embryo that appear simultaneously, as we discussed previously, somites in the vertebrate are formed sequentially. The somites form (as bilateral pairs) one after another, in a regular rhythm, starting in the region of the head and ending in the tail. Depending on the species, the final number of somites ranges from fewer than 40 (in a frog or a zebrafish) to more than 300 (in a snake).

The cells that will form somites are generated in the posterior, most immature part of the mesodermal slab, called the *presomitic mesoderm*. This is a proliferative zone, and as new cells are generated, the zone is pushed tailward, extending

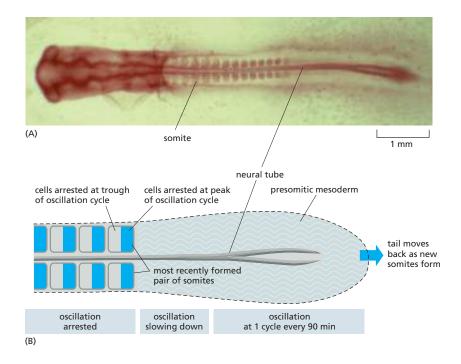

Figure 21-38 Somite formation in the chick embryo. (A) Brightfield image of a chick embryo at 40 hours of incubation. (B) How the temporal oscillation of gene expression in the presomitic mesoderm becomes converted into a spatial alternating pattern of gene expression in the formed somites. In the posterior part of the presomitic mesoderm, each cell oscillates with a cycle time of 90 minutes. As cells mature and emerge from the presomitic region, their oscillation is gradually slowed down and finally brought to a halt, leaving them in a state that depends on the phase of the cycle they happen to be in at the critical moment. In this way, a temporal oscillation of gene expression traces out an alternating spatial pattern. (Movie 21.5.) (A. from Y.J. Jiang et al., Curr. Biol. 8:R868-R871, 1998. With permission from Elsevier.)

MBOC7_ptr_ch21_1217-1278.indd 1249 02/12/21 12:24 PM

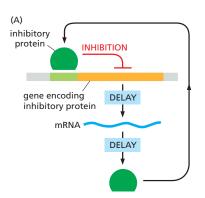

the embryo (Figure 21–38B). As the presomitic mesoderm moves tailward, it deposits a trail of somites formed from cells that group together into blocks as they emerge from the anterior end of the presomitic region. The special character of the presomitic mesoderm is maintained by a combination of fibroblast growth factor (FGF) and Wnt signals, produced by a signaling center at the tail end of the embryo, and the range of these signals seems to define the region from which somites can be formed. The somites emerge with clocklike timing, but what determines the rhythm of the process?

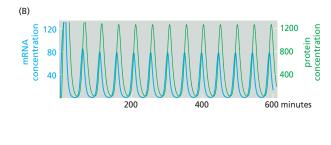

In the posterior part of the presomitic mesoderm that is destined to be segmented, the expression of certain genes oscillates in time. Such oscillations can be observed in time-lapse movies of embryos containing fluorescent reporters of individual genes. One new somite pair is formed in each oscillation cycle, and, in mutants where the oscillations fail to occur, somite segmentation is disrupted: the cells may still break up, belatedly, into separate clusters, but they do so in a haphazard, irregular way. The gene expression oscillator controlling regular segmentation is called the **segmentation clock**. The length of one complete oscillation cycle depends on the species: it is 30 minutes in a zebrafish, 90 minutes in a chick, 120 minutes in a mouse, and 300 minutes in a human.

As cells emerge from the presomitic mesoderm to form somites—in other words, as they escape from the influence of the FGF and Wnt signals—their oscillating gene expression stops. Some become arrested in one state, some in another, according to the phase of the oscillation cycle at the time they leave the presomitic region. In this way, the temporal oscillation of gene expression in the presomitic mesoderm leaves its trace in a spatially periodic pattern of gene expression in the maturing mesoderm. This in turn dictates how the tissue will break up into physically separate blocks, through effects on the pattern of cell-cell adhesion.

How does the segmentation clock work? The first somite oscillator genes to be discovered were Hes genes, which code for inhibitory transcription regulators. As well as regulating other genes, the products of Hes genes can directly regulate their own expression, creating a simple negative feedback loop. Autoregulation of Hes genes is thought to be the basic generator of the oscillations of the somite clock. Although the machinery has been modified in various ways in different species, the underlying principle seems to be conserved. When the key Hes gene is transcribed, the amount of Hes protein builds up until it is sufficient to block Hes gene transcription. Synthesis of the protein then ceases, and as the protein decays, transcription is permitted to begin again; and so on, cyclically (Figure 21-39). The period of oscillation, which determines the size of each somite, depends on the delay in the feedback loop. This delay equals the sum of the gestation delays and accumulation delays (that is, the molecular lifetimes) of the Hes mRNA and protein molecules, according to the principle discussed earlier. Mathematical modeling (see Chapter 8) allows us to relate these basic molecular parameters to the cycle time of the segmentation clock: to a first approximation, the cycle period is simply equal to twice the total delay in the negative feedback loop, and thus twice the sum of the delays occurring

Figure 21-39 Delayed negative feedback giving rise to oscillating gene expression. (A) A single gene, coding for a transcription regulator that inhibits its own expression, can behave as an oscillator. For oscillation to occur, there must be a delay (or several delays) in the feedback circuit, and the lifetimes of the mRNA and protein (which contribute to the delay) must be short compared with the total delay. The total delay determines the period of oscillation. It is thought that a feedback circuit like this, based on a pair of redundantly acting genes called Her1 and Her7 in the zebrafish-or their counterpart, Hes7, in the mouse-is the pacemaker of the segmentation clock governing somite formation. (B) The predicted oscillation of Her1 and Her7 mRNA and protein. computed using rough estimates of the feedback circuit parameters appropriate to this gene in the zebrafish. Concentrations are measured as numbers of molecules per cell. The predicted period is close to the observed period, which is 30 minutes per somite in the zebrafish.

MBOC7_ptr_ch21_1217-1278.indd 1250 02/12/21 12:25 PM

DEVELOPMENTAL TIMING 1251

at each step of the loop. Moreover, an experimental manipulation that changes one of these parameters (for example, altering the size of a *Hes* intron to perturb mRNA-processing time) results in the predicted effect on the period of somite formation.

The feedback loop just described is intracellular, and each cell in the presomitic mesoderm can generate oscillations on its own, even when cultured in a dish. But these oscillations at the single-cell level are somewhat erratic and imprecise, reflecting the fundamentally noisy, stochastic nature of the control of gene expression, as discussed in Chapter 7. A mechanism is needed to keep all the cells in the presomitic mesoderm that will form a particular somite oscillating in synchrony. This is achieved in part through cell-cell communication via the Notch signaling pathway. In this context, Notch signaling does not drive neighboring cells to be different, as in lateral inhibition, but does just the opposite: it keeps them in unison. In mutants where Notch signaling fails, including mutants defective in Delta or Notch itself, the cells drift out of synchrony, and somite segmentation is again disrupted. This leads to gross deformity of the vertebral column—an extraordinary display of the consequences of the noisy temporal control of gene expression at the single-cell level, writ large in the structure of the vertebrate body as a whole.

Cell-intrinsic Timing Mechanisms Can Lead to Different Cell Fates

Although signaling between cells plays an essential part in driving the progress of development, this does not mean that cells always require signals from other cells to prod them into changing their character as development proceeds. Some of these changes are intrinsic to the cell (like the ticking of a circadian clock, discussed in Chapter 15) and depend on *intracellular developmental programs* that can operate even when the cell is removed from its normal environment.

The best-understood example is the development of neuroblasts, the stem cells of the *Drosophila* central nervous system. These cells go through a succession of asymmetric cell divisions to generate distinct types of neurons and glial cells, always in the same sequence and with the same timing. Each neuroblast produces this wide range of daughter-cell fates using a time-dependent developmental program. As the neuroblast goes through its set schedule of divisions, it successively changes its internal state by expressing a series of different transcription regulators. For example, most embryonic neuroblasts sequentially express the transcription regulators Hunchback, Krüppel, Pdm, and Castor in a fixed order (Figure 21–40). When a neuroblast divides, the transcription regulators expressed at that moment are inherited by and maintained in its progeny; thus, the differentiated neural cells are endowed with different characters according to their time of birth.

When neuroblasts are taken from an embryo and maintained in culture, isolated from their normal surroundings, they step through much the same stereotyped developmental program as if they had been left in the embryo. Moreover, many of the neuroblast transitions occur even when cell division is blocked. The neuroblasts seem to have a built-in timer that determines when each of the transcription regulators is expressed, and this timer can continue to run in the absence of cell-cycle progression. The molecular basis of the timing is not well understood. Because cross-regulatory transcriptional cascades are involved, it likely depends on the time taken for gene switching, as described earlier, but it might also depend on slow progressive changes in chromatin structure and genome organization, which also can serve to measure the passage of time in the embryo.

Timing mechanisms can coordinate cell fates with the spatial organization of tissues. For example, during development of the mammalian cerebral cortex, the ordered expression of different transcription factors in the progenitor cells that divide to produce neurons and glial cells leads to sequential production of specific neural cell types. The newborn neurons migrate to their appropriate position

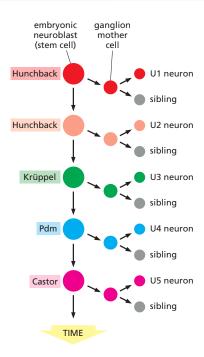

Figure 21-40 Temporal patterning of neural fate in Drosophila embryos. Each neuroblast undergoes an asymmetric cell division to renew itself and to produce a daughter called a ganglion mother cell. The ganglion mother cell subsequently divides to produce a pair of terminally differentiated neurons or glia. The types of neurons and glia are determined by the expression of a transcription regulator in the parent neuroblast that is then inherited by its ganglion-mother-cell daughter. Each neuroblast will sequentially express the transcription regulators Hunchback, Krüppel, Pdm, and Castor as it progresses through its lineage. After dividing several times while expressing one of these regulators, the neuroblast switches its pattern of gene expression, expressing an updated set of genes that will be passed along to its daughter cells, which differentiate into specific cell types accordingly. (After B.J. Pearson and C.Q. Doe, Nature 425:624-628, 2003.)

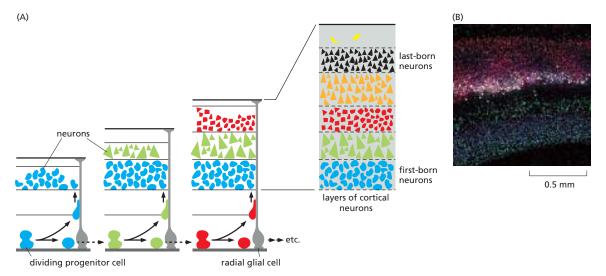

Figure 21–41 Timed expression of neural genes drives laminar organization of the brain. (A) Many neurons and glial cells in the mammalian cerebral cortex develop from a common progenitor, which proliferates on the inner surface of the cortical neuroepithelium to produce successive generations of neurons (colored here blue, green, red, orange, and black). The developing neurons migrate outward, crawling along processes that extend from radial glial cells, which also develop from the same progenitor cells. The first-born neurons settle closest to their birthplace, while neurons born later crawl past them to settle farther out. Successive generations of neurons thus occupy different layers in the cortex and have different intrinsic characters according to their birth dates. (B) Fluorescence micrograph showing the laminar organization of excitatory neurons labeled with antibodies to different transcription factors (blue, green, white, and red) in the mammalian cerebral cortex. Neural cell types are specified by the temporal sequence of transcription factor expression in their progenitors, so that birth order specifies both the fate and location of differentiated neurons. (From I. Holguera and C. Desplan, Science 362: 176–180, 2018.)

in the developing cortex, ultimately occupying different layers of the adult brain. Thus, all neurons that populate a layer form in the same time window and have common fates (Figure 21-41).

Cells Rarely Count Cell Divisions to Time Their Development

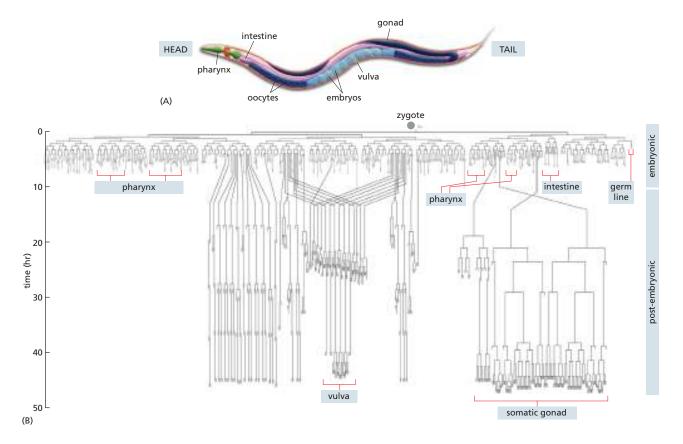

Many specialized cells develop from proliferating progenitor cells that stop dividing and terminally differentiate after a limited number of cell divisions. In these cases, it is tempting to speculate that the cell-division cycle serves as an intracellular timer to control the timing of cell differentiation. The cell cycle would be the ticking clock that sets the tempo of other developmental processes, with maturational changes in gene expression being dependent on cell-cycle progression. Most of the evidence, however, indicates that this appealing idea is wrong. Although there are examples where cells change their maturation state with each division and the change depends on cell division, this is not the general rule. As we just saw for neuroblasts in the Drosophila embryo, cells in developing animals often carry on with their normal timetable of maturation and differentiation even when cell division is artificially blocked; necessarily, some abnormalities occur, if only because a single undivided cell cannot differentiate in two ways at once. But it seems that most developing cells can change their developmental state without a requirement for cell division. Developmental control genes can switch the cell-division-cycle machinery on or off, and it is the dynamics of these genes, rather than the cell cycle, that sets the tempo of development.

MicroRNAs Can Regulate Developmental Transitions

Because genetic screens are useful for tracking down the genes involved in almost any biological process, they have been used to search for mutations that alter developmental timing. Such screens were performed in the nematode worm

MBOC7_ptr_ch21_1217-1278.indd 1252 02/12/21 12:25 PM

DEVELOPMENTAL TIMING 1253

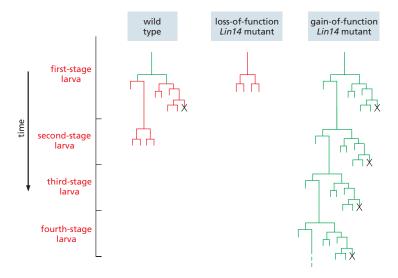

Caenorhabditis elegans (Figure 21-42). This small creature follows an astonishingly precise and predictable developmental program that has been described in extraordinary detail, so that one can map out the exact lineage of every cell in the body. The time and place of each cell division, as well as the fate of each of its daughters, are invariant from one individual to the next.

A great advantage of the lineage diagram describing the normal development of *C. elegans* is that one can see exactly how the developmental program is altered in a mutant. Genetic screens in *C. elegans* revealed mutations that disrupt developmental timing in a particularly striking way: in these so-called **heterochronic** mutants, certain cells in a larva at one stage of development behave as though they were in a larva at a different stage of development or cells in the adult carry on dividing as though they belonged to a larva (**Figure 21–43**).

Genetic analyses showed that the products of the heterochronic genes act in series, forming regulatory cascades. Unexpectedly, two genes at the top of their respective cascades, called Lin4 and Let7, were found to code not for protein but instead for microRNAs (miRNAs)—short, untranslated, regulatory RNA molecules, 21 or 22 nucleotides long. These act by binding to complementary sequences in the noncoding regions of mRNA molecules transcribed from other heterochronic genes, thereby repressing their translation and promoting their degradation, as discussed in Chapter 7. The Lin4 miRNA binds to the 3' untranslated region of mRNA produced by the heterochronic gene Lin14, which itself promotes early-stage larva-cell behaviors. A developmentally regulated increase of Lin4 levels thus governs the progression from early to late-stage larva-cell behaviors, by gradually reducing levels of Lin14 protein. Increasing levels of Let7 miRNA govern the progression from late larva to adult in an analogous way by regulating a different target gene called Lin41. In fact, Lin4 and Let7 were the first miRNAs to be described in any animal: it was through developmental genetic studies in C. elegans that the importance of this whole class of molecules for gene regulation in animals was discovered.

Figure 21–42 Cell lineage in Caenorhabditis elegans. (A) Some of the major tissues in the adult worm (see Figure 1–42). (B) The complete cell lineage of the worm was determined by meticulous analysis of the fate of every daughter cell after each cell division, beginning with the single-celled zygote and ending in the 959 cells of the adult. Each vertical line represents a single cell, with branch points reflecting a cell division. Labels indicate the cells in the lineage that make up the tissues shown in panel A. Cell and Nuclear Size Relationships Schedule the Onset of Zygotic Gene Expression

As we discussed earlier, many gene products are deposited in the egg by the mother, allowing the first steps of development to begin immediately upon fertilization. Maternal supplies eventually run out, however, and the zygote begins to produce its own gene products. This maternal-zygotic transition (MZT) occurs in most organisms after a substantial delay and marks the temporal window during which the embryo's own genome largely takes over control of development from maternal macromolecules (Figure 21-44).

The MZT occurs in most species shortly before gastrulation, when rapid and synchronous cleavage divisions give way to slower and more conventional cell cycles. During this transition, thousands of genes initiate transcription from the previously silent zygotic genome, and many maternal gene products are cleared from the embryo. In several species, including frogs, fish, and flies, some of the earliest zygotic genes to be transcribed include specific miRNAs that target maternal mRNAs for translational repression and degradation. Here again, miRNAs function to sharpen developmental transitions by blocking and removing mRNAs that define an earlier developmental stage.

How is the timing of the MZT controlled? One trigger appears to be the nuclear-to-cytoplasmic ratio. Many animal embryos do not grow or change volume during the earliest stages of development. Rather, rapid rounds of DNA replication and mitosis transform the fertilized egg into thousands of smaller cells. During these cleavage divisions, the total amount of cytoplasm in the embryo remains constant, but the number of cell nuclei in the embryo increases exponentially, thereby increasing the ratio of DNA to cytoplasm. Strikingly, haploid embryos containing

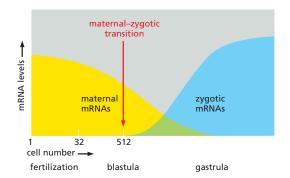

Figure 21-43 Heterochronic mutations in the Lin14 gene of C. elegans. Only the effects on one of the many altered lineages are shown. A loss-of-function (recessive) mutation in Lin14 causes premature occurrence of the pattern of cell division and differentiation characteristic of a late larva, so that the animal reaches its final state prematurely and with an abnormally small number of cells. The gainof-function (dominant) mutation has the opposite effect, causing cells to reiterate patterns of cell divisions characteristic of the first larval stage, continuing through as many as five or six molt cycles. The Lin14 gain-of-function mutations can result from altering the binding site for the Lin4 miRNA, rendering Lin14 protein immune from down-regulation. The black X denotes a programmed cell death. Green lines represent cells that contain Lin14 (which binds to DNA), red lines those that do not. (Adapted from V. Ambros and H.R. Horvitz, Science 226:409-416, 1984; and P. Arasu et al., Genes Dev. 5:1825-1833, 1991.)

Figure 21–44 The maternal–zygotic transition in a zebrafish embryo. Maternal mRNAs are deposited by the mother into the egg and drive early development. These mRNAs are degraded during different stages of embryogenesis, including blastula and gastrula stages, but a relatively abrupt change occurs at the maternal–zygotic transition (MZT). Before this, the embryonic (zygotic) genome is transcriptionally inactive; afterward, zygotic genes start to be transcribed. In zebrafish embryos, the zygotic genome begins to be activated at the 512-cell stage.

MBOC7_ptr_ch21_1217-1278.indd 1254 02/12/21 12:25 PM

DEVELOPMENTAL TIMING 1255

half the amount of DNA per cell undergo the MZT one cell cycle later than normal diploid embryos. According to one model, the nuclear-to-cytoplasmic ratio might be measured through the titration of a maternally provided transcription repressor against the increasing amount of nuclear DNA. The total amount of repressor would stay constant during cleavage divisions, but the amount of repressor per genome would decrease by half with each round of DNA synthesis until a threshold is reached that allows the zygotic genome to become transcriptionally active. One candidate for the repressor is maternal histone proteins, whose concentration regulates MZT timing in several organisms. Other evidence suggests that certain maternally provided transcription regulators trigger the MZT after they accumulate to some threshold sufficient to activate their gene targets. Different species may rely on either or both mechanisms to time activation of the zygotic genome appropriately.

Hormonal Signals Coordinate the Timing of Developmental Transitions

We have so far emphasized timing mechanisms that operate locally and separately in the different parts of the embryo or in specific subsystems of the molecular control machinery. Evolution has tuned each of these largely independent processes to run at an appropriate rate, matched to the needs of the organism as a whole. For some purposes, however, this is not enough: a global coordinating signal is required. This is especially true where changes have to occur throughout the body in response to a cue that depends on the environment. For example, when an insect or amphibian undergoes *metamorphosis*—the transition from larva to adult—almost every part of the body is transformed. The timing of metamorphosis depends on external factors such as the supply of food, which determines when the animal reaches an appropriate size. All the bodily changes have to be triggered together at the right time, even though they are occurring in widely separated sites. The coordination in such cases is provided by **hormones**—signal molecules that spread throughout the body.

The metamorphosis of amphibians provides a spectacular example. During this developmental transition, amphibians switch from an aquatic to a terrestrial life. Larva-specific organs such as gills and tail disappear, and adult-specific organs such as legs form. This dramatic transformation is triggered by thyroid hormone, produced in the thyroid gland. If the gland is removed or if thyroid hormone action is blocked, metamorphosis does not occur, although growth continues, producing a giant tadpole. Conversely, a dose of thyroid hormone given to a tadpole by an experimenter can trigger metamorphosis prematurely.

Thyroid hormone is distributed throughout the body by the vascular system and induces changes in receiving cells by binding to intracellular nuclear hormone receptors, which regulate hundreds of genes. This does not mean, however, that target tissues all respond in the same way to the hormone: organs differ not only in their levels of thyroid hormone receptors and levels of extracellular proteins that locally regulate the amount of active hormone, but also in the sets of genes that respond. Thyroid hormone induces muscle in the limbs to grow and muscle in the tail to die. The timing of the responses also differs; for example, the legs form early in response to a very low concentration of circulating hormone, but it requires a high level of the hormone to induce resorption of the tail.

A surge of thyroid hormone triggers metamorphosis, but how is the timing of the surge controlled? One mechanism depends on coupling hormone synthesis to the size of the thyroid gland, which reflects the size of the tadpole. Only when the gland attains a certain size does it produce enough thyroid hormone to initiate metamorphosis. However, environmental cues other than nutrition also play a part: conditions such as temperature and light are sensed by the nervous system, which regulates the secretion of another tier of hormones (neurohormones) that stimulate the secretion of thyroid hormone. Thus, tadpole-intrinsic factors such as size combine with environmental factors to determine when metamorphosis begins.

MBOC7_ptr_ch21_1217-1278.indd 1255 02/12/21 12:25 PM

Environmental Cues Determine the Time of Flowering

Another striking example of environmentally controlled developmental timing is the flowering of plants. Flowering involves a transformation of the behavior of the cells at the growing apex of the plant shoot—the *apical meristem*. During ordinary vegetative growth, these cells behave as stem cells, generating a steady succession of new leaves and new segments of stalk. In flowering, the meristem cells switch to making the components of a flower, with its sepals and petals, its stamens carrying pollen, and its ovary containing the female gametes.

To time the switch correctly, the plant has to take account of both past and present conditions. One important cue, for many plants, is day length. To sense this, the plant uses its circadian clock—an endogenous 24-hour rhythm of gene expression—to generate a signal for flowering only when there is light for the appropriate part of the day. The clock itself is influenced by light, and the plant in effect uses the clock to compare past to present lighting conditions. Important parts of the genetic circuitry underlying these phenomena have been identified, including the phytochromes and cryptochromes that act as light receptors (discussed in Chapter 15). The flowering signal that is carried from the leaves to the stem cells via the vasculature depends on the product of a gene called $Flowering locus \ T(Ft)$.

But this signal will trigger flowering only if the plant is in a receptive condition from prior long-term cold exposure. Many plants need winter before they will flower—a process called *vernalization*. Cold over a period of weeks or months progressively reduces the level of expression of a remarkable gene called *Flowering locus C (Flc)*. *Flc* encodes a transcriptional repressor that suppresses expression of the *Ft* flowering promoter.

How does vernalization shut down *Flc* so as to lift the block to flowering? The effect involves at least three long noncoding RNAs, including an antisense transcript called *Coolair* that overlaps with the *Flc* gene and is produced when the temperature is low (Figure 21–45). Together with cold-induced chromatin modifiers, including Polycomb-group proteins, *Coolair* coordinates the switching of *Flc* chromatin to a silent state (discussed in Chapters 4 and 7). The degree of silencing depends on the length of cold exposure, enabling the plants to distinguish the odd chilly night from the whole of winter.

The effect on the chromatin is long lasting, persisting through many rounds of cell division even as the weather grows warmer. Thus vernalization creates a

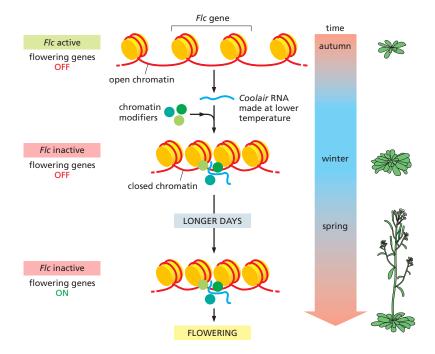

Figure 21–45 Temporal control of flowering in *Arabidopsis*. The *Flc* gene is active and blocks flowering when plants have been grown without exposure to winterlike temperatures. Exposure to a prolonged period of cold leads to the production of the noncoding RNA *Coolair*, which overlaps with the *Flc* gene. *Coolair* induces long-term chromatin changes that turn off *Flc*. These changes persist after the end of the cold period and allow the plant to flower when longer days promote flowering.

MBOC7_ptr_ch21_1217-1278.indd 1256 02/12/21 12:25 PM

MORPHOGENESIS 1257

persistent block in production of Flc, enabling the Ft signal to be generated when day length is sufficiently long.

Mutations affecting the regulation of *Flc* expression alter the time of flowering and thus the ability of a plant to flourish in a given climate. The whole control system governing the switch to flowering is thus of vital importance for agriculture, especially in an era of rapid climate change.

The example of vernalization suggests a general point about the role of chromatin modification in developmental timing. The plant uses changes in chromatin to record its experience of prolonged cold. It may be that in other organisms—animals as well as plants—slow, progressive changes in chromatin structure provide long-term timers for those mysterious developmental processes that unfold slowly, over a period of days, weeks, months, or years. Such chromatin timers may be among the most important clocks in the embryo, but as yet we understand very little about them.

Summary

Developmental timing is controlled at many levels. It takes time to switch a gene on or off, and this time delay depends on the lifetimes of the molecules involved, which can vary widely. Cascades of gene regulation involve cascades of delays. Feedback loops can give rise to temporal oscillations in gene expression, and these may serve to generate spatially periodic structures. During vertebrate segmentation, for example, expression of the Hes genes oscillates, and one new pair of somites is formed during each oscillation cycle. Hes genes encode transcription repressor proteins that can act back on expression of the Hes genes themselves. This negative feedback generates oscillations with a period that reflects the delay in the autoregulatory gene switching loop. The period of oscillation of this "segmentation clock" controls the sizes of the somites. Notch signaling between neighboring cells synchronizes their oscillations: when Notch signaling fails, the cells drift out of synchrony because of genetic noise in their individual clocks, and the segmental organization of the vertebral column is disrupted.

Timing does not always depend on cell-cell interactions; many developing animal cells have intrinsic developmental programs that play out even in isolated cells in culture. Neuroblasts in Drosophila embryos, for example, go through set programs of asymmetric divisions, generating different neural-cell types at each division with a predictable sequence and timing and through a cascade of gene switching events. Studies in both vertebrates and invertebrates show that such programs are rarely governed by the timing of cell division and can unfold even when cell division is blocked. MicroRNAs produced at critical moments sharpen developmental transitions by blocking the translation and promoting the degradation of specific sets of mRNAs. One such event is the maternal-zygotic transition, when transcription from the embryonic genome initiates. The onset of this event involves both titration of a maternal repressor by multiplying zygotic nuclei and the time-dependent accumulation of maternal transcriptional activators. Global coordination of developmental timing is achieved by hormones that disseminate and act on cells throughout the organism: as a tadpole grows, for example, thyroid hormone levels surge and trigger its metamorphosis into a frog. Environmental control of developmental timing is especially striking in plants and reveals the presence of molecular timers that act over the long term. In vernalization, for example, prolonged cold induces changes in chromatin that chart the passage through winter so as to allow flowering only in the spring. Slow, progressive changes in chromatin structure are likely to be important timers in the long-term programming of development in animals too.

MORPHOGENESIS

The specialization of cells into distinct types at specific times is important, but it is only one aspect of animal development. Equally important are the movements and deformations that cells go through to assemble into tissues and organs

MBOC7_ptr_ch21_1217-1278.indd 1257 02/12/21 12:25 PM

with specific shapes and sizes. These physical forms, which are a central output of cell-fate programs, are essential for each organ's physiological function. Like developmental timing, the process of *morphogenesis* ("form generation") is less well understood than the processes of differential gene expression and inductive signaling that lead to cell-type specialization. The cell movements can be readily described, and the underlying molecular mechanisms that coordinate the movements are now being deciphered.

In Chapter 19, we saw how cells cohere to form epithelial sheets or surround themselves with extracellular matrix to create connective tissues. We also discussed how the basic features of tissues, such as the polarity of epithelia, arise from the properties of individual cells. In this section, we consider how the dynamic rearrangements of cells during animal development give shape to the embryo and all the individual organs and appendages of the body.

A small number of cell behaviors are basic to morphogenesis. Cells can change shape, and coordinated shape changes can bend an epithelial sheet into a tube or a hollow ball. Cells can rearrange with respect to their neighbors, causing elongation, constriction, or thickening of a tissue. By stretching out while holding onto their companions, specialized sets of cells can form growing tubular networks such as the system of blood or lymph vessels. Individual cells can also extract themselves from their neighbors and form physically separate groups that then migrate through the embryo along defined tracks. Group migrations, as occur in gastrulation, can transform the entire topology of the embryo. Underlying all these processes are changes in physical forces that alter cell shape and cell contacts—either with other cells or with extracellular matrix. We begin by considering how these forces are generated.

Imbalance in Physical Forces Acting on Cells Drives Morphogenesis

Although it is alive, a cell is governed by the same physical principles that shape inanimate objects. Cells and tissues possess specific mechanical properties, and their shapes reflect the forces exerted upon them. At rest, a cell is in a mechanical equilibrium in which all forces are balanced. Morphogenesis entails a shift in that balance, as new forces are generated in an oriented way. These organized force changes then play out across increasing distances. For example, the activity of myosin motor proteins on the actin cytoskeleton may change the shape of a cell, which in turn affects its interactions with neighboring cells and thus the shape of a tissue. Such coordinated changes act to sculpt entire organs and animal bodies.

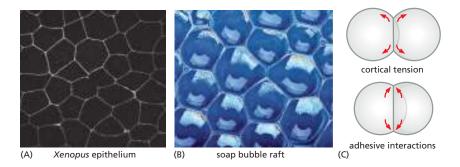

While some proteins, such as actin and myosin, generate forces within cells, others act to sense the applied forces. Such proteins, called *mechanotransducers*, initiate intracellular signaling in response to mechanical stimuli, just as the molecules described in Chapter 15 trigger signaling pathways in response to chemical cues. α -Catenin and Talin are mechanotransducers that bind to the cytosolic tail of cell adhesion molecules (see Chapter 19); these unfold in response to tension exerted by neighboring cells, and this conformational change sends biochemical signals that can elicit rapid responses in cellular mechanics as well as long-term effects on gene expression. Piezo (see p. 660) is a mechanosensitive ion channel that spans the cell membrane; it opens in response to shear stress or stretching of the plasma membrane, passing ions that then initiate signaling cascades. Through such mechanosensitive molecules, cells and tissues can read the physical environment within which they exist and respond accordingly.

Tension and Adhesion Determine Cell Packing Within Epithelial Sheets

The two-dimensional epithelial sheet found in many tissues is a simple system to illustrate principles of morphogenesis. Across animal species, stable epithelial sheets display a remarkably consistent pattern of cell shapes, in which most

MBOC7_ptr_ch21_1217-1278.indd 1258 02/12/21 12:25 PM

MORPHOGENESIS 1259

cells possess a hexagonal profile at their apical surface (Figure 21–46A). This arrangement is determined by the mechanical properties of the cells and their connections with neighbors, which are mediated primarily by *adherens junctions* (see Chapter 19). Contractility of an actomyosin ring underlying the plasma membrane adjacent to the junctions generates cortical tension within each cell, which tends to pull it away from its neighbors. However, this force is opposed by cell-cell adhesion, mediated by molecules such as cadherins within the junctions. The balance between these inward and outward forces generates a predictable configuration of cells, which can be mathematically modeled and is analogous to the packing arrangement of inorganic entities such as soap bubbles (Figure 21–46B and C). Although the physical mechanisms that balance surfacetension minimization and contact interfaces in bubbles are very different from those that shape cells, the mathematical solution representing a minimal energy of arrangement is similar.

Changing Patterns of Cell Adhesion Molecules Force Cells into New Arrangements

The shapes of tissues are ultimately determined by patterns of gene expression, which produce molecules that change the physical properties of cells in which they are expressed. One important class of genes that contributes to these properties codes for the adhesion molecules that cells display on their surface. Through changes in its surface molecules, a cell can break old attachments and make new ones. For example, cells in one region of a tissue may develop surface properties that make them cohere with one another and become segregated from a neighboring group of cells that possess different surface molecules. Cadherins and other cell-cell adhesion proteins that are differentially expressed in the various tissues of a developing animal play important roles. In Chapter 19, we saw how selective cell-cell adhesion is sufficient to drive the sorting of cells dissociated from an embryo into groups of a similar type (see Figure 19-7); treatment with antibodies that bind cadherins interferes with this process. Changes in expression of the various cadherin genes correlate closely with the different modes of association among cells during embryogenesis, as occurs, for example, during gastrulation, neural tube formation, and somitogenesis. Cadherins also control the formation and dissolution of epithelial sheets and clusters of cells (see Movie 19.1). Finally, because adhesion molecules not only glue one cell to another but also provide anchorage for intracellular actin filaments, the sites of cell-cell adhesion influence tension and cell movements in the developing tissue.

Repulsive Interactions Help Maintain Tissue Boundaries

The different types of cadherins enable different types of cells to cohere selectively: cells expressing one type of cadherin will maximize their contact with cells expressing the same cadherin and thereby segregate from other cells, creating specific tissue boundaries. Cell mixing can be inhibited and boundaries created and maintained in another way as well: cells of different types

Figure 21-46 Regular distribution of cell shapes in epithelia. (A) Fluorescence micrograph of cell membranes in an early Xenopus embryo shows that most epithelial cells have hexagonal profiles, with six neighbors forming three-way junctions where cells meet. (B) A two-dimensional "raft" of soap bubbles on the surface of water shows a similar organization. (C) The length and geometry of cell-cell contacts are set by opposing activities. The contractile network of the cortical actomyosin cytoskeleton within each cell tends to pull cells apart, while adhesive interactions mediated by cadherins and other molecules tend to hold cell surfaces together. (A, courtesy of Saranyaraajan Varadarajan and Ann Miller; B, Shebeko/Shutterstock.)

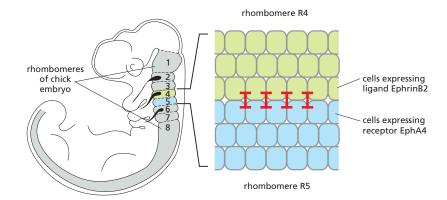

Figure 21–47 Sorting out by repulsion. Ephrin–Eph signaling in hindbrain segmentation in a chick embryo. Each pair of rhombomeres (segments in the hindbrain) is associated with a branchial arch (a modified gill rudiment) to which the pair sends innervation. Rhombomeres are distinguished from one another by expression of different *Hox* genes (see Figure 21–30). Differences in surface tension at the interface between cells that express EphrinB2 in rhombomere R4 and EphA4 in rhombomere R5 lead to mutual repulsion (red bars), creating a sharp boundary.

can sometimes actively repel one another. The bidirectional activation of Eph receptors and ephrins discussed in Chapter 15 often mediates such repulsion, acting at interfaces between different groups of cells to keep the groups from mixing, and repelling invasion by inappropriate visitors. Ephrin-Eph signaling operates at the boundaries of the somites in the vertebrate embryo discussed earlier (see Figure 21–38). By modulating the cortical actomyosin cytoskeleton, ephrin-Eph signaling is thought to induce differences in cortical tension between cells, thereby decreasing the force of the cell-cell contact. Another example is in rhombomeres, which are segmented regions of the developing vertebrate brain. Neighboring rhombomeres express complementary combinations of ephrins and Eph receptors, and this keeps the cells in adjacent rhombomeres strictly segregated, with a boundary between them that is sharply defined (Figure 21–47).

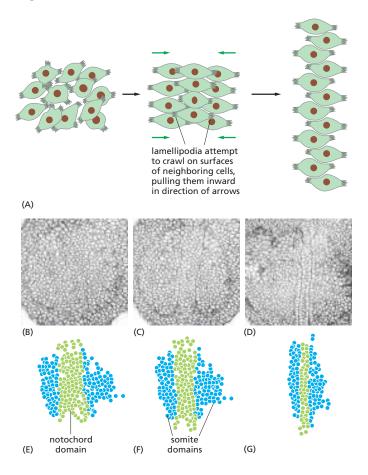

Figure 21-48 Convergent extension by mesenchymal cell migration. (A) A population of cells form lamellipodia, with which they attempt to crawl over one another. Alignment of the lamellipodial movements along a common axis, controlled by planar-polarity signaling (discussed shortly), leads to convergent extension. (B-G) The pattern of convergent extension of dorsal mesoderm during zebrafish gastrulation at 8.8 (B. E). 9.3 (C, F), and 11.3 (D, G) hours after fertilization. Cells that will give rise to the notochord are labeled in green, and cells that will give rise to somites and muscle are labeled in blue. The notochord and somite domains are spatially separate from the start of the recording (B, E), but their boundaries are at first barely visible and only a little later become obvious. Convergence narrows the notochord domain to a width of about two cells at the last time point (D, G). (A, after J. Shih and R. Keller, Development 116:901-914, 1992. MORPHOGENESIS 1261

Groups of Similar Cells Can Perform Dramatic Collective Rearrangements

Cell sorting mediated by cadherin and repulsion mediated by ephrin–Eph exemplify how differences in cell-surface properties can drive tissue arrangements, causing cells that express different sets of genes to separate from one another. However, groups of cells that are all similar can also undergo dramatic rearrangements. Many animal embryos extend their major body axis through such rearrangements, in a process called **convergent extension**. Convergent extension occurs when a population of cells moves coordinately toward a specific boundary, intercalating between each other as they do so. This causes the tissue to narrow along one axis (converge) and elongate along another (extend). The overall change in tissue shape results from cell displacement, rather than a change in shape of individual cells, and is largely autonomous to the group of cells involved. A striking demonstration is seen when small, square fragments of tissue from the appropriate region of a frog embryo are isolated in culture. These will spontaneously narrow and elongate, just as they would in the developing animal.

Convergent extension is a common movement that elongates many organs, although the cell behaviors that underlie it can differ. During frog gastrulation, for example, cells in one region of the surface epithelium lose their epithelial character as they migrate into the interior of the embryo. The loosely connected cells, called mesenchymal cells, form actin-based protrusions called lamellipodia that are oriented so that they crawl over one another and interdigitate as they converge toward the embryonic midline (Figure 21-48). In contrast, when the Drosophila embryo extends its anteroposterior axis, the cells involved remain epithelial. These cells maintain tight adhesive junctions but rearrange the relationships to their neighbors by shrinking cell junctions along one axis while extending them in another axis to accomplish cell intercalation (Figure 21-49; see also Figure 19-15). Remodeling of the junctions involves differential contractile tension on them that is generated by localized myosin activity. In both cases, whether mesenchymal migration or epithelial junction remodeling, the coordination of cell behaviors depends on a signaling pathway that can generate planar cell polarity, as we discuss next.

Planar Cell Polarity Orients Cell Behaviors Within an Embryo

Just as a compass allows us to orient ourselves in a landscape, cells undergoing morphogenetic movements must have a system to orient themselves with respect to the different body axes of the animal. We discussed in Chapter 19 how all

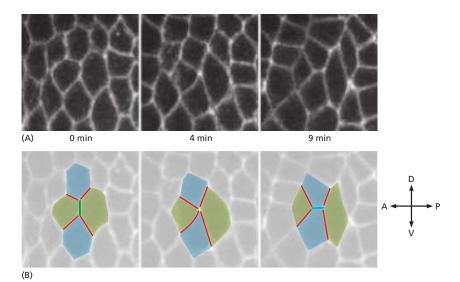

Figure 21-49 Convergent extension by rearrangement of epithelial junctions. Shown in (A) are fluorescence images of the Drosophila embryonic epidermis over a 9-minute period, with drawings in (B) that colorize specific cells and cell junctions (Movie 21.6). As in other epithelia, most cells are initially hexagonal. and their junctions are shared between three neighbors. To elongate the tissue along the anteroposterior axis, some of the dorsoventral-oriented junctions (green) shrink, forming a transient arrangement in which cells are pentagonal or quadrilateral, and a junction is shared between four neighbors. A new junction (blue) then forms along the anteroposterior axis, now shared between two cells that did not previously contact each other and separating two cells that previously did contact each other. This process of shrinking and elongating junctions in a planar-polarized fashion, occurring all along the epidermis, narrows and extends the tissue while maintaining epithelial integrity throughout. Figure 21–50 Planar cell polarity. (A) Wing hairs on the wing of a fly. Each cell in the wing epithelium forms a small, spiky protrusion or "hair" at its apex, and all the hairs point the same way, toward the tip of the wing. This reflects a planar polarity in the structure of each cell. (B) Sensory hair cells in the inner ear of a mouse similarly have a well-defined planar polarity, manifest in the oriented pattern of stereocilia (actin-filled protrusions) on their surface. The detection of sound depends on the correct, coordinated orientation of the hair cells. (C) A mutation in the gene Flamingo in the fly, coding for a nonclassical cadherin, disrupts the pattern of planar cell polarity in the wing. (D) A mutation in a homologous Flamingo gene in the mouse randomizes the orientation of the planar cell polarity vector of the hair cells in the ear. The mutant mice are deaf. (E) Micrograph showing localization of Flamingo (green) in a pupal fly wing, in relation to the hair growing from each cell (red). (F) Diagram illustrating planar-polarized localization of Flamingo to one side of each epithelial cell, and localization of another planar polarity-regulating protein called Frizzled to the opposite side, from which the hair will form. (A and C, from J. Chae et al., Development 126:5421–5429, 1999. With permission from the Company of Biologists; B and D, from J.A. Curtin et al., Curr. Biol. 13:1129–1133, 2003. With permission from Elsevier; E, courtesy of Paul Adler.)

epithelial cells have apical-basal polarity, but the cells of many epithelia show an additional polarity at right angles to this axis: the cells are arranged as if they had an arrow written on them, all pointing in a common direction in the plane of the epithelium. This type of polarity is called **planar cell polarity**. In the wing of a fly, for example, each epithelial cell has a tiny asymmetric projection, called a wing hair, on its surface, and the hairs all point toward the tip of the wing. Similarly, in the inner ear of a vertebrate, each mechanosensory hair cell has a precisely oriented asymmetric bundle of actin-filled, rodlike protrusions called stereocilia sticking up from its apical plasma membrane as a detector of sound and of forces such as gravity. Tilting the bundle in one direction causes ion channels in the membrane to open, electrically activating the cell; tilting in the opposite direction has the opposite effect. For the ear to function properly, the hair cells

MORPHOGENESIS 1263

must be oriented correctly. Planar cell polarity is also important in the respiratory tract, where every ciliated cell must orient the beating of its cilia so as to sweep mucus upward, away from the lungs.

Screens for mutants with misoriented wing hairs in *Drosophila* have identified a set of genes that control planar cell polarity in many tissues. Some of these genes code for components of the Wnt signaling pathway, and others code for transmembrane proteins such as specialized members of the cadherin superfamily that interact across neighboring cell-cell junctions. Together with intracellular proteins that influence the localization of the transmembrane proteins, two complementary, mutually exclusive domains are defined along the apical surface in such a way as to exert a polarizing influence that propagates from cell to cell, leading to polarization of the entire epithelial tissue. Essentially the same system of proteins controls planar cell polarity in vertebrates; mice deficient in homologs of the *Drosophila* planar-polarity genes have a variety of defects, including incorrectly oriented hair cells in the inner ear, making them deaf (Figure 21–50).

An Epithelium Can Bend During Development to Form a Tube

Convergent extension is an example of morphogenesis in two dimensions. When cells need to leave the plane of a tissue and produce three-dimensional structures, they engage in additional cell behaviors. The universal process of gastrulation involves future endodermal and/or mesodermal cells migrating into the interior of the embryo, and this is often initiated by a localized bending of the blastula epithelium. Similar bending can generate biological tubes from flat epithelial sheets, including the neural tube characteristic of chordates, although there are other routes to tube formation as sketched in Figure 21–51.

Tissues can be bent by a widely used cell behavior called *apical constriction*, which occurs when cells use myosin motor proteins to contract bundles of actin filaments anchored at adherens junctions near their apical surface. Shortening of these filament bundles causes the epithelial cells to narrow at their apex, transforming the cell from a columnar shape into a distinctive wedge or bottle shape. Because the cells are connected to each other by adherens junctions, coordinated contraction in a group can result in the entire sheet bending or even rolling up into a tube (Figure 21–52). The cell groups that undergo apical constriction are selected by localized expression of patterning genes that trigger the activity of the contractile actomyosin networks. In *Drosophila* embryos, the ventrally restricted transcription regulator Twist (Figure 21–26) controls myosin behavior in presumptive mesodermal cells, which then gastrulate by creating a transient tube-like invagination. In vertebrate embryos, patterns of Sonic hedgehog (Shh) and BMP

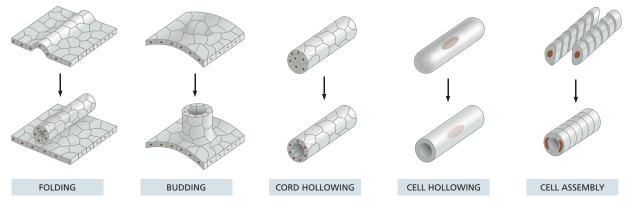

Figure 21–51 Cell behaviors involved in tube formation. Folding generates the neural tube, budding underlies the formation of lungs and trachea, cord hollowing occurs during the formation of mammalian salivary glands, cell hollowing is involved in the formation of tracheal terminal cell tubes, and cell assembly generates the heart tube that forms at the earliest stage of heart development.

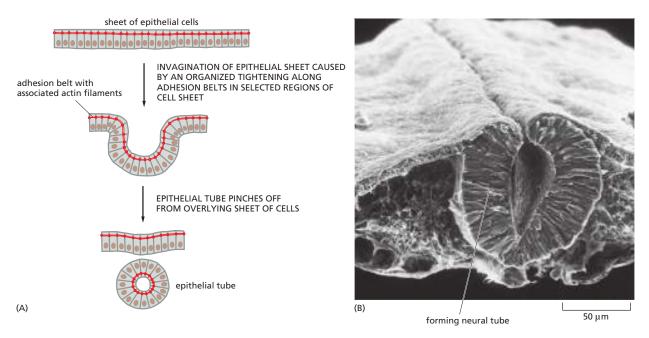

Figure 21–52 Bending of an epithelial sheet to form a tube. Contraction of apical bundles of actin filaments linked from cell to cell by adherens junctions causes the epithelial cells to narrow at their apex. Depending on the number and arrangement of cells in which the contraction occurs, the invaginated epithelium can remain connected to the original sheet or alternatively can roll up into a separated tube or a hollow sphere. (A) Diagram showing how an apical contraction along one axis of an epithelial sheet can cause the sheet to form a tube. (B) Scanning electron micrograph of a cross section through the trunk of a 2-day chick embryo, showing the formation of the neural tube by the process diagrammed in panel A. The vertebrate neural tube gives rise to the brain and spinal cord. (B, courtesy of Jean-Paul Revel.)

signaling induce apical constriction at three hinge points that transform the neural plate into a closed neural tube.

Interactions Between an Epithelium and Mesenchyme Generate Branching Tubular Structures

Embryos often develop branching tubular structures when large surfaces are required for functions such as excretion, absorption of nutrients, and gas exchange. The lungs are an example. They originate from epithelial buds that grow out from the floor of the foregut and penetrate neighboring mesenchyme to form the bronchial trees, systems of tubes that branch repeatedly as they extend, eventually making an estimated 17 million branches in humans. Endothelial cells that form the lining of blood vessels invade the same mesenchyme, thereby creating a system of closely apposed airways and blood vessels, as required for gas exchange in the lung (Figure 21–53). This whole process of *branching morphogenesis* depends on signals that pass in both directions between the growing epithelial buds and the mesenchyme. Genetic studies in mice indicate that fibroblast growth factor (FGF) proteins and their receptor tyrosine kinases play a central part in these signaling processes. FGF signaling has various roles in development, but it is especially important in the many interactions that occur between a developing epithelium and mesenchyme.

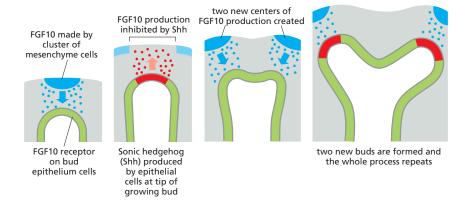

In the case of lung development, FGF10 is expressed in clusters of mesenchyme cells that lie near the tips of the growing epithelial tubes, and its receptor is expressed in the invading epithelial cells. In FGF10-deficient mutant mice, primary buds of the lung epithelium form, but fail to grow out of the mesenchyme to create branching bronchial trees. Conversely, a microscopic bead soaked in FGF10 and placed near embryonic lung epithelium in culture will induce a bud to form and grow out from the epithelium toward the bead. Evidently, the epithelium enters the mesenchyme only by invitation, in response to FGF10.

Figure 21–53 The airways of the lungs, shown in a cast of the adult human bronchial trees. Resins of different colors have been injected into different large branches of the trees. (James Cavallini/ Science Source.)

MBOC7_ptr_ch21_1217-1278.indd 1264 02/12/21 12:25 PM

MORPHOGENESIS 1265

But what makes the growing epithelial tubes of the lung branch repeatedly as they invade the mesenchyme? This depends on a Sonic hedgehog signal that is sent in the opposite direction, from the epithelial cells at the tips of the buds back to the mesenchyme, where it inhibits FGF10 production to promote bifurcation as shown in Figure 21–54. In mice lacking Sonic hedgehog, the lung epithelium grows and differentiates, but it forms a sac instead of a branching tree of tubules.

FGF is also the major signal in formation of the air-exchange system of insects, which consists of a pattern of fine, air-filled channels called *tracheae* and *tracheoles*. These originate from the epidermis covering the surface of the body and extend inward to invade the underlying tissues, branching and narrowing as they go (Figure 21–55). The FGF acts on cells at the tips of the advancing tracheae, causing them to extend filopodia and migrate toward the source of the FGF signal. Because the tip cells remain connected to the remainder of the tracheal epithelium, the pulling force that they generate elongates the tracheal tube.

Initially, the pattern of FGF production in fly embryos is defined by the D-V and A-P patterning systems discussed earlier. In later stages of development, however, FGF expression is induced by transcription regulators called *hypoxia-inducible factors* (*HIFs*) that are activated by hypoxia (low oxygen levels). In this way, hypoxia stimulates the formation of finer and finer and more extensively branched trachea, until the oxygen supply is sufficient to stop the process.

The Extracellular Matrix Also Influences Tissue Shape

So far, we have considered only forces generated by cells during morphogenesis. However, we must not ignore another important constituent of organs: the extracellular matrix. As detailed in Chapter 19, this network of insoluble molecules is found in most animal tissues, and a specialized matrix called the basal lamina underlies all epithelial sheets. Extracellular matrices provide substrates for morphogenetic cell-migration events, as we will discuss shortly. Furthermore, the mechanical stiffness of the matrix can provide instructive signals for shaping organs by modifying the resistance against which cellular forces are generated. During branching morphogenesis of the mammalian salivary gland, for

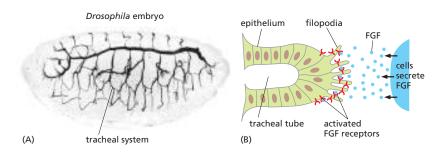

Figure 21-54 Branching morphogenesis of the lung. How FGF10 and Sonic hedgehog are thought to induce the growth and branching of the buds of the bronchial tree. Many other signal molecules, such as BMP4, are also expressed in this system, and the illustrated branching mechanism is only one of several possibilities. As indicated, FGF10 protein is expressed in clusters of mesenchyme cells near the tips of the growing epithelial tubes, and its receptor is expressed in the epithelial cells themselves. The Sonic hedgehog signal is sent in the opposite direction, from the epithelial cells at the tips of the buds back to the mesenchyme. The patterns of gene expression and their timing suggest that the Sonic hedgehog signal may serve to shut off FGF10 expression in the mesenchyme cells closest to the growing tip of a bud, splitting the FGF10-secreting cluster into two separate clusters, which in turn cause the bud to branch into two.

Figure 21–55 Branching morphogenesis of airways in a fly. (A) *Drosophila* embryonic tracheal system. (B) FGF (produced in *Drosophila* by the *Branchless* gene) signals from surrounding cells to the tracheal epithelium and activates its FGF receptors, leading to filopodia formation and tube elongation. [A, from G. Manning and M.A. Krasnow, in The Development of *Drosophila melanogaster* (A. Martinez-Arias and M. Bate, eds.), Vol. 1, pp. 609–685. New York: Cold Spring Harbor Laboratory Press, 1993. With permission from Cold Spring Harbor Laboratory Press.]

example, the basal lamina surrounding the growing bud is perforated by matrix-degrading enzymes. This localized softening of the matrix encourages preferential outgrowth of the epithelium into the more pliable regions. Changes in extracellular resistance, as well as dynamic intracellular forces, can therefore create force imbalances that drive morphogenetic events.

Cell Migration Is Guided by Environmental Signals

The birthplace of cells is often far from their ultimate location in the body. Our skeletal muscles, for example, derive from muscle-cell precursors, or *myoblasts*, in somites from which they migrate into the limbs and other regions. The routes that the migrant cells follow and the selection of sites that they colonize determine the eventual pattern of muscles in the body. The embryonic connective tissues form the framework through which the myoblasts travel, and these tissues provide the cues that guide myoblast distribution. No matter which somite they come from, the myoblasts that migrate into a forelimb bud will form the pattern of muscles appropriate to a forelimb, and those that migrate into a hindlimb bud will form the pattern appropriate to a hindlimb. It is the connective tissue that provides the patterning information.

As a migrant cell travels through the embryonic tissues, it repeatedly extends surface projections that probe its immediate surroundings, testing for cues to which it is particularly sensitive by virtue of its specific assortment of cell-surface receptor proteins. Inside the cell, these receptors are connected to the cortical actin and myosin cytoskeleton, which moves the cell along (see Chapter 16). Some extracellular matrix molecules, such as the protein fibronectin, provide adhesive sites that help the cell advance; others, such as chondroitin sulfate proteoglycan, inhibit locomotion and repel immigration. The nonmigrant cells along the migration pathway may likewise have inviting or repellent macromolecules on their surface; some may even extend filopodia to make their presence known.

In addition to general adhesive molecules, migratory cells can also be guided by specific chemical or mechanical signals that are sensed by dedicated receptors. Among many such influences, a few stand out as especially important. In particular, many types of migrating cells are guided by chemotaxis that depends on a G-protein-coupled receptor, called CXCR4, which is activated by an extracellular ligand, CXCL12. Cells expressing this receptor can shuffle their way along tracks marked out by CXCL12 (Figure 21–56). Chemotaxis toward sources of CXCL12 plays a major part in guiding the migrations of lymphocytes and various other white blood cells; of neurons in the developing brain; of myoblasts entering limb

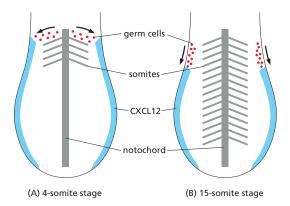

Figure 21–56 CXCL12 guides migrating germ cells. Zebrafish germ cells migrate to domains that express CXCL12. As the sites of CXCL12 expression change, cells follow the CXCL12 track and are guided to the region where the gonad develops at a later developmental stage. (A) At the 4-somite stage, germ cells move from a position that is close to the midline to more lateral regions where CXCL12 is expressed. (B) As the CXCL12 expression retracts, germ cells are guided to more posterior positions, where the gonads are developing.

MORPHOGENESIS 1267

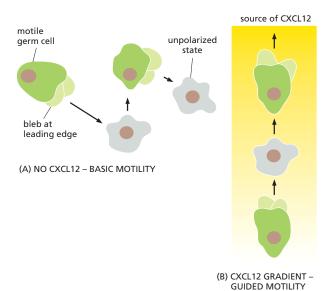

Figure 21–57 Directional migration by local blebbing. (A) Germ cells migrate via protrusions at the leading edge of the cell called blebs, where the plasma membrane detaches locally from the underlying actin cortex and is pushed outward (see Figure 16–18). (B) The persistence and site of the protrusions are biased toward higher levels of CXCL12. Thus, germ cells migrate up the CXCL12 gradient. Note that this form of cell migration is distinct from that based on actin-rich lamellipodia (see Figures 21–48 and 21–59).

buds; of primordial germ cells as they travel toward the developing gonads; and of cancer cells when they metastasize.

Detailed studies of primordial-germ-cell migration have shown that CXCL12 signaling does not induce cell migration per se but rather serves to control its direction. In the absence of CXCL12 signaling, germ cells still display the membrane blebbing associated with cell migration, but the position of the cell front where blebs form is randomly chosen (Figure 21–57), and migration is more of a random walk; if CXCL12 signaling is intact, blebbing is more frequent on the side of the cell that faces the source of CXCL12, resulting in directional migration.

The Distribution of Migrant Cells Depends on Survival Factors

The final distribution of migrant cells depends not only on the routes they take, but also on whether they survive the journey and thrive in the environment they find at their journey's end. Specific sites provide survival factors needed for specific types of migrant cells to survive.

Among the most important sets of migrant cells in the vertebrate embryo is that of the **neural crest**. They arise from the border region between the part of the ectoderm that will form epidermis and the part that will form the central nervous system. As the neural ectoderm rolls up to form the neural tube, the neural crest cells break loose from the epithelial sheet along this border region and set out on their long migrations (see Figure 19–8 and Movie 21.7). They settle ultimately in many sites and give rise to a surprising diversity of cell types. Some will differentiate into the neurons and glial cells of the peripheral nervous system—not only in the sensory ganglia that lie close to the spinal cord, but also, following a much longer migration, in the wall of the gut. Others will form skeletal tissue in the face; still others will lodge in the skin and specialize as pigment cells.

A signaling pathway required for neural crest cell survival was identified by studying animals with defective pigmentation. Many naturally occurring mouse mutants that show white spots on their normally black coat of hair are defective in a gene that encodes a secreted peptide called Stem cell factor. Stem cell factor is produced by tissues along the migration pathways and acts as a survival factor for the migrating neural crest cells. In animals defective for Stem cell factor or its receptor, a transmembrane tyrosine kinase called Kit, many of the migrating neural crest cells die by apoptosis. As a result, the mutant individuals have nonpigmented (albino) patches of skin (Figure 21–58). Stem cell factor is an important survival signal for other types of migratory cells as well, including

MBOC7_ptr_ch21_1217-1278.indd 1267 02/12/21 12:25 PM

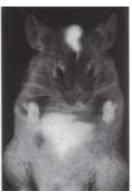

Figure 21–58 Effect of mutations in the *Kit* gene. Both the baby and the mouse are heterozygous for a loss-of-function mutation that leaves them with only half the normal quantity of *Kit* gene product, which is the receptor for stem cell factor (SCF). In both cases, pigmentation is defective because pigment cells depend on SCF for their survival. (Courtesy of R.A. Fleischman, from R.A. Fleischman et al., *Proc. Natl. Acad. Sci. USA* 88:10885–10889, 1991.)

primordial germ cells and blood-cell precursors. Mice completely lacking Stem cell factor or Kit are sterile and eventually die of anemia.

Cells Migrate in Groups to Achieve Large-Scale Morphogenetic Movements

In addition to traveling solo, cells can migrate in groups, maintaining contact with one another and exhibiting coordinated behaviors that differ from those of independently migrating cells. These movements are termed *collective cell migration*, and they come in several forms distinguished by how the cells are organized. For example, neural crest cells undergo *chain migration*, in which cells follow one another in streamlike files (Figure 21–59A). Although their association is loose, contact between the cells is required for directed migration along paths determined by chemotactic factors such as CXCL12. Whereas individual neural crest cells respond poorly to this signal, head-to-tail cell contact induces polarity within the group that drives protrusion at the leading edge of each cell in the migrating chain.

Zebrafish development provides a good example of a second form of collective cell movement, called *clustered migration* (Figure 21–59B). Such migration occurs in groups of cohesive cells that are usually mesenchymal in origin, with leader cells of the group exhibiting the most protrusive behavior. In the zebrafish embryo, a cell cluster called the lateral line primordium migrates from a position just behind the ear and crosses the trunk musculature toward the tail. Cells in the migrating primordium continue to divide, and some are left behind to form sensory structures in its wake. The specific migratory route is laid out by a prepatterned stripe of CXCL12, but interestingly this ligand is not expressed in a gradient. Instead, the cell cluster itself generates a local gradient. Leader and follower cells both express the CXCR4 receptor, but in addition the followers express a nonfunctional CXCL12 receptor called CXCL7, which acts as a "sink" to diminish the effect of the CXCL12 signal at the rear of the cluster. The result is differential signaling within the cell cluster that orients the direction of travel.

Entire epithelia can move in a third form of collective migration called sheet migration (see Figure 21–59C). Here, strong adhesion and apical-basal polarity are maintained in the group; cells at the leading edge of the sheet extend robust protrusions that explore the environment, while follower cells create short basal protrusions that are also oriented in the direction of migration. Collective sheet migration can fuse flanking epithelia together, sealing gaps that have formed during development, as seen at the end of *Drosophila* and *C. elegans* embryogenesis or during wound healing. It can also create single organs from bilateral primordia, such as through the fusion that forms the mammalian palate. Interestingly, epithelial migrations can occur in the absence of a free leading edge, as seen in the spherical epithelium of the developing *Drosophila* egg chamber. In this case, collective epithelial migration driven by oriented basal protrusions drives repeated rounds of rotation of the entire tissue, a process required to shape the mature egg. Migration of cells to the top of mammalian gut villi, which

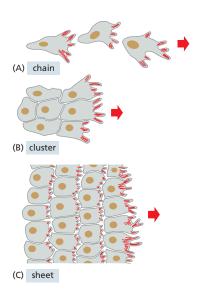

Figure 21-59 Collective cell migration. Cell protrusions are shown in red. (A) Cells undergoing chain migration are connected only loosely, but transient contact with the cell ahead polarizes the protrusions (red) of the cell behind, promoting a shared trajectory. (B) Clustered migration involves groups of adherent cells in which a few 'leader" cells extend protrusions in the direction of travel. (C) In sheet migration, large groups of tightly adherent epithelial cells move coherently together, usually with a free edge where cells take on a partially mesenchymal morphology with robust protrusions that lead to migration. Smaller oriented protrusions are also seen in cells behind the leading edge.

GROWTH 1269

preserves intestinal homeostasis (see Figure 22–4), appears to involve a similar movement of a continuous epithelial sheet.

Summary

Animal tissues are sculpted by dramatic changes in cell shape, arrangement, or position. These changes result from shifts in the balance of forces on cells, often triggered by the expression of genes that regulate actomyosin contractility or cell adhesion. Cells that have similar adhesion molecules on their surfaces cohere and tend to segregate from other cell groups with different surface properties. Selective cell-cell adhesion is often mediated by cadherins; repulsion is often driven by ephrin-Eph signaling. Within a tissue, cells can rearrange themselves to drive convergence and extension movements that result in elongation of a tissue along a body axis. Many movements are coordinated through a planar-polarity signaling pathway that is also responsible for orienting cells correctly in various types of epithelium. Epithelial tubes can originate in various ways, most simply by the rolling up and pinching off of a segment of epithelium due to constriction of the apical surface. Elaborate branched tubular structures, such as the airways of the lung, are generated through bidirectional signaling between an epithelial bud and the mesenchyme that it invades in a process called branching morphogenesis. Branching and other morphogenetic events are regulated by changes both in the extracellular matrix and within the cells themselves. Longrange migrating cells, such as those of the neural crest, break loose from their original neighbors and travel through the embryo to colonize new sites. Many migrant cells, including primordial germ cells, are guided by chemotaxis dependent on the receptor CXCR4 and its ligand CXCL12. Interconnected groups of cells can also migrate, with leader and follower cells showing distinctive behaviors. Such collective cell migrations accomplish large-scale tissue shaping.

Figure 21–60 Members of the same species can have dramatically different sizes. The Chihuahua weighs 2–5 kg, whereas a Great Dane weighs 45–90 kg. (Courtesy of Deanne Fitzmaurice.)

GROWTH

One of the most fundamental aspects of development is one we know surprisingly little about—how the size of an animal or an organ is determined. Why, for example, do we grow to be so much larger than a mouse? All mammals develop from eggs of a similar size, but there is a 100-million-fold difference in adult weight between the smallest (a shrew) and the largest (a blue whale). Even within a species, size can vary greatly; a Great Dane, for instance, can weigh over 40 times more than a Chihuahua (Figure 21–60). In addition to hereditary factors, the environment also plays a role—a goldfish released into the wild may grow 10 times the size of one kept in a home aquarium.

Three variables define the size of an organ or organism: the number of cells, the size of the cells, and the quantity of extracellular material per cell. Size differences can arise from changes in any of these factors (Figure 21–61). If we compare a mouse with a human, for example, we find that the difference lies chiefly in the number of cells, there being roughly 3000 times more cells in a human, corresponding to a body that is roughly 3000 times more massive. Wild and cultivated species of food plants, on the other hand, often differ in body size chiefly because of differences in cell size.

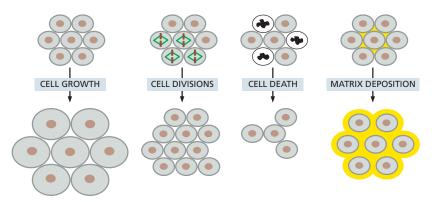

Figure 21–61 Determinants of organ size. A tissue may tune cell growth, proliferation, death, or a combination of these to regulate size. Extracellular matrix deposition also contributes, especially in animal tissues such as bone and cartilage, and in plants.

The challenge, therefore, is to understand how cell numbers, cell size, and extracellular matrix production are regulated. First, we need to identify the signals that drive or inhibit growth. Then we need to discover how the signals themselves are regulated. In some cases, organ growth is dictated by developmental programs that do not monitor the size the structure has attained. In other cases, the growth of an organ or of the body as a whole is controlled homeostatically, so that a "target size" is reached even in the face of drastic disturbances. This suggests the developing structure somehow senses its own size, through local or systemic signals, and uses this information to regulate its growth or shrinkage.

The variation in control strategies is nicely illustrated by some classic transplantation experiments. If several fetal thymus glands are transplanted into a developing mouse, each grows to its characteristic adult size. In contrast, if multiple fetal spleens are transplanted, each ends up smaller than normal, but collectively they grow to the size of one adult spleen. Thus, thymus growth is regulated by local mechanisms intrinsic to the individual organ, whereas spleen growth is controlled by a systemic feedback mechanism that senses the quantity of spleen tissue in the body as a whole; in neither case is the mechanism known. Very often, the sizes and proportions of body parts depend on combinations of size-measuring feedback controls and intracellular programs, as well as on environmental influences such as nutrition and habitat.

The Proliferation, Death, and Size of Cells Determine Organ and Organism Size

The worm *C. elegans* demonstrates the ways in which size differences can arise. As we discussed earlier, each individual of a given sex is generated by almost exactly the same sequences of cell divisions and cell deaths, and consequently has precisely the same number of somatic cells—959 in the adult hermaphrodite (see Figure 21-42). More than 1000 cell divisions generate 1090 somatic cells during hermaphrodite development, but 131 of these cells undergo apoptotic cell death. Thus, precise regulation of both cell division and cell death determines the final numbers of somatic cells in the worm.

It takes only 3 days for *C. elegans* to generate all of its adult somatic cells, after which cell divisions occur only in the germ line. Yet the worm continues to grow, doubling in size between sexual maturity and death 2–3 weeks later. This doubling results from somatic-cell growth: although the cells no longer divide, they continue to go through rounds of DNA synthesis; this *endoreplication* of the genome makes the cells *polyploid*. As in all organisms, the size of a cell is proportional to its ploidy (that is, the number of genome copies that it contains): a doubling of ploidy roughly doubles cell volume. Thus the worm's final size is set by a combination of programmed cell divisions and cell deaths, along with regulation of the sizes of individual cells through changes in ploidy.

Endoreplication of the genome as a means to increase cell size is not peculiar to *C. elegans* and occurs in a developmentally regulated manner in specific tissues of many animals. In one extreme case, neurons that innervate large areas of the mollusk *Aplysia* may contain hundreds of thousands more copies of the genome than does a diploid cell and grow up to 1 mm in diameter (Figure 21-62).

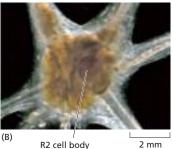

Figure 21-62 Giant neurons of the sea slug are highly polyploid. (A) The mollusk species Aplysia californica, commonly called a sea hare because its chemosensory tentacles stick up like ears, can weigh more than 2 kg. The Aplysia central nervous system contains groups of neural cell bodies called ganglia. (B) A dissected abdominal ganglion contains massive neurons such as R2, which has undergone endoreplication to produce ~300,000 copies of the diploid genome and is thought to be the largest somatic cell found in nature. Aplysia and its giant neurons enable physiological, biochemical, and genomic studies at the level of single cells, providing an accessible model for studies of how neural circuits control behavior. (A and B, courtesy of Lynne Fieber and Michael Schmale.)

MBOC7_ptr_ch21_1217-1278.indd 1270 02/12/21 12:25 PM

GROWTH 1271

Figure 21–63 Two species of the frog genus *Xenopus. X. tropicalis (top)* has an ordinary diploid genome. *X. laevis (bottom)* has roughly twice as much DNA per cell and evolved through hybridization of two *X. tropicalis*–like species followed by a whole-genome duplication event roughly 30 million years ago. (From E. Amaya, M. Offield, and R. Grainger, *Trends Genet*.14:253–255, 1998. With permission from Elsevier.)

Changes in ploidy can also arise during the evolution of new species, where they can drive size changes of the entire animal. The frog *Xenopus laevis* possesses a tetraploid genome and has a mass of about twice that of diploid relatives such as *Xenopus tropicalis* (Figure 21–63). These two species show robust size-scaling relationships at the organism, cellular, and subcellular levels, with the smaller frog possessing smaller cells, and the smaller cells, in turn, containing smaller nuclei. In plants, as in animals, cell size increases as ploidy increases (Figure 21–64). This effect has been exploited in the agricultural breeding of plants for large size: most of the major fruits and vegetables that we consume are polyploids.

Changes in Cell Size Usually Result from Modified Cell Cycles

Although fundamental to understanding how organ and organism size are determined, how cell size itself is set and maintained remains an open question. As discussed in Chapter 17, increases in cell size (growth) are usually coordinated with progression through the cell cycle (division) to maintain cell-size homeostasis. However, cells can uncouple the two processes, for example during growth of an egg, which enlarges dramatically without replicating its genome or dividing. After fertilization, this phenomenon is reversed when rounds of DNA replication and cell division occur in the absence of growth to form many small cells.

Endoreplication, which reduplicates the genome to enlarge a somatic cell, results from another variation on the cell cycle. Although S phase proceeds,

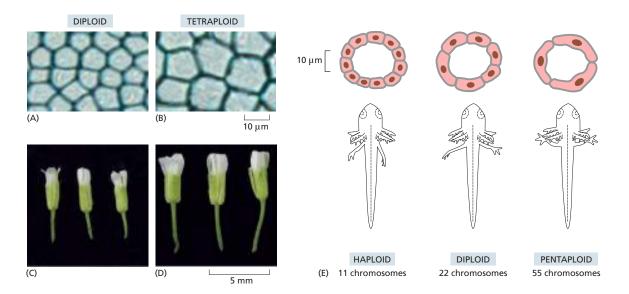

Figure 21–64 Effects of ploidy on cell size and organ size. In all organisms, from bacteria to humans, cell size is proportional to ploidy—the number of copies of the genome per cell. This is illustrated for (A–D) *Arabidopsis* flowers and (E) for salamanders. In each case, the upper panels show cells in a specific tissue [a petal for *Arabidopsis*, a pronephric (kidney) tubule for the salamander]; the lower panels show the gross anatomy—flowers for *Arabidopsis*, the whole body for the salamander. In the case of *Arabidopsis* flowers, increase in cell size increases organ size. By contrast, the salamander and its individual organs attain their normal standard size regardless of ploidy, because large cell size is compensated for by fewer cells. This indicates that the size of an organism or organ in this species is not controlled simply by counting cell divisions or cell numbers; size must somehow be regulated at the level of total cell mass. [A–D, from C. Breuer et al., *Plant Cell* 19:3655–3668, 2007. With permission from the American Society of Plant Biologists; E, adapted from G. Fankhauser, in Analysis of Development (B.H. Willier et al., eds.), pp. 126–150. Philadelphia: Saunders, 1955.]

MBOC7_ptr_ch21_1217-1278.indd 1271 02/12/21 12:25 PM

mitotic cyclin levels are too low to induce M phase, and the polyploid cells usually cease dividing completely, entering a *post-mitotic* state. Additional rounds of DNA replication in the absence of cell division lead to an increase in cell size. In some tissues, such as the liver and cardiac muscle, DNA replication is followed by nuclear division, but not cytokinesis, resulting in polyploid cells with multiple nuclei, through a process called *endomitosis*. Whether or not nuclear division occurs, ploidy increases are accompanied by cell growth and contribute to tissue function. For example, the trophoblast cells of the mammalian placenta undergo eight rounds of endoreplication, producing giant cells crucial for formation of the tissue barrier between mother and fetus.

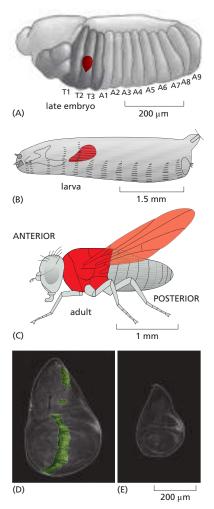

How do increases in ploidy increase the size of cells? One idea is that elevated gene-copy numbers increase the biosynthetic capacity by allowing production of more gene products. However, a strong positive correlation between genome size and cell size is observed across all species, independent of the fraction of the genome that codes for proteins. For example, although all vertebrates have a similar number of coding genes, axolotl salamanders possess a diploid genome that is 10 times the size of the human genome (containing 10 times more noncoding DNA). Remarkably, axolotl cells are also 10 times larger than human cells. The molecular basis of the scaling relationship between genome size and cell size is one of the many outstanding mysteries in biology.

Animals and Organs Can Assess and Regulate Total Cell Mass

The size of an animal or organ depends on both cell size and cell number; that is, on total cell mass. Remarkably, many animals and organs can somehow assess their total cell mass and regulate it, providing evidence for feedback controls of the sort highlighted earlier in our introductory account of the general principles of growth control. In contrast with *C. elegans*, if cell size is artificially increased or decreased in these cases, cell numbers adjust to maintain the same total cell mass. This has been beautifully illustrated by experiments done long ago in salamanders, where cell size can be manipulated by altering the animal's ploidy. As shown in Figure 21–64E, salamanders of different ploidies end up being the same size with very different numbers of cells. The individual cells in a pentaploid salamander, for example, are about five times the size of those in a haploid salamander, but there are only one-fifth as many cells. This scaling operates not only in the body as a whole, but also in its individual organs. Pentaploid salamanders possess the same size brain as their diploid counterparts, but with many fewer neurons and a simplified structure.

The **imaginal discs** of *Drosophila* provide another striking example of homeostatic size control. The discs are epithelial pouches that grow by cell proliferation during the larval period and, during the pupal stage, form the organs and extremities of the adult fly (**Figure 21–65**). Experiments have been chiefly done on the wing imaginal disc. Mutations in components of the cell-cycle control machinery can be used to speed up or slow down the rate of cell division in the disc. Remarkably, such mutations result in an excessive number of abnormally small cells or a reduced number of abnormally large cells, respectively, leaving the size (area) and patterning of the adult wing practically unchanged. Thus, the size of

Figure 21–65 Growth of the *Drosophila* wing imaginal disc. Drawings in panels A–C show the locations of cells that give rise to the adult wing and dorsal thorax after metamorphosis. (A) Initially, $\sim\!30$ cells are specified in the second thoracic segment of the embryo as precursors to the wing and dorsal thorax. These cells divide rapidly during the 4 days of larval life. (B) In the larva before metamorphosis, these cells are organized into a simple pouch-like epithelial organ called the wing imaginal disc, which contains $\sim\!30,000$ cells and is $\sim\!400~\mu\mathrm{m}$ in diameter. Other imaginal discs (not shown) give rise to most of the other external structures of the fly. (C) The final adult wing is $\sim\!2.25~\mathrm{mm}$ long. (D, E) The morphogen Dpp is expressed in a stripe down the center of the wing imaginal disc (green), diffusing out toward the edges and influencing disc growth as well as cell fates. When Dpp expression is removed from the disc late during larval development, the wing disc and resultant wing is proportionally smaller. (D and E, from S. Matsuda and M. Affolter, eLife 6:e22319, 2017, doi 10.7554/eLife.22319.)

MBOC7_ptr_ch21_1217-1278.indd 1272 02/12/21 12:25 PM

GROWTH 1273

the disc is not determined by counting the number of cell divisions so as to produce a set number of cells. Instead, there must be a regulatory mechanism that halts growth when the disc's total cell mass reaches the appropriate value, so that the adult wing that subsequently develops is normal. Moreover, if young discs or even disc fragments are taken out of their normal context and transplanted into the growth-permissive abdominal cavity of an adult female, they will grow until they reach their normal size and then stop. Clearly, the mechanisms that regulate organ size are intrinsic to the disc.

We know little about how organisms or organs assess total cell mass or monitor their own growth. Nevertheless, we are beginning to understand some of the signal molecules that drive or halt growth in response to the mysterious cues that convey information about the size attained.

Various Extracellular Signals Stimulate or Inhibit Growth

To produce an organ with the correct morphology and proportions, cell proliferation and cell growth must be coordinated within a tissue. While some control occurs systemically through growth-regulatory hormones, discussed later, there are also interesting examples in which tissues regulate their own growth. One example of how this may be achieved has been investigated in the Drosophila wing imaginal disc (see Figure 21–65), where the TGF β family member Dpp plays a role. We encountered Dpp before as a morphogen involved in patterning the dorsoventral axis of the fly embryo; in the disc, it works analogously, diffusing from a narrow stripe down the middle of the disc to dictate different cell fates at different distances. Some experiments indicate that the gradient of Dpp emanating from this central source also influences tissue size, perhaps because growth of the disc leads cells farther from the source to experience lower levels of Dpp signaling (see Figure 21–65D and E). Linking tissue growth to pattern formation would ensure that changes in organ size are accompanied by appropriate changes in cell differentiation and distribution.

Not all growth-regulating extracellular signals stimulate growth; some inhibit it by promoting cell death or inhibiting cell growth, cell division, or both. Myostatin is another TGF β family member that specifically inhibits the growth and proliferation of myoblasts—the precursor cells that fuse to form the huge, multinucleated cells of skeletal muscle. In this case, the tissue itself produces the signal, so as more muscle forms, myostatin levels increase and eventually turn off muscle growth. The importance of this simple organ-size feedback mechanism can be seen when the Myostatin gene is deleted: the muscles of mutant mice grow to be several times larger than normal. Remarkably, two breeds of cattle that were bred long ago for large muscles both have mutations in the Myostatin gene, as does a breed of dogs (Figure 21–66).

The Hippo Pathway Relays Mechanical Signals Regulating Growth

Organ growth is governed in many tissues by an intracellular signaling system called the Hippo pathway. It was discovered in *Drosophila*, but it operates in vertebrates as well. Named after the overgrown, buckled tissues that result when

(B) myostatin mutant

Figure 21–66 Myostatin limits muscle growth. (A) A standard whippet and (B) a bully whippet that lacks myostatin. (A, Bianca Grueneberg/Getty Images; B, ©2020 Stuart Isett. All rights reserved.)

Figure 21-67 The Hippo pathway in Drosophila. Hippo, a protein kinase, limits growth by phosphorylation and activation of the kinase Warts, which in turn phosphorylates and inactivates the transcriptional coactivator Yorkie (Yap and Taz in vertebrates). When unphosphorylated, Yorkie/ Yap drives tissue growth: it activates the transcription of the growth-promoting gene Myc, the cell-cycle progression gene Cyclin E, the anti-apoptotic gene Diap, and the microRNA Bantam. Hippo-induced phosphorylation of Yorkie/Yap blocks this effect.

the pathway is inactive, Hippo signaling in wild-type animals inhibits growth both by promoting cell death (by blocking an apoptosis inhibitor) and by inhibiting cell-cycle progression (by inhibiting the expression of the cell-cycle gene Cyclin E). Some components of the pathway in Drosophila are shown in Figure 21-67. The organs of animals that are abnormally resistant to Hippo repression can grow to a monstrous size (Figure 21-68).

Unlike many signaling pathways that involve binding of a signal molecule to a dedicated receptor, the Hippo pathway instead appears to be controlled primarily by mechanical forces and cell architecture. Cell-cell and cell-matrix contact, cytoskeletal tension, and the apical-basal polarity of the cell can each influence Hippo activation. Through this mechanism, tissues can sense physical as well as chemical cues in their environment and regulate their growth accordingly.

Hormones Coordinate Growth Throughout the Body

We have already seen how some signals act systemically as hormones to regulate the development of the animal as a whole. Some of these serve to regulate growth. In mammals, for instance, growth hormone (GH) is secreted by the pituitary gland into the bloodstream and stimulates growth throughout the body: excessive production of GH leads to pituitary gigantism, and too little leads to dwarfism (Figure 21-69). Pituitary dwarfs with lower GH levels have bodies and organs that are proportionately small, and stand in contrast to achondroplastic dwarfs, whose limbs are disproportionately short usually because of a mutation in a gene encoding an FGF receptor that disrupts normal cartilage and bone development (Figure 21-70).

Growth hormone stimulates growth primarily by inducing the liver and other organs to produce insulin-like growth factor 1 (IGF1), which acts mainly as a local signal within many tissues. IGF1 and related factors are potent growth promoters that increase cell survival, cell growth, cell proliferation, or some combination of these, depending on the cell type. Large breeds of dogs such as Great Danes owe their great size to high levels of IGF1, while miniature breeds such as Chihuahuas have low levels (see Figure 21-60).

It is important to note that in all species, nutritional conditions also play a fundamental part in regulating the pace and extent of growth, and in animals they do so through hormonal signal networks that are highly conserved between

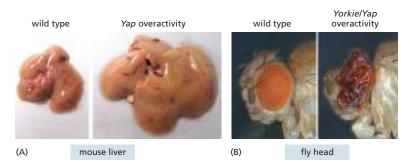

Figure 21-68 Overcoming Hippo repression increases organ size. (A) When Yap is overexpressed in the mouse liver, Hippo signaling cannot repress its activity and excess growth results. (B) Similar overgrowth is seen when fly eyes express a form of Yorkie/Yap that cannot be phosphorylated and inhibited by Hippo signaling. (A, from J. Dong et al., Cell 130:1120-1133, 2007. MBOC7_ptr_ch21_1217-1278.indd 1274 02/12/21 12:25 PM GROWTH 1275

Figure 21–69 Pituitary dwarf and pituitary giant. The "giant" on the right is Robert Wadlow (1914–1940), the tallest recorded man at 8 feet 11 inches (2.72 m), together with his father, who was almost 6 feet tall (1.82 m). The dwarf on the left is General Tom Thumb, which was the stage name of Charles Sherwood Stratton (1838–1883). On his 18th birthday, he was measured at 2 feet 8.5 inches (82.6 cm) tall, and at his death, he was 3 feet 4 inches (102 cm). (Left, Bettman/Getty; right, History and Art Collection/Alamy Stock Photo.)

vertebrates and invertebrates. Genetic experiments, especially in *Drosophila*, have begun to unravel the logic of these controls and to indicate how they may operate alongside other machinery, such as the Hippo pathway, to determine final size.

The Duration of Growth Influences Organism Size

In addition to rate of growth, the final size of an organism will be determined by the time over which growth occurs. Some animals have a defined period of the life span during which growth is permitted; these species are said to show *determinate growth*. In humans, the growth period terminates at the end of puberty, while in many insects it terminates with the onset of metamorphosis. In both cases the change is triggered by the release of hormones that transition the organism into sexual maturity. Thereafter, cell proliferation is restricted to supporting tissue homeostasis via the action of adult stem cells (see Chapter 22), although significant cell growth can continue in cells such as fat cells. The timing of hormone release is set by many influences, among which both nutritional status and juvenile body size provide important inputs to set final body size.

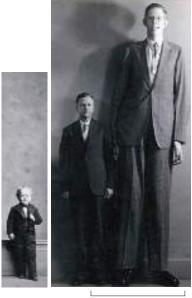

Other species show *indeterminate growth* and are capable of size increases throughout their life as long as environmental conditions are amenable. Lobsters and many fish are familiar examples, but indeterminate growth is found along numerous branches of the tree of life. Plants, in which cell proliferation takes place in specialized regions called meristems (see Chapter 19), also show both determinate and indeterminate growth patterns. Giant sequoias and other redwood trees are an example of the latter, whereas the former include agricultural crops selected for maximal and synchronous fruit production. Some species, including tomatoes, exist in both determinate and indeterminate varieties. The mechanisms that assign a terminal growth point to one organism while enabling a closely related species to continue growth throughout life remain unknown.

Summary

The sizes of animal species and their organs vary widely and depend mainly on the size and number of cells, which are increased through cell growth and cell division, respectively. Cell numbers are reduced by cell death—mainly by apoptosis. The mystery is how decisions about growth, division, and death within individual cells are regulated and coordinated to produce the characteristic final size of the adult animal.

Some signals such as growth factors, mitogens, and survival factors act in organs to stimulate growth, while other signal molecules do the opposite. These signals are deployed under the control of developmental patterning programs and influence the cell cycle or apoptotic machinery to produce tissue-specific growth outcomes. Many animals and organs can assess their own total cell mass and regulate it, reaching a consistent target size in the face of artificial changes to cell growth or cell numbers. The compensatory mechanisms are not known, but signaling pathways that ensure that organs do not grow beyond a certain size have been identified.

Although most of these signals operate locally to help sculpt the size of organs and appendages, others act as hormones to regulate the growth of the animal as a whole. Nutrients can regulate growth through stimulating the release of hormonal signals throughout the body. The period of life during which growth is permitted can also be controlled by hormones. Final organism size reflects the integrated output of all the above mechanisms.

1 meter

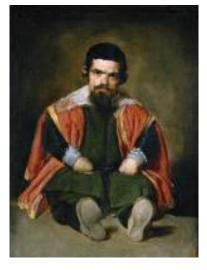

Figure 21-70 Achondroplasia. This type of dwarfism, shown in Velázquez's painting, occurs in one of 10,000-100,000 births; in more than 99% of cases it results from a mutation at an identical site in the genome, corresponding to amino acid 380 in the FGF receptor FGFR3 (a glycine in the transmembrane domain). The mutation is dominant, and almost all cases are due to new, independently occurring mutations, implying an extraordinarily high mutation rate at this particular site in the genome. The defect in FGF signaling causes dwarfism by interfering with the growth of cartilage in developing long bones. (The Picture Art Collection/Alamy Stock Photo.)

PROBLEMS

Which statements are true? Explain why or why not.

- **21–1** In the early cleavage stages, when the embryo cannot yet feed, the developmental program is driven and controlled entirely by the material deposited in the egg by the mother.
- **21–2** Because of the many later developmental transformations that produce the elaborately structured organs, the body plan set up during gastrulation bears little resemblance to the body plan in the adult.
- **21–3** As development progresses, individual cells within a lineage become more and more restricted in the range of cell types they can give rise to.
- **21–4** At different stages of embryonic development, the same signals are used over and over again by different cells, but with different biological outcomes.
- **21–5** Changes in the coding regions of genes involved in development are primarily responsible for the differences between species.
- **21–6** The cell cycle is the ticking clock that sets the tempo of developmental processes, with maturational changes in gene expression being dependent on cell-cycle progression.

Discuss the following problems.

- **21–7** Name the three processes that are fundamental to animal development, and describe each of them in a single sentence.
- **21–8** Name the three germ layers of the early embryo that are formed during gastrulation, and list the principal structures each gives rise to in the adult.
- **21–9** In the early *Drosophila* embryo, there seems to be no requirement for the usual forms of cell-cell signaling; instead, transcriptional regulators and mRNA molecules move freely between nuclei. How can that be?
- **21–10** Morphogens play a key role in development, creating concentration gradients that inform cells of where they are and how to behave. Examine the simple patterns represented by the flags in Figure Q21–1. Which do you suppose could be created by a gradient of a single morphogen? Which would require gradients of two morphogens? Assuming that such patterns were present in a sheet of cells, explain how they could be created by morphogens.

Figure Q21–1 National flags from three countries (Problem 21–10). (Left, railway fx/Shutterstock; center, Creative Photo Corner/Shutterstock; right, Derek Brumby/Shutterstock.)

21-11 Two adjacent cells in the nematode worm normally differentiate into an anchor cell (AC) and a ventral uterine precursor (VU) cell, but which of the two becomes the AC and which becomes the VU cell is completely random. The cells have an equal chance of adopting either fate, but they always adopt opposite fates. Mutations of the Lin12 gene alter these fates. In hyperactive Lin12 mutants, both cells become VU cells, while in inactive Lin12 mutants, both cells become ACs. Thus, Lin12 is central to the decision-making process. In genetic mosaics in which one precursor cell has the hyperactive *Lin12* and the other precursor has the inactive Lin12, the cell with the hyperactive Lin12 gene always becomes the VU cell, and the cell with the inactive Lin12 gene always becomes the AC. Assuming that one cell sends a signal and the other cell receives it, explain how these results suggest that the Lin12 gene encodes a protein required to receive the signal. Offer a suggestion for how the fates of these two precursor cells are normally decided in wild-type worms.

21–12 It was clear from the early days of studying development that certain "morphogenetic" substances were present in the egg and segregated asymmetrically into cells of the developing embryo. One such investigation in ascidian (sea squirt) embryos examined endodermal alkaline phosphatase, which could be visualized using a histochemical stain. Treatment of embryos with cytochalasin B stopped cell division but did not block expression of alkaline phosphatase at the appropriate time. Treatment with actinomycin D, which blocks transcription, did not interfere with expression of alkaline phosphatase. Treatment with puromycin, which blocks translation, eliminated expression of alkaline phosphatase. What is the likely nature of the morphogenetic substance that gives rise to alkaline phosphatase?

21–13 The mouse *HoxA3* and *HoxD3* genes are paralogs that occupy equivalent positions in their respective Hox gene clusters and share roughly 50% identity in their protein-coding sequences. Mice with defects in HoxA3 have deficiencies in pharyngeal tissues, whereas mice with defects in HoxD3 have deficiencies in the axial skeleton, suggesting quite different functions for the paralogs. Thus, it came as a surprise when it was found that replacing a defective HoxD3 gene with the normal HoxA3 gene corrected the deficiency, as did the reciprocal experiment of replacing a mutant *HoxA3* gene with a normal *HoxD3* gene. Neither transplaced gene, however, could supply its normal function; that is, a normal HoxA3 gene at the HoxD3 locus could not correct the deficiency caused by a mutant HoxA3 gene at the HoxA3 locus. The same was true for the HoxD3 gene. If the HoxA3 and HoxD3 genes are equivalent, how do you suppose they can play such distinct roles in development? Why do you suppose they cannot perform their normal function in a new location?

21–14 The segmentation of somites in vertebrate embryos is thought to depend on oscillations in the expression of the *Hes7* gene. Mathematical modeling explains

MBOC7_ptr_ch21_1217-1278.indd 1276 02/12/21 12:25 PM

PROBLEMS 1277

these oscillations in terms of the delays in production of the unstable Hes7 protein, which acts as a transcription regulator to shut off its own expression. Once Hes7 decays, with a half-life of about 20 minutes, its transcription resumes. To test this model, you decide to reduce the total delay by removing one, two, or all three of the introns from the *Hes7* gene in mice. Why do you expect that intron removal would reduce the delay? What would you predict would happen to the oscillation time, and somite formation, if the model were correct?

21-15 The oscillatory clock that drives somite formation in vertebrates involves three essential components: Her7 (an unstable repressor of its own synthesis), Delta (a transmembrane signaling molecule), and Notch (a transmembrane receptor for Delta). Notch is bound by Delta on neighboring cells, activating the Notch signaling pathway, which then activates Her7 transcription. Normally, this system works flawlessly to create sharply defined somites (Figure Q21-2A). In the absence of Delta, however, only the first five somites form normally, and the rest are poorly defined (Figure Q21-2B). If a pulse of Delta is supplied later, somite formation returns to normal in the regions where Delta was present (Figure Q21-2C). A diagram of the connections between the components of the clock and how they interact in adjacent cells is shown in Figure Q21-2D. In the absence of Delta, why do the cells become unsynchronized?

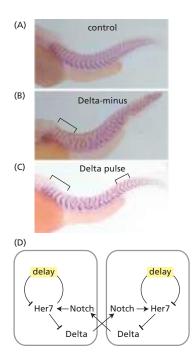

Figure Q21–2 Somite formation in zebrafish embryos (Problem 21–15). (A) Wild-type embryos with normal somites. (B) Somite formation in embryos lacking Delta. The bracket indicates normal-looking somites where they initially form. (C) Somite formation in embryos lacking Delta but receiving a pulse of Delta expression at the time indicated by the right-hand bracket. (D) Interactions among components of the oscillatory clock in adjacent cells. (Adapted from C. Soza-Ried et al., Development 141:1780–1788, 2014. With permission from the Company of Biologists.)

What is it about the presence of Delta that keeps adjacent cells oscillating in synchrony?

21–16 The extracellular protein factor Decapentaplegic (Dpp) is critical for proper wing development in *Drosophila* (Figure Q21–3A). It is normally expressed in a narrow stripe in the middle of the wing, along the anterior-posterior boundary. Flies that are defective for Dpp form stunted "wings" (Figure Q21–3B). If an additional copy of the gene is placed under control of a promoter that is active in the anterior part of the wing or in the posterior part of the wing, a large mass of wing tissue composed of normal-looking cells is produced at the site of Dpp expression (Figure Q21–3C and D). Does Dpp stimulate cell division, cell growth, or both? How can you tell?

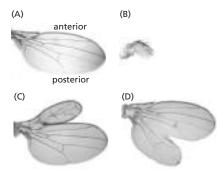

Figure Q21–3 Effects of Dpp expression on wing development in *Drosophila* (Problem 21–16). (A) Normal Dpp expression. (B) Absence of Dpp expression. (C) Additional anterior Dpp expression. (D) Additional posterior Dpp expression. (From M. Zecca et al., *Development* 121:2265–2278, 1995. With permission from the Company of Biologists.)

Stem Cells in Tissue Homeostasis and Regeneration

22

Cells evolved originally as free-living individuals, and such cells still dominate Earth and its oceans. But the cells that matter most to us, as humans, are specialized members of a multicellular community. These cells have lost features needed for independent survival and acquired peculiarities that serve the needs of the body as a whole. Although they share the same genome, they are spectacularly diverse in structure, chemistry, and behavior. There are more than 200 different named cell types in the human body that collaborate with one another to form many different tissues, which are arranged into organs performing widely varied functions. To understand them, it is not enough to analyze cells in a culture dish: we need also to know how they live, work, and die in their natural habitat, the intact body.

In Chapters 7 and 21, we saw how the various cell types become different in the embryo and how cell memory and signals from their neighbors enable them to remain different thereafter. In Chapter 19, we discussed the mechanisms that cells use to self-assemble into multicellular tissues, including the use of molecular devices that bind cells together and the extracellular materials that give tissues and organs support. But the adult body is not static: it is a structure in dynamic equilibrium, where new cells are continually being born, differentiating, and dying. Homeostatic mechanisms maintain a proper balance, so that tissue architecture is preserved despite the constant replacement of old cells by new.

In this chapter, we focus on these homeostatic processes that continue throughout life. In doing so, we illustrate some of the diversity of differentiated cell types, examining in particular the part played in many adult tissues by stem cells—undifferentiated cells that are specialized to provide a fresh supply of differentiated cells where these need to be continually replaced or when they are required in large number for tissue repair and regeneration. We will see that many adult tissues constantly renew and repair themselves, but others do not, in which case, lost cells are lost forever, causing deafness, blindness, dementia, and other disorders. We discuss how stem cells are maintained within a selfrenewing tissue and how the fate of their daughter cells is determined. We then describe the remarkable ability of some animal species to regenerate entire limbs or organs, in one extreme example, reproducing all of the tissues of the organism from a single stem cell. In the final section of the chapter, we discuss how stem cells can be generated and manipulated artificially, raising the practical question that underlies a current storm of interest in stem-cell technology: How can we use our understanding of the processes of cell differentiation and tissue renewal to improve upon nature and make good those injuries and degenerations associated with disease and aging of the human body that have hitherto seemed beyond repair?

STEM CELLS AND TISSUE HOMEOSTASIS

In self-renewing adult tissues, cells are continually being born, differentiating, and dying. This "flow" of cells can be compared with the flow of water in a river: the river may look the same from day to day, but, as it flows downstream, the water

Control of Stem-cell Fate and Self-Renewal

Regeneration and Repair

Cell Reprogramming and Pluripotent Stem Cells

MBOC7_ptr_ch22_1279-1312.indd 1279 02/12/21 12:22 PM

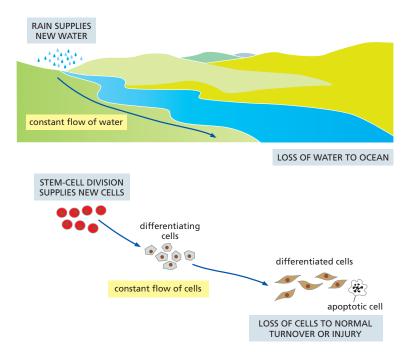

Figure 22–1 Tissue homeostasis compared to a river. In a self-renewing adult tissue, a constant flow of new cells produced by cell division "upstream" and a constant loss of differentiated cells "downstream" maintain the tissue in a dynamic equilibrium.

in the river is never the same (Figure 22–1). Similarly, the characteristic architecture of a self-renewing tissue is maintained even though the cell population is always changing, with differentiated cells lost "downstream" and stem cells producing new cells "upstream." Thus, the stem cells in such tissues must be able to both replicate themselves and produce differentiated cells for the life span of the organism. Without stem cells, these tissues and organs would fail rapidly, being unable to keep up with the natural turnover of cells. Indeed, defects in stem-cell functions can contribute to disease and aging for this reason.

In this first section, we define the essential characteristics of stem cells, using two epithelial tissues as examples, the lining of the gut and the outer surface of the skin. We then consider how we can identify stem cells in tissues—by cell lineage tracing or, in the case of blood cells, by cell transplantation studies. We finally discuss tissues that can maintain themselves in the absence of stem cells.

Stem Cells Are Defined by Their Ability to Self-renew and Produce Differentiated Cells

Many adult tissues, especially those with high cell turnover rates, contain tissue-specific stem cells (also called adult stem cells). Each of these tissues contains its own unique stem-cell population, capable of producing the differentiated cells characteristic of that tissue and not those of other tissues. The stem cells of each tissue possess their own distinct developmental history, without necessarily sharing molecular characteristics with the stem cells of other tissues.

All stem cells, however, share two fundamental properties that define them: (1) they are able to replenish themselves as stem cells, generally throughout the lifetime of the organism—a process called *self-renewal*; and (2) they can also produce differentiated cells. Thus, when a stem cell divides, each daughter has a choice: it can either remain a stem cell or it can embark on a course that commits it to differentiation (Figure 22–2).

Stem cells usually do not produce differentiated cells directly; instead, they make an intermediate cell type that is committed to a differentiation pathway but continues to proliferate, thereby generating greater numbers of differentiated cells. These cells are called *progenitor cells*; they are also called *transit-amplifying cells* because their divisions serve to amplify the number of differentiated cells that

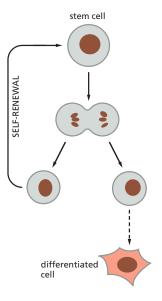

Figure 22–2 The defining characteristics of a stem cell. Each daughter cell produced when a stem cell divides can either remain a stem cell, in the process of self-renewal, or commit to differentiation, usually after a number of cell divisions. The self-renewal process maintains the pool of stem cells in the tissue.

MBOC7_ptr_ch22_1279-1312.indd 1280 02/12/21 12:22 PM

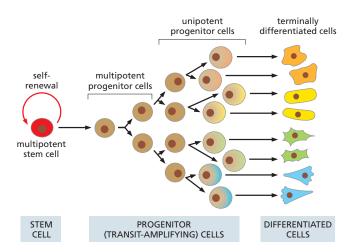

Figure 22–3 A hierarchy of stem cells, progenitor cells, and differentiated cells. In addition to self-renewal, tissue-specific stem cells generally produce progenitor (transit-amplifying) cells that divide a limited number of times before they terminally differentiate. Stem cells and progenitor cells can be unipotent or multipotent, depending on whether they produce only one type or multiple types of differentiated cells.

ultimately result from each stem-cell division (**Figure 22-3**). Unlike stem cells, these intermediate cells only go through a limited number of divisions before they differentiate. When a cell reaches the end of its differentiation pathway and does not divide again, it is *terminally differentiated*. When an adult stem cell or progenitor cell generates multiple differentiated cell types, it is *multipotent*; when it generates only one differentiated cell type, it is *unipotent* (see Figure 22-3).

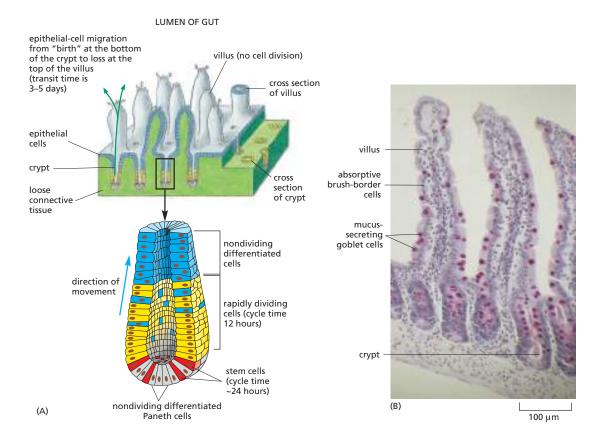

We now consider two epithelial tissues to illustrate how these different categories of cells are organized in a self-renewing adult tissue—the lining of the gut and the outer layer of the skin. In both cases, the stem cells continually produce transit-amplifying progenitor cells at one surface of the tissue, while terminally differentiated cells are lost from the opposite surface—upstream and downstream, respectively, in our river analogy.

The Epithelial Lining of the Small Intestine Is Continually Renewed Through Cell Proliferation in Crypts

The lining of the small intestine (and of most other regions of the gut) is a single-layered epithelium, only one cell thick. The **intestinal epithelium** covers the surfaces of the *villi* that project into the gut lumen, and it lines the *crypts* that descend into the underlying connective tissue (**Figure 22-4**). Dividing cells, including the stem cells and progenitor cells, are restricted to the crypts, and terminally differentiated cells pour out of the crypts in a steady stream onto the villi. There are four main types of differentiated cells—one absorptive and three secretory (**Figure 22-5**):

- 1. Absorptive cells (also called brush-border cells or enterocytes) are the majority cell type in the epithelium and have densely packed microvilli on their exposed surfaces. Their job is to take up nutrients from the gut lumen. To this end, they also produce hydrolytic enzymes that perform some of the final steps of extracellular digestion of food.
- 2. *Goblet cells* secrete mucus into the gut lumen; this mucus covers the epithelium with a protective coat.
- 3. *Paneth cells* form part of the innate immune defense system (discussed in Chapter 24) and secrete proteins that kill bacteria; they also secrete Wnt signal proteins (discussed in Chapter 15) required to maintain the stem-cell population.
- 4. *Enteroendocrine cells*, of more than 15 different subtypes, secrete serotonin and peptide hormones that act on neurons and other cell types in the gut wall and regulate the growth, proliferation, and digestive activities of cells of the gut and other tissues.

MBOC7_ptr_ch22_1279-1312.indd 1281 02/12/21 12:22 PM

As if on a conveyor belt, the absorptive, goblet, and enteroendocrine cells travel upward from their site of birth in the crypt, by a sliding movement in the plane of the epithelial sheet, to cover the surfaces of the villi. Within 3–4 days (in the mouse) after emerging from the crypts, the differentiated cells reach the tips of the villi, where they are discarded into the gut lumen (see Movie 20.7). The Paneth cells in the crypts are produced in much smaller numbers and have a different migration pattern. They live at the bottom of the crypts, where they too are continually replaced, although not so rapidly, persisting for several weeks before undergoing apoptosis and being phagocytosed by their neighbors.

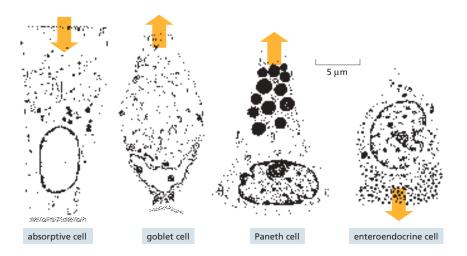

The stem cells that give rise to the intestinal epithelium are located just above the base of the crypt, interspersed among the Paneth cells. The stem cells can be identified because only they express a particular G-protein-coupled receptor called *Lgr5*, which serves as a specific marker for the stem cell population. When the stem cells divide, which they do every 24 hours or so in the mouse intestine, some of the progeny commit to differentiation, becoming transit-amplifying progenitor cells that migrate upward, while others remain stem cells in the process of self-renewal. The stem cells are multipotent, producing all the differentiated cell types in the epithelium.

Epidermal Stem Cells Maintain a Self-renewing, Waterproof, Epithelial Barrier on the Body Surface

Stem-cell systems are organized in a variety of different ways depending on the tissue. For example, the outer epithelial covering of the body, the **epidermis**, undergoes continual renewal, but, unlike the intestinal epithelium, it is multilayered, or *stratified*. Stem cells are located in the basal layer, as are the dividing transit-amplifying progenitor cells. Once the progenitor cells stop dividing, they leave the basal layer and move outward toward the exposed surface, undergoing

Figure 22-4 Renewal of the gut epithelial lining. (A) The pattern of cell turnover and proliferation in the epithelium that forms the lining of the small intestine. Stem cells (red) lie at the crypt base, interspersed among nondividing differentiated cells (Paneth cells). Progeny of the stem cells move mainly upward from the crypts onto the villi; after a few quick divisions, they cease dividing and differentiate—some of them while still in the crypt, most of them as they emerge from the crypt. The Paneth cells, like the other nondividing differentiated cells, are continually replaced by the progeny of the stem cells, but they migrate downward to the crypt base and survive there for many weeks. (B) Micrograph of a section of part of the lining of the small intestine, showing the crypts and villi. Note the mixture of differentiated cell types, all generated from the stem cells: these are primarily absorptive cells, with mucus-secreting goblet cells (stained red) interspersed among them.

MBOC7_ptr_ch22_1279-1312.indd 1282 02/12/21 12:22 PM

terminal differentiation as they go. They end up as lifeless scales, or *squames*, which are eventually shed from the surface of the skin (Figure 22–6).

Even though the architecture of the epidermis is very different from that of the intestinal epithelium, many of the same basic principles apply. The stem cells are maintained by signals within a specific region of the tissue, which in the epidermis is the basal lamina and underlying connective tissue. The daughters of stem cells that are committed to differentiation undergo several divisions as transit-amplifying

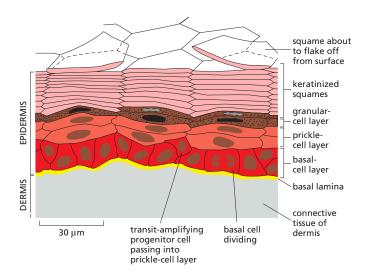

Figure 22-6 The multilayered structure of the epidermis. The epidermis forms the outer covering of the skin, creating a waterproof barrier that is self-repairing and continually renewed Beneath this lies a relatively thick layer of connective tissue, which includes the tough, collagen-rich dermis (from which leather is made). The cells of the epidermis are called keratinocytes, because their characteristic differentiated activity is the synthesis of keratin intermediate filament proteins, which give the epidermis its toughness. These cells change their appearance and properties from one layer to the next, progressing through a regular program of terminal differentiation. Those in the innermost layer, attached to an underlying basal lamina, are termed basal cells, and it is normally only these that divide: the basal-cell population includes relatively small numbers of stem cells along with larger numbers of transit-amplifying progenitor cells derived from them. Above the basal cells are several layers of larger prickle cells. Beyond the prickle cells lies the thin, darkly staining granular-cell layer, where the cells are sealed together to form a waterproof barrier; this marks the boundary between the inner, metabolically active strata and the outermost layer of the epidermis, consisting of dead cells whose intracellular organelles have disappeared. These outermost cells are reduced to flattened scales, or squames, filled with densely packed keratin, which are eventually shed from the surface of the skin. The time from exit of a cell from the basal layer to its loss by shedding at the surface is a week or two, depending on body region and species.

Figure 22-5 The four main differentiated cell types found in the epithelial lining of the small intestine. All cells are oriented with the gut lumen at top. Broad orange arrows indicate direction of secretion or uptake of materials for each type of cell. All of these cells are generated from undifferentiated multipotent stem cells living near the bottoms of the crypts (see Figure 22-4). Absorptive (brush-border) cells outnumber the other cell types in the epithelium by about 10:1 or more. The microvilli on their apical surface provide a 30-fold increase in surface area, not only for the import of nutrients but also for the anchorage of enzymes that perform the final stages of extracellular digestion, breaking down small peptides and disaccharides into monomers that can be transported across the cell membrane Goblet cells secrete mucus; these are the most common of the secretory cell types. Paneth cells secrete (along with some growth factors) cryptdins—proteins of the defensin family that kill bacteria. Different subtypes of enteroendocrine cells secrete serotonin and peptide hormones into the gut wall (and thence the blood). Cholecystokinin is a hormone released from enteroendocrine cells in response to the presence of nutrients in the gut. It binds to receptors on nearby sensory nerve endings and causes the release of digestive enzymes from the pancreas and bile from the gall bladder; it also signals to the brain to stop the feeling of hunger once one has eaten enough. (Absorptive and goblet cells, Don W. Fawcett/Science Source; Paneth and enteroendocrine cells, from R.V. Krstić, Illustrated Encyclopedia of Human Histology. Berlin: Springer-Verlag, 1964. MBOC7_ptr_ch22_1279-1312.indd 1283 02/12/21 12:23 PM

cells in the basal layer before differentiating. Moreover, most of the signaling pathways that organize the intestinal stem-cell system are also involved in regulating the epidermal stem-cell system, although with different individual roles.

Cell Lineage Tracing Reveals the Location of Stem Cells and Their Progeny

Stem cells in adult tissues are usually rare and difficult to identify in conventional tissue sections, unless a stem cell-specific marker like Lgr5 is available. Recombinant DNA technology provides a general and powerful way to identify stem cells and their progeny in any renewing tissues using a technique called *cell lineage tracing*. The method uses transgenic animals to create a visible genetic mark in just a few cells, which, over time, give rise to widely separated and easily distinguished clones of progeny cells, as explained in **Figure 22–7** and **Figure 22–8**. This approach does not require prior knowledge as to whether a tissue contains stem cells or not. If they exist, the stem cells will be marked randomly and will lead to a persistent clonal lineage that contains stem cells as well as differentiated cells (see Figure 22–7B); dividing progenitor cells will also be randomly marked and produce labeled clones, but all of these will eventually disappear (see Figure 22–7C). The analysis of the clones not only indicates whether stem cells are

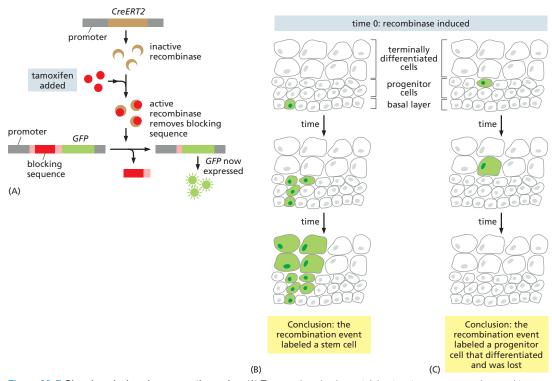

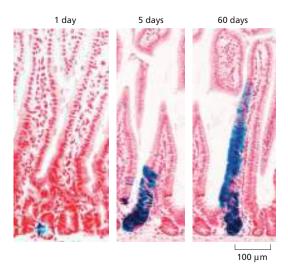

Figure 22–7 Clonal analysis using a genetic marker. (A) Transgenic animals containing two transgenes can be used to drive expression of a readily detected and heritable marker in a small set of cells. The first transgene encodes a marker gene, such as one that encodes green fluorescent protein (GFP). However, the expression of the GFP transgene, shown here in green, is prevented by a blocking sequence (red) that is flanked by LoxP sites (pink; see Figure 5–66). The second transgene, CreERT2 (brown), encodes a chimeric form of the Cre recombinase called CreERT, which consists of the Cre recombinase linked to the estrogen receptor protein; this enzyme becomes active as a recombinase only when it binds the artificial estrogen analog tamoxifen (red spheres). Addition of tamoxifen leads to a recombination event that removes the blocking DNA sequence. As a result, the GFP marker is expressed. Because the blocking DNA has been permanently removed from the genome, the marker continues to be expressed in all the descendants of a cell in which the recombination event has occurred. With a low dose of the inducer molecule tamoxifen, it is possible to activate the marker at random in just a few widely spaced cells, giving rise to distinguishable clones. (B) If the recombination event occurs in a stem cell, a clonal lineage will be marked, and the labeling will persist over time as the marked stem cell self-renews and produces differentiated cells. (C) If the recombination event occurs in a cell that is not a stem cell, the label will disappear over time as the marked cell differentiates and is eventually lost.

MBOC7_ptr_ch22_1279-1312.indd 1284 02/12/21 12:23 PM

present, but also where the stem cells are located and whether they are unipotent or multipotent.

A more directed approach can be used for cell lineage tracing if a gene that is expressed specifically in the stem cells in a tissue is known, as is the case for the *Lgr5* gene in the mouse intestine. In this case, one can use the gene's promoter to express the genetic marker specifically in the stem cells. It was this type of experiment that initially established that Lgr5-expressing cells in the mouse intestinal epithelium are stem cells and that they are multipotent (see Figure 22–8).

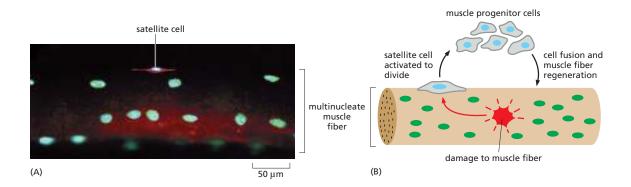

Quiescent Stem Cells Are Difficult to Identify by Lineage Tracing

The lineage tracing method just described assumes that the stem cells in a tissue are actively dividing to generate daughter cells that self-renew or differentiate. Some adult stem cells, however, reside in a quiescent state, serving as a "reservoir" for when they are needed: they divide only rarely or not at all, unless they are induced to do so by a stimulus, such as tissue injury. In these cases, it can require extra time or stimulation to reveal the stem cells by lineage tracing.

Human **skeletal muscle** provides an example. It consists of multinucleated muscle cells (muscle fibers) that form during development by the fusion of terminally differentiated *myoblasts*. Humans do not normally generate new skeletal muscle in adult life, but they still have the capacity to do so when there is a need for muscle growth or repair. Cells capable of serving as myoblasts are retained as small, flattened, and nondividing cells lying in close contact with the mature muscle fiber and contained within its sheath of basal lamina (**Figure 22–9**). If the muscle is damaged or stimulated to grow, these *satellite cells* are activated to proliferate, and their progeny can fuse with the existing muscle fiber to repair

Figure 22-8 Lgr5-expressing stem cells and their progeny in the small intestine. The basic method shown in Figure 22-7 was modified here to mark single intestinal stem cells and trace the fates of their progeny. The Lgr5 gene encodes a member of the family of G-protein-linked transmembrane receptors, and it is expressed specifically in stem cells near the crypt base. In this case, the Lgr5 promoter was used to drive expression of CreERT2, and treatment with a low dose of tamoxifen resulted in occasional stem cells expressing the marker protein LacZ (rather than GFP). These cells and all of their progeny could subsequently be detected with a blue histochemical stain. All of the blue cells in these images derive from a single Lar5-expressing stem cell. After 60 days, the blue progeny of this cell are seen to extend almost all the way up a villus. These progeny can be shown to include all types of differentiated cells, as well as persistent Lgr5-expressing cells at the crypt base. This proves that Lgr5expressing cells are multipotent stem cells. (From N. Barker et al., Nature 449:1003-1007, published 2007 by Nature Publishing Group. Reproduced with permission of SNCSC.)

Figure 22–9 The repair of skeletal muscle fibers by satellite cells. (A) The specimen is stained with an antibody (red) against a muscle cadherin, M-cadherin, which is present on both the satellite cell and the muscle fiber and is concentrated at the site where their membranes are in contact. The nuclei of the muscle fiber are stained green, and the nucleus of the satellite cell is stained blue. (B) Schematic drawing of the repair of a damaged muscle fiber by the proliferation and fusion of satellite cells. (A, courtesy of Terence Partridge.)

MBOC7_ptr_ch22_1279-1312.indd 1285 02/12/21 12:23 PM

the damaged muscle or to allow muscle growth. Satellite cells or some subset of them are thus the stem cells of adult skeletal muscle, normally held in reserve in a quiescent state but available when needed as a self-renewing source of terminally differentiated myoblasts.

The process of muscle repair by means of satellite cells is limited in what it can achieve. In one form of *muscular dystrophy*, for example, a genetic defect in the cytoskeletal protein dystrophin slowly but progressively damages differentiated skeletal muscle cells. As a result, satellite cells proliferate to repair the damaged muscle fibers. But this regenerative response is unable to keep pace with the damage, and connective tissue eventually replaces the muscle fibers, blocking any further possibility of repair. A similar decline in the capacity for repair contributes to the progressive muscle weakening that occurs in the elderly.

Hematopoietic Stem Cells Can Be Identified by Transplantation

A different method to identify stem cells in adult tissues is by cell transplantation. The method was first used to identify the stem cells of the *hematopoietic* (blood-making) *system*, the most complex stem-cell system in the adult mammalian body. The **hematopoietic stem cells** that give rise to both the red blood cells (**erythrocytes**) and white blood cells (**leukocytes**) are located in the adult bone marrow, where they also produce blood *platelets*. There are many different white blood cell types, including monocytes that can exit the bloodstream and develop into *macrophages*, which are found in most organs. When an animal is exposed to a large dose of x-rays, most of the hematopoietic cells in the bone marrow are destroyed, and, as a result, the animal dies within days because of its inability to produce new blood cells. The animal can be saved, however, by a transfusion of cells taken from the bone marrow of a healthy donor mouse of the same inbred

TABLE 22–1 Blood Cells		
Type of cell	Main functions	Typical concentration in human blood (cells/liter
Red blood cells (erythrocytes)	Transport O ₂ to and CO ₂ from tissues	5 × 10 ¹²
White blood cells (leukocytes)		
Granulocytes		
Neutrophils (polymorphonuclear leukocytes)	Phagocytose and kill invading bacteria	5 × 10 ⁹
Eosinophils	Destroy larger parasites and modulate allergic inflammatory responses	2 × 10 ⁸
Basophils	Release histamine (and in some species serotonin) in certain immune reactions	4 × 10 ⁷
Monocytes	Become tissue macrophages, which phagocytose and digest invading microorganisms and foreign bodies as well as damaged senescent cells; some also differentiate into dendritic cells	4 × 10 ⁸
Lymphocytes		
B cells	Make and secrete antibodies	\sim 0.3 \times 10 ⁹
T cells	Kill virus-infected cells and regulate activities of other leukocytes	~2 × 10 ⁹
Natural killer (NK) cells	Kill virus-infected cells and some tumor cells	1 × 10 ⁸
Platelets (cell fragments arising from megakaryocytes in bone marrow)	Initiate blood clotting	3 × 10 ¹¹

Humans contain about 5 liters of blood, accounting for 7% of body weight. Red blood cells constitute about 45% of this volume and white blood cells about 1%, the rest being the liquid blood plasma.

MBOC7_ptr_ch22_1279-1312.indd 1286 02/12/21 12:23 PM

Figure 22–10 Rescue of an irradiated mouse by a transfusion of bone marrow cells. An essentially similar procedure is used in the treatment of leukemia in humans by bone marrow transplantation after irradiation or chemotherapy.

strain. Among these cells there are some that can colonize the irradiated host and permanently re-equip it with hematopoietic tissue (Figure 22–10). Such experiments prove that the bone marrow contains an entire hematopoietic stem-cell system, and they have allowed scientists to isolate the relevant stem cells and discover the molecular features that distinguish them.

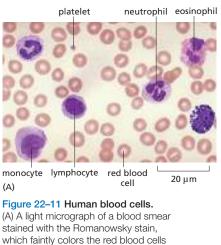

For this purpose, cells taken from mouse bone marrow are sorted (using a fluorescence-activated cell sorter) according to their cell-surface antigens, and the different fractions are transfused into irradiated mice. If a fraction rescues the irradiated mice, it must contain hematopoietic stem cells. In this way, it was shown that the hematopoietic stem cells display a specific combination of cell-surface proteins and that, by appropriate cell sorting, one can obtain virtually pure stemcell preparations. The stem cells turn out to be a tiny fraction of the mouse bone marrow population—about 1 cell in 50,000–100,000; but this is enough. Remarkably, a single such cell injected into a host mouse with defective hematopoiesis is sufficient to reconstitute its entire hematopoietic system, generating a complete set of blood-cell types, as well as fresh stem cells. This and lineage tracing experiments have established that an individual hematopoietic stem cell is *multipotent* and can self-renew and give rise to the complete range of blood-cell types.

Blood contains large numbers of many types of differentiated cells (Table 22–1), many of which can be seen in a standard, stained smear of human blood (Figure 22–11). Erythrocytes are homogeneous and remain in the blood vessels, where they transport O₂ and CO₂ bound to hemoglobin. By contrast, leukocytes are heterogeneous in morphology and function and must crawl across the walls of small blood vessels into tissues to function. Terminally differentiated

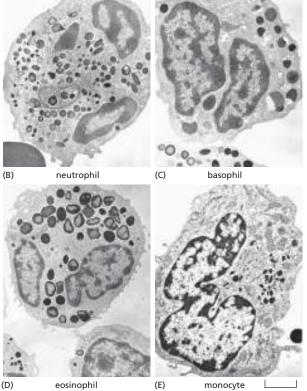

x-irradiation halts blood cell production; mouse would die if no further treatment were given

INJECT BONE MARROW CELLS FROM HEALTHY DONOR

mouse survives; the injected stem cells colonize its hematopoietic tissues and generate a steady supply of new blood cells

which faintly colors the red blood cells red and strongly colors the white blood cells blue. (B-E) Electron micrographs of (B) a neutrophil, (C) a basophil, (D) an eosinophil, and (E) a monocyte, (Electron micrographs of lymphocytes are shown in Figure 24-14.) Each of the cell types shown here has a different function (see Table 22-1), which is reflected in the distinctive types of secretory granules and lysosomes each cell type contains. There is only one nucleus per cell, but it has an irregular lobed shape, and in panels B, C, and D the connections between the lobes are out of the plane of section. (A-D. courtesy of Dorothy Bainton: E. courtesy of David Mason.)

MBOC7_ptr_ch22_1279-1312.indd 1287 02/12/21 12:23 PM

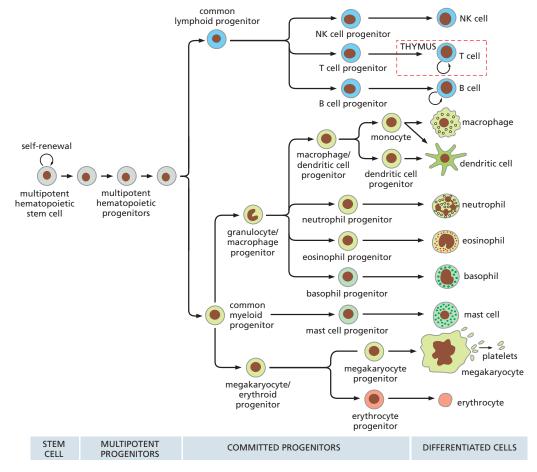

blood cells have relatively short life spans and are produced throughout the life of the animal, so hematopoietic stem cells must generate enormous numbers of these differentiated cells each day. But they do not produce them directly. Instead, the stem cells continually produce large numbers of transit-amplifying progenitor cells in the bone marrow, which are committed to differentiation but go through multiple divisions before they terminally differentiate.

The stem cells, however, do not jump directly from a multipotent stem-cell state into a committed and specific pathway of differentiation; instead, they go through a number of cell divisions, in which they progressively restrict their developmental options in a series of steps (Figure 22-12). The first step is usually to become committed to either a myeloid or a lymphoid fate, by way of two kinds of multipotent transit-amplifying progenitor cells. One is capable of generating large numbers of all the different types of myeloid cells, including blood granulocytes (neutrophils, eosinophils, and basophils), monocytes (the precursors of macrophages and dendritic cells), erythrocytes, and megakaryocytes (which remain in the bone marrow and produce blood platelets by pinching off cell fragments) (Movie 22.1). The other type of multipotent progenitor cell gives rise to large numbers of different types of lymphoid cells, including the B and T lymphocytes of the adaptive immune system and the lymphocyte-like *natural killer* (NK) cells of the innate immune system (discussed in Chapter 24). Further commitment steps ultimately give rise to progenitor cells committed to the production of just one cell type, although this final commitment step occurs well before the cells cease proliferating and terminally differentiate. Many different signal molecules, produced inside and outside the bone marrow, control the survival, proliferation, and pathway commitment of hematopoietic cells and their committed progeny in the bone marrow and thereby regulate how many of each type of differentiated blood cell is eventually produced.

mouse and human hematopoiesis. A multipotent hematopoietic stem cel either more multipotent stem cells,

Figure 22-12 A simplified scheme of

normally divides infrequently to generate which are self-renewing, or multipotent progenitor cells, which give rise to all the cells of the blood and immune system. The progenitor cells divide a limited number of times and go through multiple stepwise intermediates before they develop into fully differentiated cells. As they go through their divisions, the progenitors become progressively more specialized in the range of cell types that they can give rise to, as indicated by the branching of this cell lineage diagram. In adult mammals, all of the cells shown develop mainly in the bone marrow-except for T lymphocytes, which as indicated develop in the thymus, and macrophages and some dendritic cells, which develop from monocytes that are circulating in the blood. Note that not all stem cells generate the identical patterns of progeny via precisely the same sequence.

MBOC7 ptr ch22 1279-1312.indd 1288 02/12/21 12:23 PM In this hierarchical hematopoietic system, only the stem cells can self-renew for the life of the individual, and a single stem-cell division can lead to the production of thousands to millions of differentiated progeny. This explains why the number of stem cells is such a tiny fraction of the total population of hematopoietic cells in the bone marrow. Keeping the number of stem-cell divisions low has important advantages. If these divisions on their own had to keep up with the high demand for terminally differentiated blood cells, they would result in rapid replicative cell senescence and exhaustion of the stem-cell pool, with dire consequences. Moreover, the lower the number of stem-cell divisions, the lower the risk of the cells accumulating dangerous mutations, which would persist in mutant clones; as discussed in Chapter 20, such clones are a particular danger in the hematopoietic system, where a relatively small number of mutations can be sufficient to cause blood-cell cancers.

Some Tissues Do Not Require Stem Cells for Their Maintenance

Some types of cells can divide even though fully differentiated, allowing for renewal and regeneration without the use of stem cells. The insulin-secreting **pancreatic \beta cells** are one example. Their mode of renewal has a special importance, because it is their loss through autoimmune attack that is responsible for type 1 (juvenile-onset) diabetes, and their functional decline with age and obesity is also a significant factor in type 2 (adult-onset) diabetes. The β cells are normally sequestered in cell clusters called *islets of Langerhans*. The islets seem not to contain stem cells, yet new β cells are continually generated within the islets. Lineage tracing studies, similar to those described earlier, show that the renewal of this population normally occurs by the simple division of differentiated insulin-producing β cells.

Another tissue that can renew by simple division of fully differentiated cells is the liver. The main cell type in the liver is the **hepatocyte**, a large cell that performs the liver's many metabolic functions. Hepatocytes normally live for a year or more and divide at a very slow rate. Powerful homeostatic mechanisms operate to adjust both their rate of cell proliferation and their rate of cell death, to keep the liver at its normal size and to restore that size in the case of damage. A dramatic effect is seen if large numbers of hepatocytes are removed surgically or killed by poisoning with carbon tetrachloride. Within a day or so after either sort of damage, a surge of cell division occurs among the surviving hepatocytes, quickly replacing the lost tissue. If two-thirds of a rat's liver is removed, for example, a liver of nearly normal size can regenerate by hepatocyte proliferation within about 2 weeks.

Both the pancreas and the liver also contain small populations of stem cells that can be called into play as a backup mechanism to produce the differentiated cell types in more extreme circumstances.

In Response to Injury, Some Differentiated Cells Can Revert to Progenitor Cells and Some Progenitor Cells Can Revert to Stem Cells

Although the pathways from stem cell to progenitor cell to differentiated cell are normally unidirectional, there are some cases where injury can reverse the direction. One striking example occurs when a myelinated mammalian nerve is cut: the axon distal to the cut degenerates, and the differentiated myelinating Schwann cells (see Figure 11–35) *dedifferentiate* to form proliferating Schwann-cell progenitor cells. These progenitor cells help guide the regenerating axons back to their original targets and then remyelinate the axons to complete the regeneration process.

Similarly, in some tissues, when stem cells are lost, progenitor cells that have committed to differentiation can reprogram to revert to stem cells. In both the mouse and *Drosophila* testis, for example, spermatogonial cells typically follow a unidirectional development pathway from stem cell to proliferating progenitor cells, which undergo meiosis and finally differentiate into sperm. If stem cells are lost, either naturally or experimentally, the mitotically proliferating progenitor

MBOC7_ptr_ch22_1279-1312.indd 1289 02/12/21 12:23 PM

cells can reprogram and revert to stem cells. More generally, this process might contribute to the long-term maintenance of stem-cell populations, allowing the lifetime of individual stem cells to be shorter than the lifetime of the organism. Unfortunately, cancer cells often also acquire stem cell-like properties, allowing them to self-renew indefinitely (discussed in Chapter 20).

Some Tissues Lack Stem Cells and Are Not Renewable

Some adult tissues that lack stem cells are not able to regenerate. The remarkable variation in the ability of different tissues to regenerate is illustrated by comparing the olfactory epithelium in the nose, the auditory epithelium of the inner ear, and the photoreceptive epithelium of the retina, which exhibit striking differences in their renewal capacity. The *olfactory epithelium* contains a population of stem cells that give rise to differentiated cells that have a limited life span and are continually replaced. But unlike the epidermis discussed earlier, these differentiated olfactory cells are neurons; they have their cell bodies in the olfactory epithelium and extend their axons back to the olfactory bulbs in the brain. The renewal of this epithelium therefore involves the continual production of new axons that have to navigate back to specific sites in the brain, where they form new synapses.

In contrast, in mammals at least, the *auditory epithelium* and *retinal photore-ceptive epithelium* lack stem cells, and their sensory receptor cells—the sensory hair cells in the ear and the photoreceptors in the retina—are irreplaceable. If they are destroyed—whether by too much exposure to loud noise, by looking into the beam of a laser, or through degenerative processes occurring in disease or in old age—the loss is permanent.

We will return to tissue regeneration later in the chapter.

Summary

Many adult tissues, particularly those with a high cell turnover rate such as the intestinal lining, skin epidermis, and blood, are continually renewed by stem cells to maintain tissue homeostasis throughout the lifetime of the organism. Stem cells are defined by their ability to both self-renew and to generate terminally differentiated cells, usually by way of rapidly dividing, transit-amplifying progenitor cells. These properties can be revealed experimentally through lineage-tracing or transplantation experiments. Tissue-specific, or adult, stem cells are restricted in their differentiation potential, only generating one or more of the specific cell types of a particular tissue.

In the single-layer lining of the small intestine, multipotent stem cells are located near the base of each crypt, where they self-renew and produce dividing committed progenitor cells, most of which flow upward and terminally differentiate into one of three main types of gut cells when they reach the villus; other progenitor cells move in the opposite direction and become Paneth cells, which remain at the base of the crypt and help maintain the stem cells. Other self-renewing epithelia, such as the epidermis, have a multilayered (stratified) architecture, with stem cells and their differentiating progeny arranged in different ways, but are governed by similar basic principles.

The hematopoietic system is the most complex mammalian stem-cell system; all the red blood cells and the many types of white blood cells derive from a common, multipotent, hematopoietic stem cell in the adult bone marrow, where it divides slowly and produces multipotent and unipotent progenitor (transit-amplifying) cells, which divide rapidly and differentiate into a large number and variety of terminally differentiated cell types every day. In other tissues, such as skeletal muscle, stem cells are quiescent and only divide and differentiate when tissue growth or repair is required. Adult tissue renewal and repair do not always depend on stem cells; in the pancreas and liver, for example, differentiated cells can divide throughout life to replace lost cells and maintain tissue homeostasis. In some cases, progenitor cells can be generated from differentiated cells, and stem cells can be

MBOC7_ptr_ch22_1279-1312.indd 1290 02/12/21 12:23 PM

generated from progenitor cells. At the opposite extreme, some sensory epithelia of the adult mammalian ear and eye are not renewable; their sensory cells do not undergo turnover—once lost, they are lost forever.

CONTROL OF STEM-CELL FATE AND SELF-RENEWAL

Adult stem cells maintain tissue homeostasis in renewing tissues, owing to their ability both to self-renew and to produce differentiated cells for the lifetime of the organism. How do these cells maintain their stem-cell identity for so long, and how do their daughter cells choose between self-renewal and a commitment to differentiation? While maintaining a stem-cell population is critically important for self-renewing tissues, stem-cell proliferation must be kept in check, as uncontrolled production of undifferentiated cells is a hallmark of cancer (discussed in Chapter 20). In this section, we discuss the mechanisms that allow stem cells to maintain their identity while producing differentiated cells and keeping their own proliferation under control.

The Stem-Cell Niche Maintains Stem-Cell Self-Renewal

The identity and self-renewal of stem cells depend on extracellular signals from their environment that both promote their proliferation and inhibit their commitment to differentiation. In many tissues, stem cells inhabit a special microenvironment called the **stem-cell niche**, where these signal molecules are provided in high concentration (**Figure 22–13**). The stem cells remain in close physical proximity to the niche-supporting cells, which produce the signals and provide a local special environment. Outside this environment, the concentration of the signal molecules is insufficient to maintain the self-renewal of the stem cells, and their daughter cells therefore commit to differentiation.

The existence of the stem-cell niche was first inferred from the experiment in which bone marrow cells were transplanted into a mouse that had been subjected to a high dose of x-rays (see Figure 22–10). Without the prior irradiation, the transplanted cells were unable to reestablish hematopoiesis, suggesting that the resident hematopoietic stem cells first had to be removed before the transplanted stem cells could successfully seed the host's bone marrow. The hypothetical special "place" occupied by either the host or donor hematopoietic stem cells was referred to as the *stem-cell niche*. Because of the complexity of bone marrow and the rarity of the stem cells there, the location of the niche remained unclear until many years later, when immunofluorescence microscopy and the use of cell markers provided evidence that the surface of sinusoids in the bone marrow is the likely site of the niche.

The molecular nature of stem cell-renewal signals provided within the niche varies across species and tissues, but they frequently are secreted signal proteins of the Wingless (Wnt), Hedgehog (Hh), or transforming growth factor (TGF) families (discussed in Chapter 15). Other niche signals are cell-surface proteins that depend on direct contact between the stem cells and the niche-supporting cells. The mammalian intestinal crypt provides a well-studied example (see

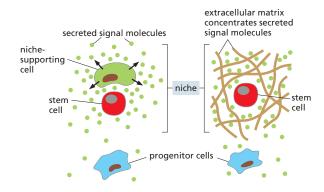

Figure 22–13 The stem-cell niche. Stem cells undergo self-renewal only in a specialized microenvironment where they are exposed to the necessary signal molecules. These signal molecules can be provided by niche-supporting cells or by a specialized extracellular matrix that serves to concentrate them. The niche environment can be very small. In some cases, a stem cell directly adjacent to the niche is capable of self-renewal, while a cell just one cell-diameter away from the niche is not.

MBOC7_ptr_ch22_1279-1312.indd 1291 02/12/21 12:23 PM

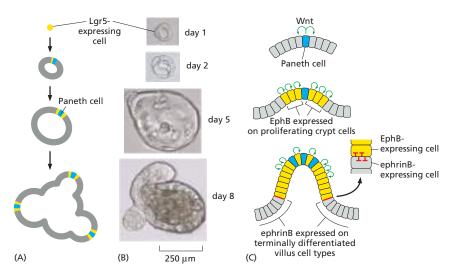

Figure 22–14 Genesis of a minigut from a single Lgr5-expressing cell cultured in a cell-free matrix. (A) Schematic drawing and (B) phase-contrast micrographs of the developing organoid. The founder cell first divides to form a small sack or vesicle. At random, one or more of the cells in this vesicle differentiates as a Paneth cell (blue). The Paneth cells secrete Wnt proteins that stimulate stem-cell self-renewal and maintain Lgr5 expression (yellow) in their immediate neighbors; besides generating more stem cells, the stem cells produce progenitor cells that differentiate into the full range of intestinal epithelial-cell types. (C) Schematic diagram showing how Paneth cell–derived Wnt signals help organize the developing crypt: besides keeping neighboring cells in the crypt proliferating in a stem-cell state, these signals activate repulsive interactions mediated by membrane-bound ephrin and Eph proteins on contacting cells (discussed in Chapter 15). These interactions cause dividing crypt cell types (which express EphB, induced by Wnt) to segregate from the nondividing, terminally differentiated villus cell types (which express ephrinB). In many tissues, cells that interact via ephrin–Eph binding repel each other when they touch (see Figure 15–52 or Figure 21–47). (Adapted from T. Sato and H. Clevers, Science 340:1190–1194, 2013. With permission from AAAS.)

Figure 22–4). We saw earlier that the stem cells that give rise to all the terminally differentiated cells in the intestinal epithelium express the cell-surface receptor protein Lgr5 and are located just above the base of the crypt, interspersed among the Paneth cells. The Paneth cells help create the stem-cell niche in two ways. They secrete Wnt proteins that act over a short range to stimulate stem-cell self-renewal. They also express *Delta*, a ligand for the signaling receptor Notch, on their surface, which activates Notch on the stem cells they directly contact, thereby inhibiting the cells from differentiating—an example of lateral inhibition (see Figure 15–59).

Remarkably, a single Lgr5-expressing stem cell embedded in a cell-free extracellular matrix can proliferate in a culture dish and form a tiny gut-like structure, an *organoid*, containing all the cell types normally found in gut tissue, including stem cells. Figure 22–14 shows this process and outlines the key signaling events that establish the crypt stem-cell niche, where different cell types are produced that arrange themselves into miniature villi to form the three-dimensional organoid structure.

The Size of the Niche Can Determine the Number of Stem Cells

In each intestinal crypt, the stem-cell niche is created by 15 Paneth cells, and it only has space for a limited number of stem cells. When the stem cells divide, it is a random matter as to which of the daughter cells are pushed out of the nest; failing to get the signals they need to maintain their stem-cell identity, they are condemned to commit to differentiation. In most other stem-cell systems where this question of balance between self-renewal and commitment to differentiation has been examined, it appears that a similar mechanism operates.

The *Caenorhabditis elegans* germ-line cell lineage provides a visually striking example (Figure 22–15). In this system, the stem cells are maintained within a

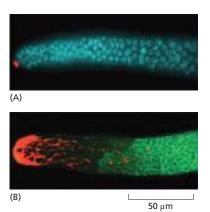

Figure 22-15 Stem-cell niche of the C. elegans gonad. (A) Fluorescence micrograph showing the nuclei (blue) in a portion of the C. elegans gonad. The nucleus of the distal tip cell is shown in red. (B) The same tissue is stained to show the cytoplasm and processes of the distal tip cell in red and the differentiated germ cells in green. The distal tip cell processes extend across multiple stem-cell diameters. maintaining stem-cell identity through Notch signaling. Those cells moved out of reach of the distal tip cell processes initiate meiosis and begin the differentiation program that will produce either eggs or sperm. (Courtesy of Judith Kimble and Sarah Crittenden.)

MBOC7_ptr_ch22_1279-1312.indd 1292 02/12/21 12:23 PM

niche that is formed by a large somatic cell called a *distal tip cell*, which forms long, thin cellular processes. Notch ligand located on the surface of the distal tip cell signals to Notch on the stem cells to maintain their stem-cell identity. As in the intestinal crypt, the stem cells undergo self-renewal proliferation in the niche, until some of their progeny are pushed out of range of the distal tip cell processes, and, as a result, they begin to differentiate. In this way, a steady stream of cells at different stages of differentiation move away from the distal tip cell and the stem cells, as if on a conveyor belt, on their way to becoming terminally differentiated germ cells—either eggs or sperm.

Niche size, however, is not the only way to control stem-cell numbers—asymmetric stem-cell division is another, as we now discuss.

Asymmetric Stem-Cell Division Can Maintain Stem-Cell Number

As discussed earlier, when a stem cell divides, the two daughter cells must make a choice between remaining a stem cell or committing to differentiation. The balance between these two fates is critically important for tissue homeostasis, because excessive self-renewal would lead to an excess of stem cells, whereas excessive differentiation would deplete the stem-cell pool. We have just discussed how the size of the stem-cell niche can help control stem-cell numbers. Asymmetric stem-cell division is another mechanism for such control.

In an asymmetric stem-cell division, a process internal to the dividing stem cell causes a biased inheritance of one or more important molecules that influences the fate of the two daughter cells. For example, only one of the two daughter cells might inherit a *cell-fate determinant* that is required to maintain stem-cell identity, causing the other daughter to commit to differentiation (Figure 22–16A). Each such asymmetric stem-cell division produces one stem cell and one cell committed to differentiation; as a result, the number of stem cells is preserved irrespective of how many cell divisions the stem cells undergo. In symmetric stem-cell divisions, both daughters inherit such cell-fate determinants and remain stem cells, thereby increasing the pool of stem cells (Figure 22–16B).

As shown in Figure 22–16, prior to an asymmetric stem-cell division, the cell becomes polarized, with the cell-fate determinant localized on one side of the cell. The cell then positions the mitotic spindle to orient the plane of cell division so that only one daughter inherits the fate determinant.

Another way the orientation of the division plane in a stem cell can influence the fate of the daughter cells is to determine their position relative to the stem-cell

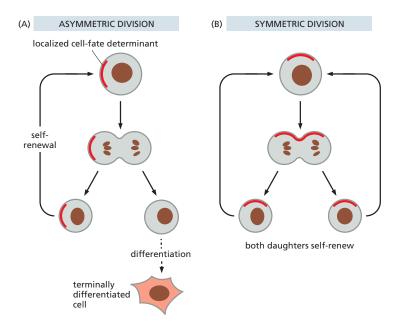

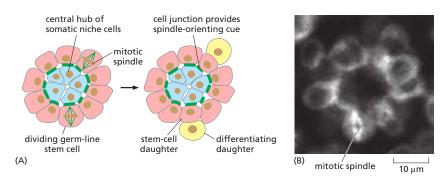

Figure 22–16 Asymmetric and symmetric stem-cell divisions. (A) In the asymmetric stem-cell division schematized here, a cell-fate determinant (red) that maintains stem-cell identity is localized to the cell cortex at one side of the cell. When the cell divides, only one daughter cell inherits the determinant and remains a stem cell, while the other daughter commits to differentiation, differentiating after a number of progenitor-cell divisions (not shown). (B) In the symmetric stem-cell division shown, both daughter cells inherit such determinants and remain stem cells.

MBOC7_ptr_ch22_1279-1312.indd 1293 02/12/21 12:23 PM

niche, such that the niche is asymmetrically inherited. In the *Drosophila* testis, for example, the germ-line stem cells orient their spindles perpendicular to the niche-supporting cells: as a result, when the stem cell divides, one daughter cell remains attached to the niche and adopts a stem-cell fate, while the other daughter is displaced away from the niche, where it is deprived of self-renewal signals and therefore commits to differentiation (Figure 22–17).

In Many Symmetric Stem-Cell Divisions, Daughter Cells Choose Their Fates Independently and Stochastically

As we have seen, asymmetric stem-cell division provides a straightforward way to maintain stem-cell numbers while generating differentiated cells in a self-renewing adult tissue. However, it leaves little room for a tissue to adapt to changing conditions, such as fluctuating nutrient availability or in response to tissue injury. In many self-renewing adult tissues, the mode of stem-cell division changes to adapt to such altered conditions. And similar adaptive changes occur during tissue development: for example, both the neural and epidermal stem cells in early developing mice mainly divide symmetrically to expand the stem-cell pool to support the rapidly growing organs; later in development, however, the stem cells shift to more asymmetric cell divisions to produce more differentiated cells (see Figure 22–16).

Stem cells in many renewing tissues, including the intestinal epithelium, adopt an even more flexible strategy. In these cases, when the stem cells divide, they do so symmetrically, and each daughter cell makes the choice between remaining a stem cell (self-renewal) and committing to differentiation, independently of its sister. In this *independent-choice mechanism*, sometimes the two daughter cells make the same choice, other times the opposite choice. The choice each cell makes might either be stochastic (probabilistic), like the flip of a coin, or governed by the environment the daughter cell finds itself in (Figure 22–18). Compared to the asymmetric-division strategy, the independent-choice mechanism is flexible, allowing local and more general environmental factors to regulate the balance of probabilities according to need—adjusting them in favor of the stem-cell option where more stem cells are required, as they often are, either for growth or for damage repair, or in favor of differentiated cells when they have been lost.

Lineage tracing experiments in the small intestine of mice reveal that some stem-cell lineages disappear while others expand and persist, as expected if the daughter cells of the stem-cell divisions make their choices stochastically (see Figure 22–18).

A Decline in Stem-Cell Function Contributes to Tissue Aging

Despite the remarkable ability of adult stem cells to persist and maintain tissue homeostasis, this ability often declines over time, contributing to tissue aging. In the case of the hematopoietic stem cells, this decline can be demonstrated experimentally using *serial transplantation*. In these experiments, the stem cells are transplanted from donor mice to irradiated host mice of the same inbred strain.

Figure 22-17 How the plane of division in a dividing, germ-line stem cell in the Drosophila testis determines which daughter cell maintains contact with the niche. (A) The niche consists of a hub of somatic cells, and the germ-line stem cells are arranged in a ring around the hub. When a stem cell divides, its mitotic spindle is oriented perpendicular to the niche, so that only one daughter cell maintains contact with the niche and remains a stem cell; the other daughter loses contact with the niche cells and is therefore deprived. of self-renewal signals and commits to differentiation. (B) The light micrograph shows germ-line stem cells surrounding the niche and a dividing stem cell with its mitotic spindle oriented perpendicular to the niche. The stem cells have been genetically engineered to express fluorescently labeled tubulin. (B, from Y.M. Yamashita et al., Science 301: 1547-1550, 2003. With permission from AAAS.)

MBOC7_ptr_ch22_1279-1312.indd 1294 02/12/21 12:23 PM

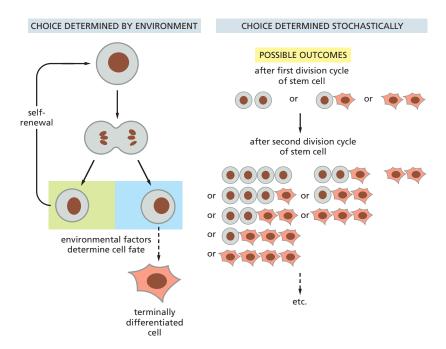

Figure 22-18 The independent-choice mechanism for how the two daughters of a stem-cell division choose their fates. The outcomes of this mechanism are more variable than that of symmetric stem-cell divisions. The choice might be determined by the local environment a daughter finds itself in (left side of the drawing) or it might be entirely stochastic (right side of drawing). With a choice made stochastically by each daughter and with a 50% probability for each one to remain a stem cell or commit to differentiation. there is, for example, a 25% chance at the first division that both daughters will commit to differentiation, so that the clone will eventually disappear. Or, at this division or later, a preponderance of daughters might choose to remain stem cells, creating a clone that persists and increases in size. With the help of some mathematics, the probability distribution of clone sizes generated from a single stem cell at any given time can be predicted on this stochastic assumption. The observations in the gut and often elsewhere fit this stochastic independent-choice strategy.

After the donor cells have repopulated the hematopoietic system of the host mice (see Figure 22–10), the hosts' hematopoietic stem cells are then transplanted into new irradiated hosts, and this sequence is repeated again and again. After multiple rounds of transplantation, the stem cells gradually lose their ability to repopulate the hematopoietic system of the new hosts, demonstrating that the stem cells change with age, apparently undergoing replicative cell senescence after repeated divisions.

To investigate whether the supportive functions of the hematopoietic stemcell niche also decline with age, hematopoietic stem cells from young or old donor mice are transplanted into irradiated young or old host mice. Comparisons of the results from these four types of experiments (young-to-young, young-toold, old-to-young, old-to-old—Figure 22–19A) indicate that a young stem-cell

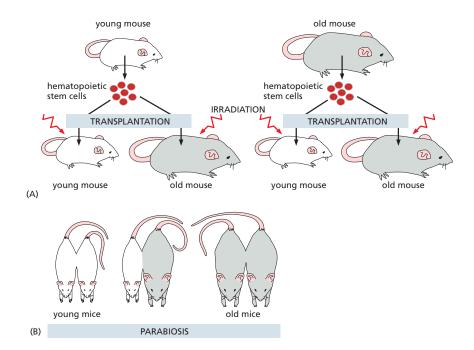

Figure 22-19 Methods to distinguish the contribution of cell-autonomous versus environmental factors to declines in hematopoietic stem-cell function during aging. (A) Hematopoietic stem cells are transplanted from young or old donor to young or old host, so that the function of stem cells can be assessed. A four-way comparison will reveal the contribution of the autonomous aging of stem cells versus the aging of the environment or niche in the decline of stem-cell function. (B) In parabiosis, animals are joined to develop a shared circulatory system. Cells in one animal will be exposed to the systemic environment of the other animal. The cellular functions in young or old partners in the heterochronic pairs (young-to-old) are compared with those in isochronic pairs (young-to-young and oldto-old). Such comparisons reveal the role of autonomous stem-cell aging compared to the role of circulating factors or the stem-cell niche in the decline of stem-cell function. [Based on M.A. Goodell and T.A. Rando, Science 350(6265):1199-1204, 2015, doi 10.1126/science.aab3388.]

MBOC7_ptr_ch22_1279-1312.indd 1295 02/12/21 12:23 PM

niche cannot rescue old hematopoietic stem cells and that an old stem-cell niche can support young hematopoietic stem cells, suggesting that niche changes do not contribute to the decline of hematopoiesis with age, at least in mice.

A more general method for studying stem-cell function in aging is *parabiosis*, in which the circulatory systems of two mice of different age are connected—young-with-young, young-with-old, or old-with-old (Figure 22–19B). This three-way comparison provides a way of determining the contributions of different factors to a decline in stem-cell function with aging: the stem cells themselves, the stem-cell niche, and circulating factors in the blood. There is evidence from such studies, for example, that circulating factors from old mice can decrease neurogenesis in the hippocampus of the brain in young mice, impairing their learning and memory, mimicking the decline that occurs in the normal mouse brain during aging. Conversely, other studies find that circulating factors from young mice can restore skeletal muscle stem-cell function in old mice and can counteract age-related dysfunction in tissues including liver, pancreas, bone, and heart. Blood components that contribute to tissue aging or rejuvenation are likely to include molecules with direct actions on stem cells, and identification of these circulating factors is an active area of research.

Summary

Multiple extracellular signals operate in each stem-cell niche, enabling tissue-specific stem cells to maintain adult tissue homeostasis throughout an organism's life. These signals regulate when and where the stem cells self-renew and their daughter cells commit to differentiation. An individual stem cell's decision to self-renew or commit to differentiation is controlled to ensure the tissue maintains an adequate number of stem cells and produces an appropriate number of terminally differentiated cells. In some cases, asymmetric stem-cell divisions that produce one stem cell and one differentiating cell at each division achieve this balance. In other cases, the stem-cell divisions are symmetric, and the two daughter cells independently choose between self-renewal and commitment to differentiation, with the choice being either stochastic or in response to local environmental signals. The ability of adult stem cells to self-renew and produce terminally differentiated cells declines over time, contributing to tissue aging.

REGENERATION AND REPAIR

As we have seen, many of the tissues of the body are not only self-renewing but also self-repairing, and this is largely thanks to stem cells and the feedback controls that regulate the stem cells' behavior to maintain tissue homeostasis. There are, however, limits to what these natural repair mechanisms can achieve. In most parts of the human brain, for example, nerve cells that die, as in Alzheimer's disease, are not replaced. Likewise, when heart muscle cells die for lack of oxygen during a heart attack, they are replaced by scar tissue rather than by new heart muscle cells.

Some animals do far better than humans and can regenerate entire organs, such as whole limbs after amputation. Among the invertebrates, there are some species that can even regenerate all the tissues of the body from a single somatic cell. These phenomena encourage the hope that human cells might be coaxed by artificial measures into similar feats of repair and regeneration, to replace the nerve cells that die in individuals with Alzheimer's disease or Parkinson's disease, the insulin-secreting β cells that are lost in type 1 diabetes, the heart muscle cells that die in a heart attack, and so on. As we learn more about the basic cell biology of regeneration, these goals, once only a dream, are beginning to seem attainable.

In this section, we start with some examples of the remarkable regenerative abilities of some animal species, as an indication of what is possible in principle. We then discuss how we can improve on the natural repair processes of the human body and treat disease by exploiting the properties of the various types of stem cells found in adult human tissues.

REGENERATION AND REPAIR 1297

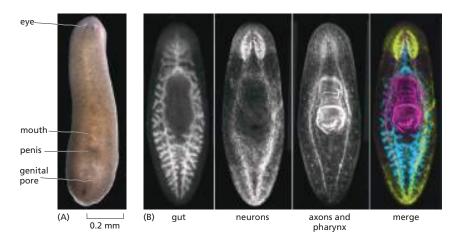

Figure 22–20 The planarian worm, Schmidtea mediterranea. (A) External view. (B) Immunostaining with three different antibodies, revealing the internal anatomy. (A, courtesy of A. Sánchez Alvarado; B, from A. Sánchez Alvarado, BMC Biol. 10:88, 2012. With permission from the author.)

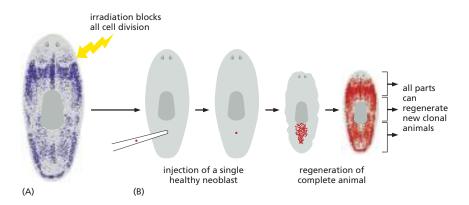

Planarian Flatworms Contain Stem Cells That Can Regenerate a Whole New Body

Schmidtea mediterranea is a small freshwater flatworm, or planarian, a centimeter or so long when grown to full size (Figure 22–20). It has an epidermis, a gut, a brain, a pair of primitive eyes, a peripheral nervous system, musculature, and excretory and reproductive organs—most of the basic body parts familiar in other animals, although all relatively simple by vertebrate standards and built from about 20–25 distinct differentiated cell types. For more than a century, planarians such as Schmidtea have intrigued biologists because of their extraordinary capacity for regeneration: a small tissue fragment taken from almost any part of the body will grow and regenerate a complete new animal. This property goes with another: when the animal is starved, it gets smaller and smaller, by reducing its cell numbers while maintaining essentially normal body proportions. This behavior is called degrowth, and it can continue until the animal is as little as one-twentieth of its full size. Supplied with food, it will grow back to full size again. Cycles of degrowth and growth can be repeated indefinitely, without impairing survival or fertility.

Underlying this behavior is a process of continual cell turnover. Along with the differentiated cells, which do not divide, there is a population of small, undifferentiated dividing cells called *neoblasts*. The neoblasts constitute about 20% of the cells in the body and are widely distributed within it; by cell division, they serve as stem cells for the production of new differentiated cells. The differentiated cells, meanwhile, are continually dying by apoptosis, allowing their corpses to be phagocytosed and digested by neighboring cells (discussed in Chapter 18). Through this cell cannibalism, the constituents of the dying cells can be efficiently recycled. Cell division continues in a dynamic balance with cell death and cell cannibalism, no matter whether the animal is fed or starved. In conditions of starvation, the balance is tilted toward cell death and cannibalism, and in conditions of plenty, toward cell growth and division.

A high dose of x-rays halts all cell division, putting a stop to cell turnover and destroying the capacity for regeneration. The result is death after a delay of several weeks. The animal can be rescued, however, by an injection into it of a single neoblast isolated from an unirradiated donor (Figure 22–21). In a certain proportion of cases, the injected cell divides to form a clone of progeny that eventually repopulates the entire body, creating a healthy regenerative individual with an apparently complete set of terminally differentiated cell types, as well as dividing neoblasts. A gradient of positional information regarding head-to-tail identity is continually expressed by the muscle cells along the worm's body and instructs the neuroblasts' appropriate development. Genetic markers prove that the differentiated cells are all derived from the single neoblast that was injected, suggesting that at least some neoblasts are *totipotent* stem cells, in that they are able to give

MBOC7_ptr_ch22_1279-1312.indd 1297 02/12/21 12:23 PM

planarian from a single somatic cell. (A) The distribution of dividing cells (neoblasts; blue) in the adult body. Irradiation blocks all cell division and prevents regeneration. (B) A single unirradiated neoblast cell injected into the irradiated animal is able to proliferate and reconstitute all tissues. This eventually produces a complete animal that consists entirely of the progeny of this one cell and can regenerate normally. A gradient of information concerning headto-tail identity is continually expressed in muscle cells along the body and instructs the neuroblasts. (Adapted from E.M. Tanaka and P.W. Reddien, Dev. Cell 21:172-185, 2011.)

Figure 22-21 Regeneration of a

rise to all the cell types that make up the body of the flatworm, including more neoblasts like themselves.

Some Vertebrates Can Regenerate Entire Limbs and Organs

One might think that such powers of regeneration would be a prerogative of only small, simple, primitive animals. But some vertebrates, too, especially fish and amphibians, show remarkable regenerative abilities. Salamanders, including newts and axolotls, for example, can regenerate a whole or a part of an amputated limb, as well as many other body parts, including brain tissue and spinal cord (Figure 22-22). In the process of limb regeneration, a blastema—a small bud resembling an embryonic limb bud-forms at the site of amputation. The rapid lateral migration of adjacent epidermal cells serves to seal the wound site. The underlying blastema cells are mostly derived from activated stem cells and progenitor cells in the stump that are highly proliferative. Although the cells all look alike, they retain a memory of their tissue of origin and enough positional information to enable them to differentiate into the appropriate cell types and to form a correctly patterned replacement for the limb or the part of the limb that was amputated. The regenerative process looks like a recapitulation of embryonic limb development. As in the developing limb, all of the required cell behaviors are orchestrated by intercellular signals that are produced by the overlying epidermis, the ingrowing nerves, the proliferating lineage-restricted stem cells, and the transit-amplifying progenitor cells and their differentiated

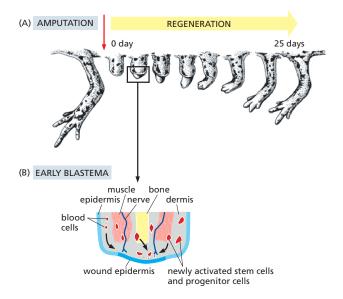

Figure 22–22 Newt limb regeneration. (A) The time-lapse sequence shows the stages of regeneration after amputation at the mid-humerus level. The sequence spans the events of wound healing, activation and proliferation of stump stem cells and progenitor cells in the process of blastema formation, and differentiation of various limb-cell types. (B) Schematic diagram of the early blastema. (A, courtesy of Susan Bryant and David Gardiner.)

MBOC7_ptr_ch22_1279-1312.indd 1298 02/12/21 12:23 PM

progeny. Most of the signaling pathways involved are the same as those used in limb development, including those activated by Hedgehog, Wnt, and FGF family members.

Why a salamander can regenerate so many body parts whereas a mammal cannot remains a profound mystery.

Stem Cells Can Be Used Clinically to Replace Lost Hematopoietic or Skin Cells

Earlier in this chapter, we saw how mice can be irradiated to kill off their hematopoietic stem and progenitor cells and then rescued by a transfusion of new stem cells, which repopulate the bone marrow and restore blood-cell production (see Figure 22–10). In the same way, human individuals with some forms of leukemia or lymphoma can be irradiated or chemically treated to destroy their cancer cells, along with the rest of their hematopoietic tissue, and then can be rescued by a transfusion of healthy, noncancerous hematopoietic stem cells. In favorable cases, the stem cells can be sorted out from samples of an individual's own hematopoietic tissue before it is ablated; the stem cells are then transfused back afterward, thereby avoiding problems of immune rejection.

Another example of the use of stem cells is in the repair of the skin after extensive burns. By culturing cells from undamaged regions of the burned person's skin, it is possible to generate enough epidermal stem cells by long and complicated procedures to repopulate the damaged body surface.

Neural Stem Cells Can Be Manipulated in Culture and Used to Repopulate a Diseased Central Nervous System

The vertebrate central nervous system (the CNS) is the most complex tissue in the body, at an opposite extreme from the epidermis. And yet fish and amphibians can regenerate large parts of their brain, spinal cord, and eyes after these have been cut away. In adult mammals, however, these tissues have very little capacity for self-repair, and stem cells capable of generating new neurons are hard to find—so hard to find that for many years they were thought to be absent.

We now know, however, that neural stem cells that generate neurons, glial cells, or both, do persist in certain parts of the adult mammalian brain, as shown in Figure 22–23 for stem cells that give rise to neurons in the mouse olfactory bulb. In both the adult mouse and human brain, there is also a continual turnover of neurons in the hippocampus, a region specifically concerned with learning and memory. Here, plasticity of adult brain function is associated with turnover of a particular subset of neurons: about 1400 new neurons in this class are generated every day, which is a turnover rate of 1.75% of the cells per year.

A more dramatic neuronal turnover is observed in the brains of certain songbirds. In these birds, large numbers of neurons die each year and are replaced by new neurons, as part of a process by which the birds refine their song for each new breeding season.

Brain neural stem cells can be studied in culture. Fragments taken from self-renewing regions of the adult or fetal mammalian brain, for example, can be dissociated and cultured under conditions where they form floating "neurospheres"—clusters consisting of a mixture of neural stem cells and their neuronal and glial progeny cells. The neurospheres can be propagated through many cell generations, and their cells can be taken at any time and implanted back into the brain of an intact animal, where they will produce differentiated neurons and glial cells.

Using slightly different culture conditions, with the right combination of growth factors in the culture medium, the neural stem cells can be grown as dissociated cells in a culture dish and induced to proliferate as an almost pure stem-cell population without attendant differentiated progeny. By a further change in the culture conditions, these cells can be induced at any time to differentiate to give

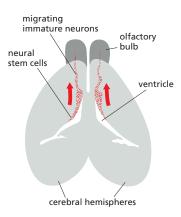

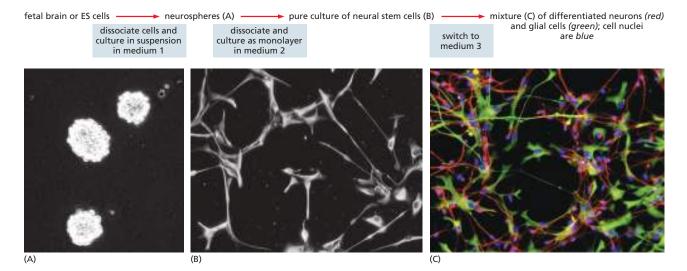

Figure 22–23 The continuing production of neurons in an adult mouse brain.

The brain is viewed from above, in a cutaway section, to show the region lining the ventricles of the forebrain where neural stem cells are found. These cells continually produce progeny that migrate to the olfactory bulb, where they terminally differentiate into neurons. The constant turnover of neurons in the olfactory bulb is presumably linked in some way to the turnover of the olfactory receptor neurons that project to it from the olfactory epithelium in the nose. In adult mice and humans, there is also a continuing turnover of neurons in the hippocampus (not shown), a region specially concerned with learning and memory. (Adapted from B. Barres, Cell 97:667-670, 1999.)

either a mixture of neurons and glial cells (Figure 22-24) or just one of these two classes of cells, according to the composition of the medium.

Neural stem cells, whether derived as above or from the pluripotent stem cells that we describe in the final section of this chapter, can be grafted into an adult brain. Once there, they show a remarkable ability to adjust their behavior to match their new location. Stem cells from the mouse hippocampus, for example, when implanted into the migration pathway of the mouse olfactory-bulb precursor cells (see Figure 22–23), give rise to neurons that become correctly incorporated into the olfactory bulb. This capacity of neural stem cells and their progeny to adapt to a new environment in animals suggests applications in the treatment for central nervous system diseases or injury.

Summary

Animals vary in their capacity for regeneration. At one extreme, planarian flatworms contain stem cells (neoblasts) that support the continual turnover of all cell types, and an entire worm can be regenerated from practically any small body fragment or even from a single neoblast cell. Salamanders can regenerate limbs and other large body parts after amputation, but the regenerating cells remain restricted according to their origins: muscle cells in the regenerate derive from muscle, epidermis from epidermis, and so on. In mammals, regeneration is more limited. Nevertheless, it is becoming possible to go beyond the natural limits of wound healing by exploiting stem-cell biology. Certain regions of the nervous system contain stem cells that support production of neurons in these sites throughout life. Neural stem cells can be obtained from these sites or from fetal brains, grown in culture, and then grafted back into other sites in the brain, where they are able to generate neurons appropriate to the new location.

CELL REPROGRAMMING AND PLURIPOTENT STEM CELLS

When cells are transplanted from one site in the mammalian body to another or are removed from the body and maintained in culture, they remain largely faithful to their origins. Each type of specialized cell has a memory of its developmental history and seems fixed in its fate. Some limited transformations can certainly occur, and, as we have seen, some stem cells can generate a variety of differentiated cell types, but the possibilities are restricted. Each type of adult stem cell serves for the renewal of one particular type of tissue, and the whole pattern of self-renewing stem cells to differentiated cells in the adult body is amazingly stable. What, at a fundamental molecular level, is the nature of these stable differences between cell types and cell states? Is there any way to override

Figure 22-24 Neural stem cells. Shown are the steps leading from fetal brain tissue or embryonic stem cells, via neurospheres (A), to a pure culture of neural stem cells (B). These stem cells can be kept proliferating as such indefinitely or, through a change of medium, can be caused to differentiate (C) into neurons (red) and glial cells (green). Neural stem cells with the same properties can also be derived, via a similar series of steps, from embryonic stem (ES) or induced pluripotent stem (iPS) cells (discussed later in this chapter). the cell-memory mechanisms and force a switch from one state to another that is radically different?

We have already discussed these fundamental questions from a general standpoint in Chapter 7. Here we consider them more closely in the context of stem-cell biology, where there has been a recent revolution in our understanding and in our ability to manipulate states of cell differentiation. With further research, these advances will likely have many important medical applications.

Nuclei Can Be Reprogrammed by Transplantation into Foreign Cytoplasm

If we cannot switch the basic character of a specialized cell by changing its environment, can we do so by interfering with its inner workings in a more direct and drastic way? An extreme treatment of this sort is to take the nucleus of the cell and transplant it into the cytoplasm of a large cell of a different type. If the factors that define and maintain a particular cell type are in the cytoplasm, the transplanted nucleus should switch its pattern of gene expression to conform with that of the host cell. In Chapter 7, we described a famous experiment of this sort, using the frog Xenopus. In this experiment, the nucleus of a differentiated cell (a cell from the lining of a tadpole's gut) was used to replace the nucleus of an oocyte (an egg-cell precursor arrested in prophase of the first meiotic division, in readiness for fertilization). The resulting hybrid cell went on, in a certain fraction of cases, to develop into a completely normal frog (see Figure 7-2A). This was crucial evidence for what is now a central principle of developmental biology: the cell nucleus, even that of a differentiated cell, contains a complete genome, capable of supporting development of all the normal cell types of the organism. At the same time, the experiment showed that cytoplasmic factors can indeed reprogram a nucleus; the oocyte cytoplasm can drive the gut-cell nucleus back to an early embryonic state, from which it can then step through the changing patterns of gene expression that lead all the way to a complete adult organism.

The full story, however, is not quite so simple. First, the reprogramming in such experiments is not perfect. When the transplanted nucleus is taken from a gut cell, for example, a gene that is normally specific to the gut is found to be expressed persistently, even in the muscle cells of the final animal. Second, the experiment succeeds in only a limited proportion of cases, and this success rate becomes lower and lower, the more mature the animal from which the transplanted nucleus is taken: very large numbers of transplantations must be performed to achieve a single success if the nucleus comes from a differentiated cell of an adult frog.

Nuclear transplantation can be done in mammals too, with basically similar results. For example, a nucleus taken from a differentiated cell in the mammary gland of an adult sheep and transplanted into an enucleated sheep's egg was able to support development of an apparently normal sheep—the famous Dolly. Again, the success rate is low: many transplantations have to be done to obtain one such individual.

Reprogramming of a Transplanted Nucleus Involves Drastic Changes in Chromatin

In a typical fully differentiated cell, there seem to be mechanisms maintaining the pattern of gene expression that cytoplasmic factors cannot easily override. An obvious possibility is that the stability of the pattern of gene expression in an adult cell may depend, in part at least, on self-perpetuating modifications of chromatin, as discussed in Chapter 4 (see Figure 4–44). As explained in Chapter 7, the phenomenon of X-inactivation in mammals provides a clear example of such epigenetic control. Two X chromosomes are present in each female cell, exposed to the same chemical environment, but while one remains active, the other persists from one cell generation to the next in a condensed inactive state; cytoplasmic factors cannot be responsible for the difference, which must instead reflect

MBOC7_ptr_ch22_1279-1312.indd 1301 02/12/21 12:23 PM

mechanisms intrinsic to the individual chromosome. Elsewhere in the genome also, controls at the level of chromatin act in combination with other forms of regulation to govern the expression of each gene. Genes can be shut down completely, or switched on constitutively, or maintained in a labile state where they can be readily switched on or off according to changing circumstances.

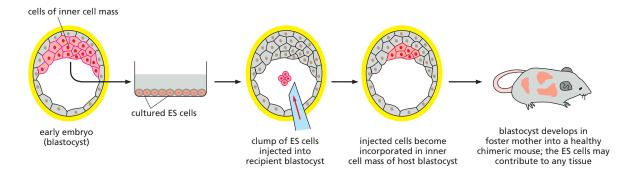

The reprogramming of a nucleus transplanted into an oocyte involves dramatic changes in chromatin. The nucleus swells, increasing its volume 50-fold as the chromosomes decondense; there is a wholesale alteration in patterns of methylation of DNA and histones; the linker histone H1 (the histone that links adjacent nucleosomes) is replaced by a variant form that is peculiar to the oocyte and early embryo; and the preexisting type of histone H3 is also replaced at many sites by a distinct isoform. Evidently, the egg contains factors that reset the state of the chromatin in the nucleus, wiping out old histone modifications on chromatin and imposing new ones. Reprogrammed in this way, the genome becomes competent once again to initiate embryonic development and to give rise to the full range of differentiated cell types.

Embryonic Stem (ES) Cells Can Generate Any Part of the Body

A fertilized egg, or an equivalent cell produced by nuclear transplantation, is a remarkable thing: it can generate a whole new multicellular individual, which means that it can give rise to every normal type of specialized cell, including even egg or sperm cells for production of the next generation. A cell in such a state is said to be **totipotent**; a cell that can give rise to most cell types but not absolutely all is said to be **pluripotent**. Nevertheless, such a totipotent or pluripotent cell is not a stem cell as it is not self-renewing, but is instead dedicated to a program of progressive differentiation. If it were the only available starting point for study and exploitation of pluripotent cells, the enterprise would require a continual supply of fresh fertilized eggs or fresh nuclear transplantation procedures—an awkward requirement for studies in experimental animals, and unacceptable for practical applications in humans.

Here, however, nature has been unexpectedly kind to scientists. It is possible to take an early mouse embryo, at the blastocyst stage, and through cell culture to derive from it a class of stem cells called **embryonic stem cells**, or **ES cells**. ES cells originate from the inner cell mass of the early embryo (the cluster of cells that give rise to the body of the embryo proper, as opposed to extraembryonic structures), and they have an extraordinary property: given suitable culture conditions, they will continue proliferating indefinitely and yet retain an unrestricted developmental potential. Their only limitation is that they do not give rise to extraembryonic tissues such as those of the placenta. Thus they are classified as pluripotent, rather than totipotent. But this is a minor restriction. If ES cells are put back into a blastocyst, they become incorporated into the embryo and can give rise to all the tissues and cell types in the body, integrating perfectly into whatever site they may come to occupy, and adopting the character and behavior that normal cells would show at that site (Figure 22–25). They can even give rise to germ cells, from which a new generation of animals can be derived.

Figure 22-25 Production and pluripotency of ES cells. ES cells are derived from the inner cell mass (ICM) of the early embryo. The ICM cells are transferred to a culture dish containing an appropriate medium, where they become converted to ES cells and can be kept proliferating indefinitely without differentiating. The ES cells can be taken at any time-after genetic manipulation, if desired-and injected back into a developing blastocyst. There they incorporate into the inner cell mass and take part in formation of a well-formed chimeric animal that is a mixture of ordinary and ES-derived cells. The ES-derived cells can differentiate into any of the cell types in the body, including germ cells from which a new generation of mice can be produced, which are no longer chimeric, but consist of cells that all inherit half their genes from the cultured ES cell line.

MBOC7_ptr_ch22_1279-1312.indd 1302 02/12/21 12:23 PM

ES cells let us move between cell culture, where we can use powerful techniques for genetic transformation and selection, and the intact organism, where we can discover how such genetic manipulations affect development and physiology. Thus, ES cells opened the way to efficient genetic engineering in mammals, leading to a revolution in our understanding of mammalian molecular and developmental biology.

Cells with properties similar to those of mouse ES cells can also be derived from early human embryos and from human fetal germ cells, and even, as we explain shortly, from differentiated cells taken from adult mammalian tissues. In this way, one can obtain a potentially inexhaustible supply of pluripotent cells. Grown in culture, these cells can be manipulated, by suitable choice of culture conditions, to give rise to large quantities of almost any type of differentiated cell, opening the way to many practical applications. Before discussing them, however, we consider the underlying biology.

A Core Set of Transcription Regulators Defines and Maintains the ES-Cell State

What is it that gives ES cells and related types of pluripotent stem cells their extraordinary developmental potential? And what can they tell us about the fundamental mechanisms underlying stemness, commitment to differentiation, and the stability of the differentiated state?

For some ES-cell attributes, the answer is simple. For example, an essential feature of ES cells is that they must avoid *replicative cell senescence*. As discussed in Chapter 17, this is the fate of fibroblasts and many other types of proliferating somatic cells: such cells are limited in the number of times they will divide, in part at least because they lack telomerase activity, with the result that their telomeres become shorter with each division cycle, leading eventually to a permanent cell-cycle arrest. ES cells, by contrast, express high levels of active telomerase, allowing them to escape replicative cell senescence and continue to divide indefinitely. This is a property shared with other, more developmentally restricted types of stem cells, such as those of the adult intestine, which similarly can carry on dividing for hundreds or thousands of cell cycles.

The deeper problem is to explain how the whole complex pattern of gene expression in an ES cell is organized and maintained. As a first step, one can look for genes expressed specifically in ES cells or in the corresponding pluripotent cells of the early embryo. This approach identifies a relatively small number of candidate *ES-critical genes*; that is, genes that seem to be essential in one way or another for the peculiar character of ES cells. A gene called *Oct4*, for example, is exclusively expressed in ES cells and in related classes of cells in the intact organism—specifically, in the germ-cell lineage and in the inner cell mass and its precursors. *Oct4* codes for a transcription regulator. When it is lost from ES cells, they lose their ES-cell character, and when it is missing in an embryo, the cells that should specialize as inner cell mass are diverted into an extraembryonic pathway of differentiation, and the embryo's development is aborted.

Fibroblasts Can Be Reprogrammed to Create Induced Pluripotent Stem (iPS) Cells

In Chapter 7, we saw that fibroblasts and some other cell types can be driven to switch their character and differentiate as muscle cells if the master muscle-specific transcription regulator MyoD is artificially expressed in them. Could the same technique be used to convert fibroblasts and other cell types into ES cells, through forced expression of ES-critical genes such as *Oct4*? This question was tackled by transfecting mouse fibroblasts with retroviral vectors carrying genes that one might hope to have such an effect. A total of 24 candidate ES-critical genes were tested in this way. None of them was able by itself to cause the conversion, but in certain combinations they could do so. In 2006, the first breakthrough experiments whittled down the requirement to a core set of four

MBOC7_ptr_ch22_1279-1312.indd 1303 02/12/21 12:23 PM

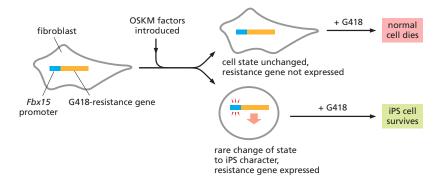

genes, all of them encoding transcription regulators—Oct4, Sox2, Klf4, and Myc, known as the OSKM factors for short. When co-expressed, these could reprogram mouse fibroblasts, permanently converting them into cells very similar to ES cells (Figure 22–26). ES-like cells created in this way are called **induced pluripotent stem cells**, or **iPS cells**. Like ES cells, iPS cells can continue dividing indefinitely in culture, and when incorporated into a mouse blastocyst they can participate in creation of a perfectly formed chimeric animal. In this animal, they can contribute to the development of any tissue and can turn into any differentiated cell type, including functional germ cells from which a new generation of mice can be raised (see Figure 22–25).

iPS cells can now be derived from adult human cells, including from various differentiated cell types besides fibroblasts. Numerous methods can be used to drive expression of the transforming OSKM factors, including methods that leave no trace of foreign DNA in the reprogrammed cells. Variations of the original cocktail of transcription regulators can drive the conversion, with different specialized cell types having somewhat different requirements. Myc overexpression, for example, turns out not to be absolutely necessary, although it enhances the efficiency of the process. And differentiated cell types may express some of the required factors as part of their normal phenotype. For example, certain cells of hair follicles already express Sox2, Klf4, and Myc; to convert them into iPS cells, it is enough to force them artificially to express Oct4.

Reprogramming Involves a Massive Upheaval of the Gene Control System

Converting a differentiated cell into an iPS cell is not like flicking a switch on some predictable, precisely engineered piece of machinery. Only a few of the cells that receive the OSKM factors will actually become iPS cells—one in several thousand in the original experiments, and still only a small minority with more recent, improved techniques. In fact, the success of the original experiments depended on clever selection strategies to pick out those few cells where the conversion had occurred (Figure 22–27).

Conversion to an iPS state by the OSKM factors is not only inefficient but also slow: fibroblasts take 10 days or more from introduction of the conversion factors before they begin to express markers characteristic of iPS cells. This suggests the transformation involves a long cascade of changes. These changes have been extensively studied, and they affect both the expression of individual genes and the state of the chromatin. The time course is outlined in Figure 22–28. The process begins with a Myc-induced cell proliferation and loosening of chromatin structure that promotes the binding of the other three transcription regulators to many hundreds of different sites in the genome. At a large proportion of these sites, Oct4, Sox2, and Klf4 all bind in concert. The binding sites include the endogenous Oct4, Sox2, and Klf4 genes themselves, which eventually creates positive feedback loops like those just described, making expression of these genes self-sustaining (see Figure 22–26). But self-induction

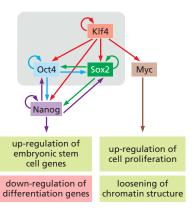

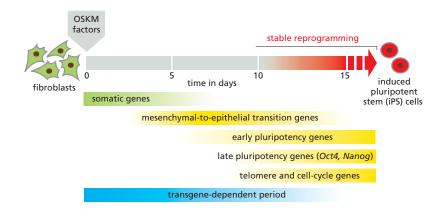

Figure 22–26 Reprogramming fibroblasts to iPS cells with the OSKM factors. As indicated, the transcription regulatory proteins Oct4, Sox2, and Klf4 (OSK factors) induce both their own and each other's synthesis (gray shading). This generates a self-sustaining feedback loop that helps to maintain cells in an ES cell-like state, even after all of the experimentally added OSKM initiators have been removed. Myc overexpression speeds up early stages of the reprogramming process through the mechanisms shown (see Figure 17-59). Stable reprogramming also involves the permanently induced expression of the Nanog gene, which encodes an additional transcription regulator (see Figure 7–10). (Adapted from J. Kim et al., Cell 132: 1049-1061, 2008.)

Figure 22–27 A strategy used to select cells that have converted into iPS cells.

The experiment makes use of a gene (Fbx15) that is present in all cells but is normally expressed only in ES and early embryonic cells (although not required for their survival). G418 is an aminoglycoside antibiotic that blocks protein synthesis in both bacteria and eukarvotic cells. A fibroblast cell line is genetically engineered to contain a gene that produces an enzyme that degrades G418 under the control of the Fbx15 regulatory sequence. When the OSKM factors are artificially expressed in this cell line, a small proportion of the cells undergo a change of state and activate the Fbx15 regulatory sequence, driving expression of the G418-resistance gene. When G418 is added to the culture medium, these are the only cells that survive and proliferate. When tested, they turn out to have iPS-cell characteristics.

of *Oct4*, *Sox2*, and *Klf4* is only a small part of the transformation that occurs. These three core factors activate some target genes and repress others, producing a cascade of effects that reorganize the gene control system globally and at every level, changing the patterns of histone modification, DNA methylation, and chromatin compaction, as well as the expression of innumerable proteins and noncoding RNAs. By the end of this complex process, the resulting iPS cell is no longer dependent on the artificially generated OSKM factors that triggered the change: it has settled into a stable, self-sustaining state of coordinated gene expression, making its own OSKM factors (and all the other essential ingredients of a pluripotent stem cell) from its own endogenous copies of the genes.

An Experimental Manipulation of Factors That Modify Chromatin Can Increase Reprogramming Efficiencies

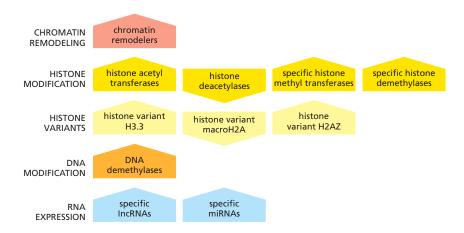

The low efficiency and slow rate of conversion in early iPS-cell studies suggested that there are barriers that normally block the switch from the differentiated state to the iPS state in these experiments, and that overcoming them can be a difficult process that involves a large element of chance. This probably helps explain why the outcome is often variable, with significant differences between the individual iPS cell lines generated, even when the initial differentiated cells are genetically and phenotypically identical. Only some of the candidate iPS lines produced have passed all the tests of pluripotency. Moreover, at a molecular level, there are differences even among the fully validated iPS lines: although they share many features, they vary in details of their gene expression patterns and, for example, in their patterns of DNA methylation.

Overcoming these difficulties is critical for improving our understanding of how cell specialization is controlled and organized in multicellular organisms; it should also facilitate many medical advances. Thus, intensive research is being carried out on the reprogramming process. One approach aims at obtaining a much clearer picture of the role that chromatin structures play in gene regulation in eukaryotes.

From our discussion of nuclear transplantation, one might expect that any reprogramming of a differentiated cell would require a radical and widespread change in the chromatin structure associated with selected genes. Not only are such changes observed, but a large number of different experiments reveal that the efficiency of the reprogramming process can be substantially increased by altering the activity of proteins that affect chromatin structure. Figure 22–29 categorizes some of the factors that when manipulated can enhance the transformation of fibroblasts to iPS cells; those in the top three rows—chromatin remodelers, histone modifiers, and histone variants—are especially well known to have profound effects on the organization of nucleosomes in chromatin (discussed in Chapter 4).

Figure 22-28 A summary of some of the major events that accompany the reprogramming of fibroblasts to iPS cells. Expression of the OSKM factors induces a series of events over a period of days to weeks. Reprogramming begins with down-regulation of somaticcell markers. Morphological changes characteristic of a mesenchymal-toepithelial transition ensue (see p. 1197), driven in part by changes in the expression of cell adhesion and signal proteins. Induction of early pluripotency markers is followed by the expression of pluripotency genes such as Nanog and Oct4. With similar timing, cells become immortalized as telomerase is induced and cell-cycle genes are regulated to enable stem-cell self-renewal. Stable reprogramming occurs in the time window when cells activate endogenous pluripotency genes and become independent of the OSKM factors. Notably, the vast majority of fibroblasts expressing the OSKM factors fail to downregulate somatic markers and activate pluripotency genes and do not convert to iPS cells. (Adapted from M. Stadtfeld et al., Cell Stem Cell 2:230-240, 2008. With permission from Elsevier.)

MBOC7_ptr_ch22_1279-1312.indd 1305 02/12/21 12:23 PM

ES and iPS Cells Can Be Guided to Generate Specific Adult Cell Types and Even Organoids

We can think of embryonic development in terms of a series of choices presented to cells as they follow a road that leads from the fertilized egg to terminal differentiation. After their long sojourn in culture, the ES cells or iPS cells and their progeny can still read the signs at each branch in the highway and respond as normal early embryonic cells would. If ES or iPS cells are implanted directly into an embryo at a later stage of development or into an adult tissue, however, they fail to receive the appropriate sequence of cues; their differentiation then is not properly controlled, and they will often give rise to a tumor called a *teratoma*, containing a mixture of cell types inappropriate to the site in the body (Figure 22–30).

By exposing ES or iPS cells in culture to an appropriate sequence of growth factors and other signal proteins, delivered with the right timing, it is possible to guide the cells along a pathway that approximates a normal developmental pathway and convert them into standard, differentiated, adult cell types (Figure 22–31 and Movie 22.2). Success requires trial and error but has now been achieved for many differentiated mouse and human cell types, including human dopaminergic neurons and human insulin-producing β cells, the cells lost in Parkinson's disease and type 1 diabetes, respectively.

Remarkably, under appropriate conditions, mouse or human ES and iPS cells and their progeny can proliferate, differentiate, and self-assemble in culture to form miniature, three-dimensional organs called **organoids**, which closely resemble the normal organ in its organization. An early striking example is shown in **Figure 22–32**, where a developing eye organoid is formed from human ES cells.

Mouse and human ES and iPS cells, and progenitor cells derived from them, have been used to form organoids that resemble a large variety of developing organs, including important parts of the human brain, arguably the most complex and sophisticated structure on Earth. Such organoids provide powerful models for studying organ development in a culture dish, where one can identify and study the genes involved and explore the roles of cell–cell interactions in ways not possible in the intact organism. We discussed earlier the remarkable demonstration that a single multipotent intestinal stem cell can form a complex intestinal organoid under appropriate conditions in culture (see Figure 22–14).

Cells of One Specialized Type Can Be Forced to Transdifferentiate Directly into Another

The route we have just described, from one type of differentiated cell to another type of differentiated cell via conversion to an iPS cell, seems needlessly round-about. Could we not convert differentiated cell type A into differentiated cell type B directly, without backtracking to a pluripotent stem cell? For many years, it has been known that such *transdifferentiation* can be achieved in a few special cases,

Figure 22-29 Factors that have been observed to enhance reprogramming efficiency. Emphasized here are those factors that can alter chromatin states, with those in the top three rows having the most direct effects. An up arrow indicates that reprogramming is increased when the activity of the indicated factor is increased; a down arrow indicates that reprogramming is increased when the activity of the indicated factor is decreased. Thus, for example, increased activity of histone acetyl transferases and increased activity of histone deacetylases have opposite effects, as expected from their biochemical activities (see p. 206). Note that histone chaperones also contribute to programming efficiency and may do so either positively or negatively depending on the histone variants assembled into chromatin.

Figure 22–30 A teratoma. These tumors contain tissues derived from each of the embryonic germ layers: endoderm, mesoderm, and ectoderm (including hair and teeth, as seen here). The tumors are usually benign and can develop when ES or iPS cells are injected into an immunocompatible adult animal, demonstrating the pluripotency of these stem cells. (Courtesy of Cao Xuan Cu.)

MBOC7_ptr_ch22_1279-1312.indd 1306 02/12/21 12:23 PM

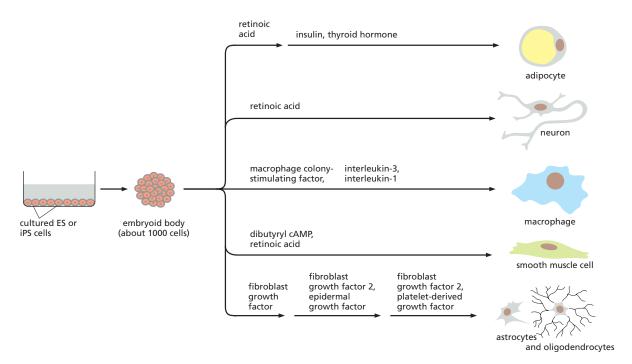

Figure 22–31 Production of differentiated cells from mouse or human ES or iPS cells in culture. ES and iPS cells can be cultured indefinitely as pluripotent cells when attached as a monolayer to a dish. Alternatively they can be detached and allowed to form aggregates called *embryoid bodies*, which causes the cells to begin to specialize. Cells from embryoid bodies, cultured in media with different factors added, can then be driven to differentiate in various ways. Notably, it takes very much longer to generate the differentiated cells from human compared to mouse pluripotent stem cells, reflecting the much slower rate of human development compared to a mouse. (Based on E. Fuchs and J.A. Segre, *Cell* 100:143–155, 2000.)

such as the conversion of fibroblasts into skeletal muscle cells by forced expression of MyoD (see p. 428). But now, with the insights that have come from the study of ES and iPS cells, ways have been found to bring about such interconversions in a much wider range of cases, including conversion of fibroblasts into neurons, hepatocytes, and intestinal epithelial cells.

An elegant example with special medical relevance comes from studies of the heart. By forcing expression of an appropriate combination of transcription

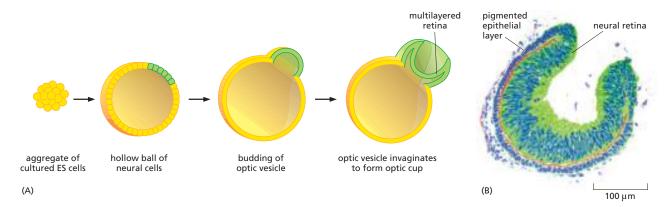

Figure 22–32 Cultured human ES cells can give rise to a three-dimensional organoid. (A) Schematic drawing shows how, under appropriate conditions, mouse or human pluripotent stem cells and their progeny in culture can proliferate, differentiate, and self-assemble into a three-dimensional eye-like structure (an optic cup), which includes a multilayered retina similar in organization to the one that forms during normal eye development *in vivo*. (B) Fluorescence micrograph of an optic cup formed by human ES cells in culture. The structure includes a development in a containing multiple layers of neural cells (stained *green*) and an underlying layer of pigmented epithelium, the apical surface of which is stained *red*. All nuclei are stained *blue*. (A, adapted from M. Eiraku and Y. Sasai, *Curr. Opin. Neurobiol.* 22:768–777, 2012; B, from T. Nakano et al., *Cell Stem Cell* 10:771–785, 2012. With permission from Elsevier.)

MBOC7_ptr_ch22_1279-1312.indd 1307 02/12/21 12:23 PM

regulators—not Oct4, Sox2, Klf4, and Myc, but Gata4, Mef2c, and Tbx5—it is possible to convert heart fibroblasts directly into heart muscle cells. This has been done in the living mouse, using retroviral vectors, and the transformation occurs with high efficiency when the vectors carrying the transgenes are injected directly into the heart muscle tissue itself. Although fibroblasts occupy only a small fraction of the heart tissue volume, they outnumber the heart muscle cells in the normal heart, and they survive in large numbers in areas of the heart where heart muscle cells have died. Thus, in a typical nonfatal heart attack, when heart muscle cells have died for lack of oxygen, the fibroblasts proliferate and make collagenous extracellular matrix, replacing the lost muscle with a fibrous scar. This is a poor sort of repair. By forcing expression of the appropriate factors in the heart, as described above, it has proved possible, in the mouse at least, to do better than nature and regenerate lost heart muscle through transdifferentiation of heart fibroblasts.

We are still a long way from putting this technique into practice as a treatment for heart attacks in humans, but it shows what the future may hold—not only for this medical problem but also for many others.

ES and iPS Cells Are Also Useful for Drug Discovery and Analysis of Disease

A large part of the excitement surrounding ES and iPS cells and the technology of transdifferentiation comes from the prospect of using the artificially generated cells for tissue repair. It begins to seem that virtually any type of tissue might be replaceable, allowing treatment of degenerative diseases that have previously had no cure, other than by organ transplantation. Research in this area is moving rapidly, but there are many difficulties to be overcome.

With the advent of iPS cells and direct transdifferentiation, at least one major hurdle that has challenged organ transplantation has been surmounted, in principle at least: the problem of immune rejection. ES cells, because they are created from early embryos that generally come from unrelated donors, will never be genetically identical to the cells of the individual receiving the cell transplant. The transplanted cells and their progeny are therefore prone to rejection by the immune system. Both iPS and transdifferentiated cells, in contrast, can be generated from a small sample of the individual's own tissue and so should escape immune attack when transplanted back into the same individual.

Tissue repair by cell and organoid transplantation, however, is not the only application for which ES, iPS, and transdifferentiated cells can be used: there are other ways that promise to be more immediately valuable. In particular, the cells can be used to generate large, homogeneous populations of specialized cells of any chosen type in culture, and these can serve both for investigation of disease mechanisms and for the search for new drugs acting on a specific cell defect (Figure 22–33).

Where a disease has a genetic cause, one can derive iPS cells from an affected individual and use the cells to produce the specific cell types that malfunction, to investigate how the malfunction occurs, and to screen for drugs that might help to put it right. *Timothy syndrome* provides an example. In this rare genetic condition, there is a severe, life-threatening disorder in the rhythm of the heartbeat (as well as several other abnormalities) as a result of a mutation in a specific type of Ca^{2+} channel. To study the underlying pathology, researchers took skin fibroblasts from individuals with the disorder, generated iPS cells from the fibroblasts, and induced the iPS cells to differentiate into heart muscle cells. These cells, when compared with heart muscle cells prepared similarly from normal control individuals, showed irregular heart muscle contractions and abnormal patterns of Ca^{2+} influx and electrical activity that could be characterized in detail. From these findings, it is a small step to development of an *in vitro* assay for drugs that might correct the misbehavior of the heart muscle cells.

Even in human disorders without a known genetic cause, iPS cells can be useful in understanding the condition. In one example, brain organoids were

MBOC7_ptr_ch22_1279-1312.indd 1308 02/12/21 12:23 PM

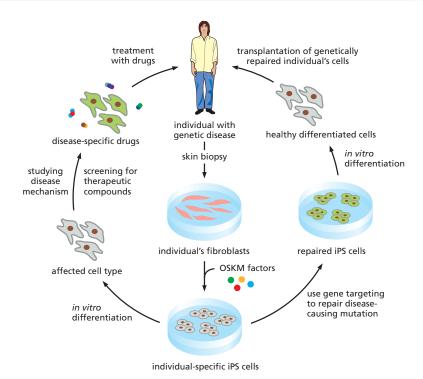

Figure 22-33 Use of iPS cells for drug discovery and for analysis and treatment of genetic disease. The left side of the diagram shows how differentiated cells that are generated from iPS cells derived from an individual with a genetic disease can be used for analysis of the disease mechanism and for discovery of therapeutic drugs. The right side of the diagram shows how the genetic defect might be repaired in the iPS cells, which could then be induced to differentiate in an appropriate way and grafted back into the individual without danger of immune rejection. (Adapted from D.A. Robinton and G.Q. Daley, Nature 481:295-305. Reproduced with permission of SNCSC.)

produced using iPS cells from an individual with microcephaly, a condition characterized by severely stunted brain growth and development. Careful analysis of these developing brain organoids revealed that the microcephaly in this case seemed to be caused by the premature cessation of proliferation and differentiation of brain progenitor cells, resulting in abnormally small numbers of differentiated brain cells.

Summary

In the adult mammalian body, the various types of tissue-specific stem cells are highly specialized, each giving rise to a limited range of differentiated cell types. Cells become restricted to specific pathways of differentiation during embryonic development. One way to force a return to a pluripotent or totipotent state is by nuclear transplantation: the nucleus of a differentiated cell can be injected into an enucleated oocyte, whose cytoplasm reprograms the genome of the injected nucleus back to an approximation of an early embryonic state. This allows the injected oocyte to develop into an entire new individual. The reversion of the genome to this state involves radical, genome-wide changes in chromatin structure and DNA methylation.

Remarkably, cells taken from the inner cell mass of an early mammalian embryo can be propagated in culture indefinitely in a pluripotent state. When transplanted back into a host early embryo, these embryonic stem (ES) cells can contribute cells to any tissue, including the germ line. ES cells have been invaluable for genetic engineering in mice. Cells with similar properties, called induced pluripotent stem (iPS) cells, can be generated from adult differentiated cells such as fibroblasts by forced expression of a cocktail of key transcription regulators. A similar method can be used to reprogram differentiated adult cells directly from one specialized cell type to another. In principle, iPS cells generated from cells taken from an adult human individual could be used for tissue repair in that same individual, avoiding the problem of immune rejection. More immediately, iPS cells provide a source of specialized cells that can be used to analyze in vitro the effects of mutations affecting human cells and to screen for drugs for treatment of genetic diseases. Both ES and iPS cells and their progeny can form tiny organs (organoids) in culture, which can serve as powerful models for studies of human development and disease.

PROBLEMS

Which statements are true? Explain why or why not.

22–1 In the mouse small intestine, stem cells in the crypts divide asymmetrically to maintain the population of cells that make up the crypts and villi; after each division, one daughter remains a stem cell and the other begins to divide rapidly to produce differentiated progeny.

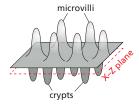

- **22–2** Stem cells are the same in all tissues.
- **22–3** Every tissue that can be renewed is renewed from a tissue-specific population of stem cells.
- **22–4** Although mice continually replace neurons in their olfactory bulbs and songbirds replace large numbers of neurons to refine their songs for each mating season, humans do not have the ability to replace neurons in their brains.

Discuss the following problems.

22–5 In the 1950s, scientists fed ³H-thymidine to rats to label cells that were synthesizing DNA, and then followed the fates of labeled cells for periods of up to a year. They found three patterns of cell labeling in different tissues. Cells in some tissues such as neurons in the central nervous system and the retina did not get labeled. Muscle, kidney, and liver, by contrast, each showed a small number of labeled cells that retained their label, apparently without further division or loss. Finally, cells such as those in the squamous epithelia of the tongue and esophagus were labeled in fairly large numbers, with radioactive pairs of nuclei visible in 12 hours; however, the labeled cells disappeared over time. Which of these three patterns of labeling would you expect to see if the labeled cells were generated by stem cells? Explain your answer.

22-6 At any given time, a single intestinal crypt of mice comprises about 15 stem cells and 10 Paneth cells. After cell division, which occurs about once a day, the daughter cells remain stem cells only if they maintain contact with a Paneth cell. This constant competition for Paneth-cell contact raises the possibility that crypts might become monoclonal over time; that is, the crypt cells at one point in time might derive from only one of the 15 stem cells that existed at some earlier time. To test this possibility, you use the so-called confetti marker that upon activation expresses one of three fluorescent proteins in the stem cells of the crypt. You then examine crypts at various times to determine whether they contain cells with multiple colors or only one color (Figure Q22-1). Do the crypts become monoclonal over time or not? How can you tell?

22–7 The origin of new β cells of the pancreas—from stem cells or from preexisting β cells—was not resolved until recently, when the technique of lineage tracing was used to decide the issue. Transgenic mice were engineered to express a tamoxifen-activated form of Cre recombinase under the control of the insulin promoter, which is

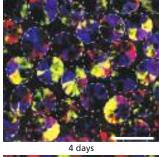

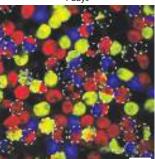

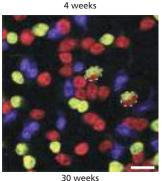

Figure Q22-1 Fluorescent cells in crypts in mouse intestines at various times after activation of expression of fluorescent proteins (Problem 22-6). The images are taken in the X-Z plane, which cuts through multiple crypts, as indicated in the schematic drawing. Roughly 50 crypts are visible in each section. Dotted white circles identify some individual crypts. Scale bars are 100 µm. (Adapted from H.J. Snippert et al., Cell 143:134-144, 2010. With permission from Elsevier.)

JO WCCK

active only in β cells. In these mice, investigators could remove an inhibitory segment of DNA by adding tamoxifen and thereby allow expression of human placental alkaline phosphatase (HPAP), which can be detected by histochemical staining. After a pulse of tamoxifen that converted about 30% of β cells in young mice to cells that express HPAP, the investigators followed the percentage of labeled β cells for a year, during which time the total number of β cells in the pancreas increased by 6.5-fold. How do you suppose the percentage of β cells would change over time if new β cells were derived from stem cells? What if new β cells were derived from preexisting β cells? Which hypothesis do the results in Figure Q22-2 support?

22–8 One of the earliest assays for hematopoietic stem cells made use of their ability to form colonies in the spleens of heavily irradiated mice. By varying the amounts of transplanted bone marrow cells, investigators showed that the number of spleen colonies varied linearly with dose and that the curve passed through the origin,

MBOC7_ptr_ch22_1279-1312.indd 1310 02/12/21 12:23 PM

PROBLEMS 1311

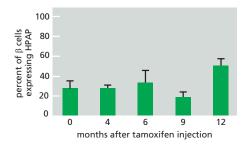

Figure Q22–2 Percentage of labeled β cells in pancreatic islets of mice at different ages (Problem 22–7). All mice were injected with a pulse of tamoxifen at 6–8 weeks of age, and then their pancreatic cells were stained for HPAP at various times afterward. Error bars represent standard deviations for all animals analyzed for that time point. (Adapted from Figure 2 of Y. Dor et al., *Nature* 429:41–46, 2004.)

suggesting that single cells were capable of forming individual colonies. However, because colony formation was rare relative to the numbers of transplanted cells, it was possible that undispersed clumps of two or more cells were the actual initiators.

A classic paper resolved this issue by exploiting rare, cytologically visible genome rearrangements generated by irradiation. Recipient mice were first irradiated to deplete bone marrow cells, and then they were irradiated a second time after transplantation to generate rare genome rearrangements in the transplanted cell population. Spleen colonies were then screened to find ones that carried genome rearrangements. How do you suppose this experiment distinguishes between colonization by single cells versus cellular aggregates?

It is possible to purify hematopoietic stem cells using a combination of antibodies directed against cell-surface targets. By removing cells that expressed surface markers characteristic of specific lineages such as B cells, granulocytes, myelomonocytic cells, and T cells, investigators generated a population of cells enriched for stem cells. They further enriched this population for putative stem cells by positively selecting for cells that expressed suspected stem-cell surface markers. Spleen colony formation in irradiated mice by these putative stem cells and the unfractionated bone marrow cells is shown in Figure Q22-3. Given that only about 1 in 10 cells lodges in the spleen, do these results support the idea that the enriched population consists mostly of hematopoietic stem cells? What additional information would you need to have to feel confident that the enriched cells are true stem cells? What proportion of bone marrow cells are hematopoietic stem cells?

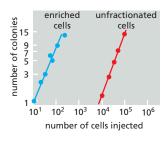

Figure Q22–3 Spleen colony formation by cells enriched for stem cells and by unfractionated bone marrow cells (Problem 22–9).

22–10 Generation of induced pluripotent stem (iPS) cells was first accomplished using retroviral vectors to carry the OSKM (Oct4, Sox2, Klf4, and Myc) set of transcription regulators into cells. The efficiency of fibroblast reprogramming was typically low (0.01%), in part because large numbers of retroviruses must integrate to bring about reprogramming, and each integration event carries with it the risk of inappropriately disrupting or activating a critical gene. In what other ways, or other forms, do you suppose you might deliver the OSKM transcription regulators so as to avoid these problems?

22-11 To test whether blood-borne factors alter neurogenesis in the central nervous system in mice, you use the technique of parabiosis—linking of circulatory systems in two individuals—to measure effects on the neurogenic niche in the dentate gyrus of the hippocampus. As indicated in Figure Q22-4A, you link the circulatory systems of two young mice, or two old mice, or a young mouse with an old mouse. Five weeks later, you stain slices of the dentate gyrus with antibodies to doublecortin (Dcx), a marker for newly born neurons, and count the new neurons, as summarized in Figure Q22-4B and C. Results in young-young parabionts and old-old parabionts were no different than in individual young or old mice. Do these results support the idea that blood-borne factors affect neurogenesis in the dentate gyrus of the hippocampus? Why or why not? Which, if either, mouse benefits in the parabiosis of a young mouse with an old mouse?

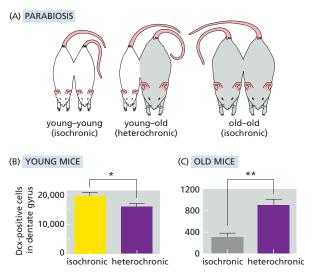

Figure Q22–4 Effects of parabiosis on the number of newly born neurons in the dentate gyrus of the mouse hippocampus (Problem 22–11). (A) Linked circulatory systems (parabiosis) between pairs of mice. (B) Dcx-positive cells (newly born neurons) in a young mouse paired with a young mouse (isochronic) or in a young mouse paired with an old mouse (heterochronic). (C) Dcx-positive cells in an old mouse paired with an old mouse (isochronic) or in an old mouse paired with a young mouse (heterochronic). Isochronic refers to parabiosis between mice of the same age; heterochronic refers to parabiosis between mice of different ages. Asterisks refer to statistical significance of the results: * is for P < 0.05, which means the result would be expected to occur by chance in less than 1 in 20 repeats; ** is for < 0.01, which means the result would be expected to occur by chance in less

Pathogens and Infection

23

Infectious diseases currently cause about one-quarter of all human deaths worldwide, more than all forms of cancer combined and second only to cardiovascular diseases. There is a continuing heavy burden of ancient diseases such as tuberculosis and malaria, and these are increasingly difficult to treat because of rising drug resistance. Newer infectious diseases continually emerge, including the current pandemic (worldwide epidemic) of COVID-19 (coronavirus disease 2019), which was first clinically observed in 2019 and has since infected hundreds of millions of people and caused millions of deaths worldwide. Moreover, some diseases long thought to result from other causes are now recognized to be associated with infections. Most gastric ulcers, for example, are caused not by stress or spicy food, but by infection of the stomach lining by the bacterium *Helicobacter pylori*.

The burden of infectious diseases is not spread equally across the planet. Poorer countries and communities suffer disproportionately, often due to poor public sanitation and overburdened health systems, as occurred in Haiti in 2010 with a severe cholera outbreak after a devastating earthquake. Some infectious diseases, however, occur primarily or exclusively in industrialized communities: Legionnaires' disease, for example, a bacterial infection of the lungs, commonly spreads through air-conditioning systems.

Since the mid-1800s, physicians and scientists have struggled to identify the microbes—collectively called **pathogens**—that are capable of causing infectious diseases. More recently, the advent of microbial genetics and molecular cell biology has greatly enhanced our understanding of the causes and mechanisms of infectious diseases. We now know that pathogens frequently exploit the attributes of their host's cells in order to infect them. This understanding can give us new insights into normal cell biology, as well as strategies for treating and preventing infections.

Although pathogens are understandably a focus of attention, only a relatively small fraction of the microbial species we encounter are pathogens. Much of the biomass of Earth is made up of microbes. They produce everything from the oxygen we breathe to the soil nutrients we use to grow food and represent the bottom of the ecological pyramid. Even those species of microbes that colonize the human body do not generally cause disease. Many of these microbes have a beneficial effect on the health of the organism, assisting its normal development and physiology.

In this chapter, we give an overview of the different kinds of pathogens. We then discuss the cell biology of infection—the molecular interactions between pathogens and their hosts. Finally, we discuss an emerging concept that the many microbes that normally colonize our body, the so-called human **microbiota**, may actually benefit our health. In Chapter 24, we consider how our innate and adaptive immune systems collaborate to defend us against pathogens while leaving our microbiota intact.

INTRODUCTION TO PATHOGENS

We normally think of pathogens as hostile invaders, but a pathogen, like any other organism, is simply exploiting an available niche in which to live and procreate. Living on or in a host organism is a very effective strategy, and it is possible that

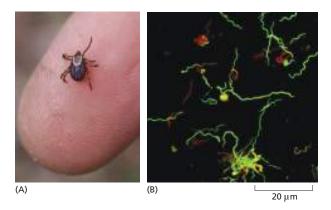

IN THIS CHAPTER

Introduction to Pathogens

Cell Biology of Pathogen Infection

The Human Microbiota

MBOC7_ptr_ch23_1313-1352.indd 1313 02/12/21 12:22 PM

every organism on Earth is subject to some type of infection (Figure 23–1). Even bacteria can be infected by viruses called bacteriophages (see Figure 1–37). It is not surprising then that many microorganisms have evolved the ability to survive and reproduce in the human body, a nutrient-rich, warm, and moist environment that remains at a uniform temperature and constantly renews itself. In this section, we discuss some of the common features that microorganisms must have in order to colonize the human body or cause disease, and we explore the wide variety of organisms that are known to cause disease.

Pathogens Can Be Viruses, Bacteria, or Eukaryotes

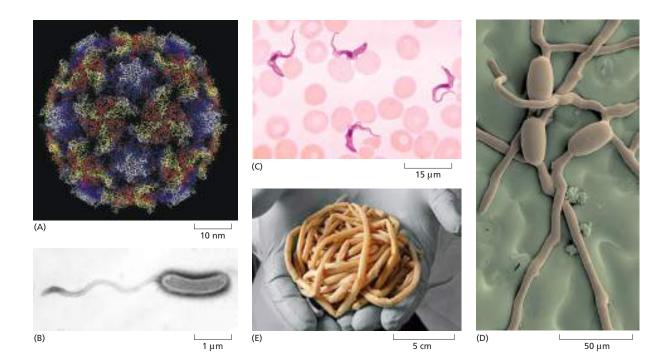

Many types of microbes cause disease in humans, and others reside on or in our bodies without causing harm. The most familiar are viruses and bacteria. Viruses cause diseases ranging from COVID-19 and Ebola virus disease to the common cold. Viruses are essentially fragments of nucleic acid (DNA or RNA) that generally encode a relatively small number of gene products and are wrapped in a protective shell of proteins (Figure 23–2A) and (in some cases) an outer membrane envelope. Much larger and more complex than viruses, bacteria are prokaryotic cells that perform most of their basic metabolic functions themselves, relying on the host primarily for nutrition (Figure 23–2B). Bacteria cause illnesses ranging from tuberculosis, which causes roughly 1.4 million deaths per year, to pneumonia, as well as diarrheal and sexually transmitted diseases.

Some other infectious agents are eukaryotic organisms. These range from single-celled protozoa (Figure 23–2C) and fungi (Figure 23–2D) to large, complex metazoa such as parasitic worms. One of the most common human parasites, shared by about a billion people at present, is the nematode worm *Ascaris lumbricoides*, which infects the gut (Figure 23–2E). It resembles its harmless nematode cousin *Caenorhabditis elegans*, which is used as a model organism for genetic and developmental biological research (see Figure 1–42). *C. elegans*, however, is only about 1 mm in length, whereas *Ascaris* can reach 30 cm.

Pathogens Interact with Their Hosts in Different Ways

Although the ability of a particular microorganism to cause disease depends on many factors, it requires that the pathogen possess specialized pathogenic characteristics that allow it to live in humans. One way we distinguish between pathogens is by classifying them as primary versus opportunistic on the basis of the circumstances under which they cause human disease. **Primary pathogens** can cause overt disease in most healthy, nonimmune people. **Opportunistic pathogens** do not cause disease in healthy people but can cause illness in individuals suffering from other conditions. Some primary pathogens cause acute, life-threatening epidemic infections and spread rapidly from one sick or dying host to another; historically important examples include the bacterium *Vibrio cholerae*, which causes cholera, and the sudden acute respiratory syndrome coronavirus 2 (SARS-CoV-2) and influenza viruses, which cause COVID-19

Figure 23-1 Parasitism at many levels. (A) Most animals harbor parasites, an example being the blacklegged tick, or deer tick (Ixodes scapularis), shown here on a human finger. Although ticks of this species thrive on white-tailed deer and other wild mammals, they can also live on humans. (B) Ticks themselves harbor their own parasites including the bacterium Borrelia burgdorferi, stained here with a vital dye that labels living bacteria green and dead bacteria red. These long spiralshaped bacteria live in deer ticks and can be transmitted to humans during a tick's blood meal. B. burgdorferi causes Lyme disease, which is characterized by a bull's-eye-shaped skin rash and fever; if the infection is left untreated, various complications can result, including arthritis and neurological abnormalities. The idea that parasites have their own parasites was noted by Jonathan Swift in 1733: "So, naturalists observe, a flea Has smaller fleas that on him prey; And these have smaller still to bite 'em; And so proceed ad infinitum." (A, National Geographic Image Collection/Alamy Stock Photo; B, courtesy of M. Embers.)

and flu, respectively. Others may persistently infect a single individual for years without causing overt disease; examples include the bacterium *Mycobacterium tuberculosis*, which causes tuberculosis, and the intestinal worm *Ascaris* (see Figure 23–2E). Although these potential primary pathogens can make some people critically ill, billions of people carry these foreign organisms in an asymptomatic way, often unaware that they are infected.

In order to survive and multiply, a successful pathogen must be able to (1) enter the host (usually by breaking an epithelial barrier); (2) find a nutritionally compatible niche in the host's body; (3) avoid, subvert, or circumvent the host's innate and adaptive immune responses; (4) replicate, using host resources; and (5) exit one host and spread to another. Pathogens have evolved various mechanisms that exploit the biology of their host organisms to help accomplish these five tasks. For some pathogens, these mechanisms are adapted to a unique host species, whereas for others the mechanisms are sufficiently general to permit invasion, survival, and replication in a wide variety of hosts. Because pathogens have evolved the ability to interface directly with the molecular machinery of host cells, we have learned a great deal about cell biological principles by studying them.

Our constant exposure to pathogens has strongly influenced human evolution. In modern times, humans have learned how to limit the ability of pathogens to infect us through improvements in public health measures and childhood nutrition, vaccines, antimicrobial drugs, and routine testing of blood used for transfusions. As we learn more about the mechanisms by which pathogens cause disease (called *pathogenesis*), we will devise new ways to supplement or augment our immune systems in fighting infections.

We now introduce the basic features of each of the three major types of pathogens—bacteria, eukaryotic parasites, and viruses—before we examine the detailed mechanisms used by these pathogens to infect their hosts.

Bacteria Are Diverse and Occupy a Remarkable Variety of Ecological Niches

Bacteria are small but highly sophisticated cells whose organization and behaviors have attracted the attention of many scientists for well over a century. Bacteria are classified broadly on the basis of their cellular and molecular features. One

Figure 23-2 Pathogens in many forms. (A) The structure of the protein coat, or capsid, of poliovirus. This virus was once a common cause of paralysis, but the disease (poliomyelitis) has been greatly reduced by widespread vaccination. (B) The bacterium Vibrio cholerae, the causative agent of the epidemic diarrheal disease cholera, shown here with its attached flagellum. (C) The protozoan parasite Trypanosoma brucei (purple) in a field of erythrocytes (red blood cells; pink). This parasite causes African sleeping sickness, a potentially fatal disease of the central nervous system. (D) Powdery mildew spores germinating on an Arabidopsis leaf. (F) This clump of Ascaris nematodes was passed rectally by a child in Africa. (A, courtesy of Robert Grant, Stephan Crainic, and James M. Hogle; B, photograph kindly provided by John Mekalanos; C, CDC, Department of Health and Human Services; D, courtesy of Kim Findlay and John Innes Centre; E, CDC/James Gathany.)

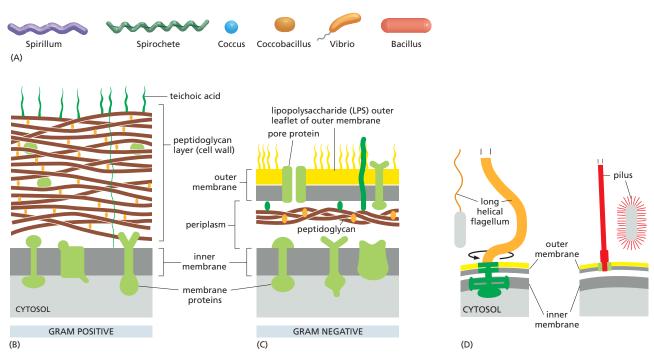

Figure 23–3 Bacterial shapes and cell-surface structures. (A) Bacteria are traditionally classified by shape. For example, the bacterium *Borrelia burgdorferi*, shown in Figure 23–1B, is spiral shaped and is thus classified as a spirochete. (B and C) Bacteria are also classified as *Gram positive* or *Gram negative* on the basis of a staining procedure first described in 1884. (B) Gram-positive bacteria such as *Streptococcus* and *Staphylococcus* have a single membrane and a thick cell wall made of cross-linked *peptidoglycan*. They are called Gram positive because they retain the violet dye used in the Gram-staining procedure. (C) Gram-negative bacteria such as *Escherichia coli* (*E. coli*) and *Salmonella enterica* have two membranes, separated by the *periplasm* (see Figure 11–17). The peptidoglycan cell wall of these organisms is located in the periplasm and is thinner than in Gram-positive bacteria; they therefore fail to retain the dye in the Gram-staining procedure. The inner membrane of both Gram-positive and Gram-negative bacteria is a phospholipid bilayer. The inner leaflet of the outer membrane of Gram-negative bacteria is also made primarily of phospholipids, whereas the outer leaflet of the outer membrane is composed of the unique glycosylated lipid *LPS*. (D) Cell-surface appendages are important for bacterial behavior. Both Gram-positive and Gram-negative bacteria swim using the rotation of helical flagella. An example is *V. cholerae*, depicted in panel A and shown in Figure 23–2B. Although the bacterium illustrated has only a single flagellum at one pole, many have multiple flagella. *Pili* (also called *fimbriae*) are used to adhere to various surfaces in the host and to facilitate genetic exchange between bacteria. Some kinds of pili can retract to generate force and thereby help bacteria move along surfaces.

such feature is their shape—rods, spheres (cocci), or spirals (Figure 23-3A). They are also traditionally classified by their so-called Gram-staining properties, which is an older staining method that is still informative. This staining reflects differences in the structure of the bacterial surface, a layer that is important for pathogens because it directly contacts host cells and the immune system. Gram-positive bacteria have a thick layer of peptidoglycan cell wall outside their inner (plasma) membrane (Figure 23-3B), whereas Gram-negative bacteria have a thinner peptidoglycan cell wall. In both cases, the cell wall protects against lysis by osmotic swelling, and it is a target of host antibacterial proteins such as lysozyme and antibiotics such as penicillin. Gram-negative bacteria are also covered outside the cell wall by an outer membrane containing lipopolysaccharide (LPS) (Figure 23-3C). Both peptidoglycan and LPS are unique to bacteria and are recognized as pathogen-associated molecular patterns (PAMPs) by the host innate immune system, as discussed in Chapter 24. The surface of bacterial cells can also display an array of appendages, including flagella and pili, which enable bacteria to swim or adhere to desirable surfaces, respectively (Figure 23-3D). Apart from cell shape and structure, differences in ribosomal RNA and genomic DNA sequence are also used for phylogenetic classification. Because bacterial genomes are small—typically between 1,000,000 and 5,000,000 nucleotide pairs (compared to more than 3,000,000,000 for humans)—they are now simple to sequence, making this an important new classification tool.

MBOC7_ptr_ch23_1313-1352.indd 1316 02/12/21 12:22 PM

Bacteria also exhibit extraordinary molecular, metabolic, and ecological diversity. At the molecular level, bacteria are far more diverse than eukaryotes, and they can occupy ecological niches having extremes of temperature, salt concentrations, and nutrient limitation. To describe how flexible bacterial pathogens are with respect to their growth niche, we discriminate between **facultative pathogens** and **obligate pathogens**. Facultative bacteria can replicate in an environmental reservoir such as water or soil and only cause disease if they happen to encounter a susceptible host. Obligate pathogens can only replicate inside the body of their host. Bacteria also differ in the range of hosts they will infect. A champion generalist is the opportunistic pathogen *Pseudomonas aeruginosa*, which can cause disease in a wide variety of plants and animals. In contrast, *Salmonella enterica* serovar Typhi only infects humans, causing typhoid fever, an ancient and life-threatening human disease that was sensationalized by the story of the cook "Typhoid Mary," who carried this bacterium asymptomatically and spread typhoid fever in New York City in the early 1900s.

Bacterial Pathogens Carry Specialized Virulence Genes

Genes that contribute to the ability of an organism to cause disease (as opposed to genes needed solely to grow and replicate) are called **virulence genes**, and the proteins they encode are called **virulence factors**. In general, the presence of a relatively small number of such virulence genes distinguishes pathogenic bacteria from their closest nonpathogenic relatives. Virulence genes are often clustered together on the bacterial chromosome; large clusters are called *pathogenicity islands*. Virulence genes can also be carried on *bacteriophages* (bacterial viruses) or *transposons* (see Table 5–4), both of which integrate into the bacterial chromosome, or on extrachromosomal *virulence plasmids* (Figure 23–4A).

Pathogenic bacteria are thought to emerge when groups of virulence genes are transferred together into a previously avirulent bacterium by a process called **horizontal gene transfer** (to distinguish it from vertical gene transfer from parent to offspring). Horizontal transfer can occur by one of three mechanisms: natural *transformation* by released naked DNA, *transduction* (infection) by bacteriophages, or sexual exchange by *conjugation* (Figure 23–4B and Movie 23.1). Sequencing the genomes of pathogenic and nonpathogenic bacteria has revealed that horizontal gene transfer has made important contributions to bacterial evolution, enabling species to inhabit new ecological and nutritional niches and to cause disease. Even within a single bacterial species, the amount of chromosomal

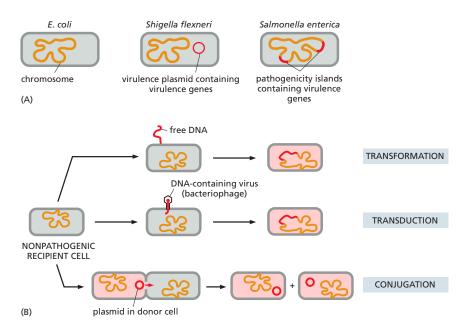

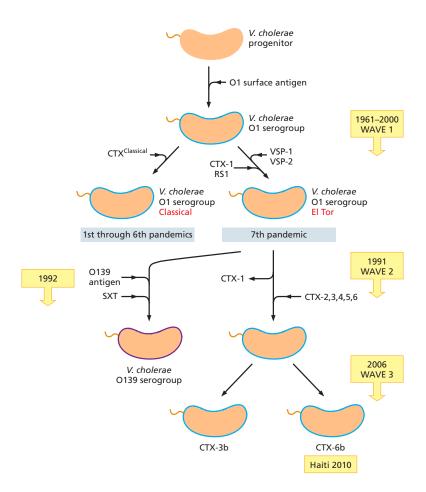

Figure 23-4 Genetic differences between pathogenic and nonpathogenic bacteria. (A) Genetic differences between nonpathogenic E. coli and two closely related food-borne pathogens-Shigella flexneri, which causes dysentery, and Salmonella enterica serovar Typhimurium, a common cause of food poisoning. Nonpathogenic E. coli has a single circular chromosome. The chromosome of S. flexneri differs from that of E. coli in a limited number of locations; most of the genes required for pathogenesis (virulence genes) are carried on an extrachromosomal virulence plasmid. The chromosome of S. enterica serovar Typhimurium carries two large inserts (pathogenicity islands) not found in the E. coli chromosome: these inserts each contain many virulence genes. (B) Bacterial pathogens evolve by horizontal gene transfer. This can occur by three mechanisms: natural transformation, in which naked DNA is taken in by competent bacteria: transduction, in which bacterial viruses (bacteriophages) transfer DNA from one bacterium (in the example shown, a pathogen) into another; and conjugation (see Movie 23.1), during which plasmid DNA, and even chromosomal DNA. is transferred from a donor to a recipient bacterium.

MBOC7_ptr_ch23_1313-1352.indd 1317 02/12/21 12:22 PM

variation is astonishing; the genomes of different strains of *Escherichia coli* can differ by as much as 25%. Such variation has led to the concept that a bacterial species has both a *core genome* common to all isolates within the species and a larger *pangenome* consisting of all genes present in the full spectrum of isolates.

Acquisition of genes and gene clusters can drive the rapid evolution of pathogens and turn nonpathogens into pathogens. Consider, for example, V. cholerae-the Gram-negative bacterium that causes the epidemic diarrheal disease cholera. Of the hundreds of strains of V. cholerae, the only ones that cause pandemic human disease are those infected (see Figure 23-4B) with a mobile bacteriophage (CTX¢); hereafter referred to as CTX) containing genes encoding the two subunits of the toxin that causes the diarrhea. As summarized in Figure 23-5, seven pandemics of V. cholerae have arisen since 1817. The first six were caused by the periodic reemergence of so-called classical strains. In addition to the toxin-encoding bacteriophage, these strains shared a similar O1 surface antigen, part of the LPS in the outer membrane (see Figure 23-3C). In 1961, the seventh pandemic began, caused by a new strain named El Tor, now also called a wave 1 strain, which arose when an O1-expressing strain acquired CTX-1 and RS1\$\phi\$ (hereafter referred to as RS1) bacteriophages and at least two new pathogenicity islands. El Tor strains have now displaced the classical strains. In 1991, new wave 2 and early wave 3 strains emerged, in which CTX-1 was replaced with CTX-2-6 bacteriophages. In 1992, another new strain emerged in which O1 was replaced with another variant called O139, which differs in a surface antigen, and thus was not recognized by antibodies present in the blood of survivors of previous cholera epidemics. Then, in 2006, current wave 3 strains emerged, which include the strain containing CTX-6b that caused the severe cholera outbreak in Haiti in 2010, infecting more than 700,000 people and leading to approximately 8500 deaths.

Figure 23-5 Model for the evolution of pathogenic V. cholerae strains. Progenitor strains in the wild first acquired the biosynthetic pathway necessary to make the O1 antigen type of carbohydrate chain (blue outline) on the outer-membrane LPS (see Figure 23-3C), a feature that is associated with the ability to cause epidemic cholera disease. Incorporation of the CTX bacteriophage created the classical pathogenic strains responsible for the first six worldwide epidemics of cholera between 1817 and 1923. Sometime in the twentieth century, an O1 strain in the environment picked up the CTX bacteriophage again, along with an associated bacteriophage RS1 and two pathogenicity islands (VSP-1 and VSP-2), creating the El Tor (wave 1) strain that emerged as the seventh worldwide pandemic in 1961. In the 1990s, an El Tor strain was isolated that had picked up a new DNA cassette, enabling it to produce the O139 antigen type of carbohydrate chain (purple outline) rather than the O1 type. This altered the bacterium's interaction with the human immune system without diminishing its virulence; this bacterium also picked up a new pathogenicity island (SXT). Separately, wave 2 strains emerged, in which CTX-1 was replaced with CTX-2-6 bacteriophages. In 2006, wave 3 strains emerged with variant CTX-3 and CTX-6 bacteriophages. The history of the V. cholerae strains shown in this diagram was deduced by comparing the DNA sequences of the genome of each strain to one another and noting the key differences. An electron micrograph of V. cholerae is

shown in Figure 23-2B.

MBOC7_ptr_ch23_1313-1352.indd 1318 02/12/21 12:22 PM

As this example makes clear, the rapid evolution of bacterial pathogens can be likened to an arms race that pits the survival of a bacterium against our immune systems and the tools of modern medicine. Similar struggles for survival take place between all pathogens and humans, and understanding these conflicts provides key insights into the evolution of pathogens and greatly informs how we treat new outbreaks of infectious diseases.

Bacterial Virulence Genes Encode Toxins and Secretion Systems That Deliver Effector Proteins to Host Cells

What are the gene products that enable a bacterium to cause disease in a healthy host? The precise nature of these products differs between classes of pathogens that are largely distinguished by whether they live outside of host cells, so-called *extracellular bacterial pathogens* (discussed in this section), or inside host cells, so-called *intracellular bacterial pathogens* (discussed in a later section). For extracellular bacterial pathogens, virulence genes often encode secreted toxic proteins (*toxins*) that are released by bacteria. These toxins diffuse to target host cells, where they bind to specific receptors on the cell surface and enter the cell, interfering with host-cell proteins to elicit a response that is beneficial to the pathogen. Several of these bacterial toxins are among the most potent of known human poisons. Bacterial toxins are often composed of two protein components—an A subunit with enzymatic activity, and a B subunit that binds to host-cell receptors and directs the trafficking of the A subunit to the cytosol by various routes (Figure 23-6). The

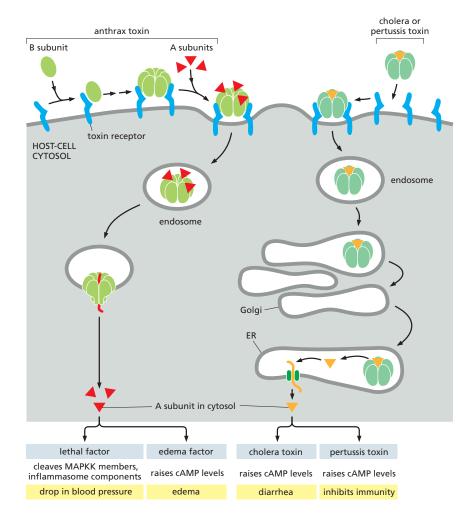

Figure 23-6 Toxins released by bacteria bind to and enter into host cells, disrupting host-cell processes. Bacterial toxins are often composed of A and B protein subunits. The B (binding) subunit of the toxin, which interacts with hostcell toxin receptors, can assemble after binding to toxin receptors (as with anthrax toxin) or prior to receptor binding (as with cholera and pertussis toxins). Binding to toxin receptors enables endocytosis and intracellular trafficking of the B subunits and the associated and enzymatically active A subunit(s). In the case of Bacillus anthracis, the B subunit changes conformation in the low-pH environment of the endosome to form a pore through which two different A subunits, lethal factor and edema factor, are transported across the membrane of the endosome in an unfolded conformation. In the cases of V. cholerae toxin and Bordetella pertussis toxin, the B and A subunits are transported to the Golgi apparatus and then to the endoplasmic reticulum (ER), where the A subunits are then translocated into the cytosol in an unfolded conformation through a protein-translocation channel (see Movie 23.2).

MBOC7_ptr_ch23_1313-1352.indd 1319 02/12/21 12:22 PM

two subunits of **cholera toxin**, for example, are encoded by the *V. cholerae* CTX phage (see Figure 23–5), which is incorporated into the bacterial genome (Movie 23.2). The A subunit catalyzes the transfer of an ADP-ribose moiety from NAD $^+$ to the trimeric G protein G_s . This ADP ribosylation alters the G-protein α subunit so that it can no longer hydrolyze its bound GTP, causing it to remain in an active state that stimulates adenylyl cyclase indefinitely (see Chapter 15). The resulting prolonged elevation in cAMP concentration within intestinal epithelial cells causes a large efflux of Cl $^-$ and water into the gut, thereby causing the severe diarrhea that characterizes cholera. Released bacteria then contaminate food and water, spreading infection to new hosts.

Some pathogenic bacteria secrete multiple toxins, each of which targets a different signaling pathway in host cells. Anthrax, for example, is an acute infectious disease of sheep, cattle, and occasionally humans. It is caused by contact with spores of the Gram-positive bacterium Bacillus anthracis. Dormant spores can survive in soil for long periods. If inhaled, ingested, or rubbed into breaks in the skin, spores can germinate and the bacteria replicate. The bacteria secrete two toxins with identical B subunits but different A subunits. The B subunits bind to a host-cell surface receptor protein to transfer the two different A subunits into host cells (see Figure 23-6). The A subunits are called lethal factor and edema factor. The latter is a calmodulin-dependent adenylyl cyclase that catalyzes the production of cyclic AMP (see Figure 15-26). Injection of edema toxin into the bloodstream of an animal leads to an ion imbalance that can cause an accumulation of extracellular fluid (edema) in the intestine and liver. Lethal toxin is a protease that cleaves several activated members of the mitogen-activated protein kinase kinase (MAP kinase kinase; MAPKK) family (see Figure 15-50) and components of the inflammasome (see Chapter 24), disrupting intracellular signaling and leading to immune-cell dysfunction. In animals, lethal toxin targets cells of the cardiovascular system, causing shock (a large fall in blood pressure) and death.

Whereas toxins are released and diffuse to target cells, pathogens that physically contact host cells often possess specialized **contact-dependent secretion systems** that directly inject so-called *effector proteins* from the bacterium into host cells. There are several such secretion systems, and we will limit our discussion to two that are present in Gram-negative bacteria and play important roles in bacterial pathogenesis: the *type III secretion system* (**Figure 23–7**) and the *type IV secretion system*. The injection of effector proteins, as depicted to occur via the **type III secretion system** in Figure 23–7, can elicit a variety of

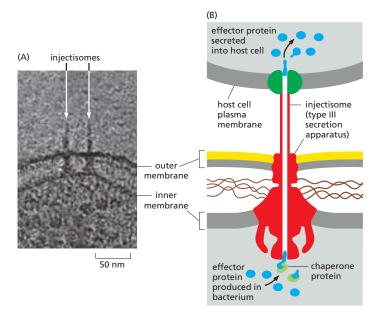

Figure 23-7 Contact-dependent type III secretion systems can deliver effector proteins from the cytosol of a bacterium directly into the host cell. (A) Electron micrograph of type III secretion systems on the surface of a bacterial cell, each of which consists of more than two dozen proteins. (B) The large lower ring is embedded in the bacterial inner membrane, and the smaller upper ring is embedded in the bacterial outer membrane. During infection, docking of the tip of the hollow needle at a host-cell plasma membrane results in the secretion of bacterial translocator proteins (dark green), which form a pore in the host membrane. Bacterial effector proteins (blue) are initially bound to chaperone proteins in the bacterial cytosol (light green), which keep them in an unfolded conformation. Unfolded effector proteins then pass through the injectisome and are secreted into the host cell, where they fold into their active conformation. (A, Hu et al., Cell 168:1065-1074, 2017. With permission from Elsevier.)

host-cell responses. For extracellular pathogens, it can enable the bacterium to block phagocytosis by immune cells. For intracellular pathogens, it can promote phagocytosis by nonimmune cells, or survival inside cells. The type III and type IV secretion systems appear to have evolved independently. There is a remarkable degree of structural similarity between type III secretion systems and the bacterial flagellum (see Figures 23–2B and 23–3D), suggesting they have a common evolutionary origin. Similarly, type IV secretion systems are closely related to the conjugation apparatus that many bacteria use to exchange genetic material (see Figure 23–4B). Although the mechanism of effector protein translocation through the type III and type IV secretion systems is not well understood, the inner diameter of the type III secretion system needle is only approximately 2 nm, so proteins must be moved through in an unfolded conformation.

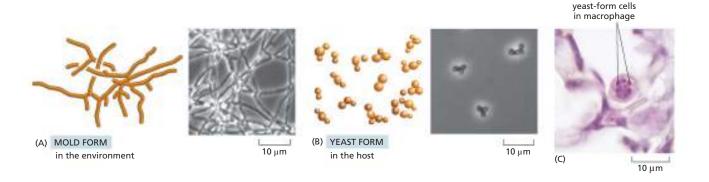

Fungal and Protozoan Parasites Have Complex Life Cycles Involving Multiple Forms

Pathogenic fungi and protozoan parasites are eukaryotes, as are their hosts. Because antifungal and antiparasitic drugs often target core molecules that are similar between parasite and host, they can be less effective and more toxic to the host than are antibiotics that target bacteria. A second characteristic of fungal and parasitic infections that makes them difficult to treat is the tendency of the pathogens to switch among several different forms during their life cycles. A drug that is effective at killing one form can be ineffective at killing another form; therefore, the population of the pathogen can survive the treatment.

Fungi include both unicellular yeasts (such as Saccharomyces cerevisiae and Schizosaccharomyces pombe, which are used to bake bread and brew beer, and as model organisms for cell biology research) and filamentous, multicellular molds (like those found on moldy fruit or bread; see Figure 23–2D). Most of the important pathogenic fungi exhibit dimorphism—the ability to grow in either yeast or mold form. The yeast-to-mold or mold-to-yeast transition is frequently associated with infection. Histoplasma capsulatum, for example, grows as a mold at low temperature in the soil, but it switches to a yeast form when inhaled into the lung, where it can cause the disease histoplasmosis (Figure 23–8). The most common human fungal pathogen, Candida albicans, which often exists as a resident of the human oral and gastrointestinal microbiota and is also an opportunistic pathogen that can cause serious disease in immunocompromised people by entering the bloodstream and rapidly dividing.

Protozoan parasites are single-celled eukaryotes with more elaborate life cycles than fungi, and they frequently require more than one host. **Malaria** is the most devastating protozoal disease, infecting more than 200 million people every year and killing upward of 400,000. It is caused by four species of *Plasmodium*, which are transmitted to humans by the bite of the female *Anopheles* mosquito. *Plasmodium falciparum* causes the most serious form of malaria and is the most intensively studied of the malaria-causing parasites. It exists in many distinct

Figure 23-8 Dimorphism in the pathogenic fungus Histoplasma capsulatum. (A) At low temperature in the soil, H. capsulatum grows as a multicellular filamentous mold consisting of many individual cells connected together. (B) After it is inhaled into the lung of a mammal, the increase in temperature to 37°C causes a switch to a veast form consisting of small clumps of round cells. (C) A stained histologic section of a mouse lung infected with H. capsulatum, showing a macrophage containing yeast forms of the pathogen. (B–D) Blood smears from people with malaria, showing three different forms of the parasite that appear in red blood cells: B, ring stage; C, schizont; and D, gametocyte. (B–D, courtesy of the Centers for Disease Control, Division of Parasitic Diseases, DPDx.)

forms, and it requires both the human and mosquito hosts to complete its sexual cycle (**Figure 23-9A** and **Movie 23.3**). Several of these forms are highly specialized to invade and replicate in specific tissues—the lining of the insect gut, the human liver, and the human red blood cell. Even within a single host-cell type, the red blood cell, the *Plasmodium* parasite undergoes a complex sequence of developmental events, reflected in striking morphological changes (**Figure 23-9B, C, and D**).

All Aspects of Viral Propagation Depend on Host-Cell Machinery

Bacteria, fungal, and protozoan pathogens are themselves living cells. They use their own machinery for DNA replication, transcription, and translation, and, for the most part, they provide their own sources of metabolic energy from nutrients in their environment. **Viruses**, by contrast, are the ultimate hitchhikers, carrying little more than genetic information in the form of nucleic acid. Many clinically

Mumps virus	Single-stranded RNA [-] strand	Mumps
Rabies virus	Single-stranded RNA [-] strand	Rabies

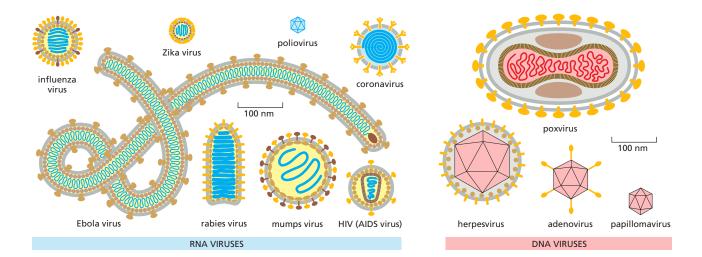

important human viruses have relatively small genomes consisting of double-stranded DNA or single-stranded RNA [either positive (+) sense RNA that can be directly translated into proteins or negative (-) sense RNA that must be replicated to produce (+) sense RNA] (Table 23–1). We now have complete genome sequences of almost all of them.

Viral genomes typically encode three types of protein: proteins for replicating the genome, proteins for packaging the genome and delivering it to more host cells, and proteins for modifying the structure or function of the host cell to enhance the replication of the virus. In general, viral replication involves the following sequence of steps: (1) entry into the host cell, (2) disassembly of the infectious virus particle, (3) replication of the viral genome, (4) transcription of viral genes and synthesis of viral proteins, (5) assembly of these viral components into progeny virus particles, and (6) release of progeny virions (Figure 23–10). A single virus particle (a *virion*) that infects a single host cell can produce thousands of progeny.

Figure 23–10 A simple viral life cycle. The hypothetical simple virus shown here consists of a small double-stranded DNA molecule that codes for only a single viral capsid protein. To reproduce, the viral genome must (1) enter a host cell, where it (2) disassembles and releases its genetic material. The genome is (3) replicated to produce multiple copies, and (4) transcribed and translated to produce the viral coat protein. The viral genomes can then (5) assemble spontaneously with the coat protein to form a new virus particle, which (6) escapes from the host cell. No known virus is this simple.

MBOC7_ptr_ch23_1313-1352.indd 1323 02/12/21 12:22 PM

Virions come in a wide variety of shapes and sizes (Figure 23–11), and although most have relatively small genomes, genome size can vary considerably. A giant virus of amoebae, called *pithovirus*, was recently revived from a 30,000-year-old ice core harvested from permafrost in Siberia and is the largest known virus by physical size, with 1.5-µm-long particles and a double-stranded DNA genome of 610,000 nucleotides. The virions of *poxviruses* are also large: they are 250–350 nm long and enclose a genome of double-stranded DNA of about 270,000 nucleotides. At the other end of the size scale are the virions of *parvovirus*, which are less than 30 nm in diameter and have a single-stranded DNA genome of fewer than 5000 nucleotides.

Viral genomes are packaged in a protein coat, called a **capsid**, which in some viruses is further enclosed by a lipid bilayer membrane, or envelope. The capsid is made of one or several proteins, arranged in regular arrays that often produce structures with either helical symmetry, which results in a cylindrical structure (for example, influenza, measles, and bunyavirus), or icosahedral symmetry (for example, poliovirus and herpesvirus; see Figure 23–11). Other viruses instead produce capsids with more complicated or irregular structures (for example, poxviruses and Ebola virus; see Figure 23–11). A capsid packaged with the viral

Figure 23–11 Examples of viral morphology. As shown, both DNA and RNA viruses vary greatly in both size and shape. Although there is a general correlation between virus physical size and genome size, there are likely to be outliers such as Ebola virus, which has a large physical size but a smaller genome size suggesting a lower degree of genome compaction.

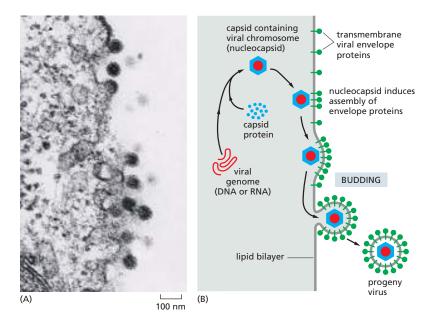

Figure 23–12 Acquisition of a viral envelope. (A) Electron micrograph of an animal cell from which several copies of an enveloped virus (Semliki Forest virus) are budding. (B) Schematic drawing of the envelope assembly and budding processes. The lipid bilayer that surrounds the viral capsid is derived directly from the plasma membrane of the host cell. In contrast, the proteins in this lipid bilayer (shown in green) are encoded by the viral genome. (A, from A. Loewy et al., J. Virol. 69:469–475, 1995. Reproduced with permission from the American Society for Microbiology.)

MBOC7_ptr_ch23_1313-1352.indd 1324 02/12/21 12:22 PM

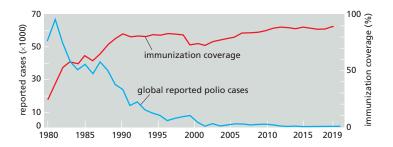

Figure 23–13 Effective control of a viral disease through vaccination. The graph shows the number of cases of poliomyelitis reported per year worldwide (blue line) and the global immunization coverage as a percentage of the human population (red line). As immunization coverage increased, disease incidence decreased. (Figure based on information found at https://polioeradication.org.)

genome is called a *nucleocapsid*. The nucleocapsids of *nonenveloped viruses* usually leave an infected cell by lysing it. For *enveloped viruses*, by contrast, the nucleocapsid is enclosed within a lipid bilayer membrane that the virus acquires in the process of budding from the host-cell plasma membrane, which it does without disrupting the membrane or killing the cell (Figure 23–12).

Because the host cell performs most of the critical steps in viral replication, the identification of effective antiviral drugs that do not harm the host can be difficult. The most effective strategy for containing viral diseases is through vaccination of potential hosts. For example, a highly successful vaccination program eradicated smallpox infection from the planet by 1980. Vaccines effective against *poliovirus*, which causes poliomyelitis and paralysis, have existed since the 1950s, and a more recent global vaccination initiative, begun in 1988, seeks to completely eradicate poliovirus infection. The number of poliomyelitis cases worldwide has declined from an estimated 350,000 in 1988, to 176 in 2019, and there is hope of eradication in the coming years (Figure 23–13).

Summary

Infectious diseases are caused by pathogens, which include viruses, bacteria, and fungi, as well as protozoan and metazoan parasites. All pathogens must have mechanisms for entering their host and for evading immediate destruction by the host. Pathogenic bacteria produce specific virulence factors that mediate their interactions with the host; these proteins change the behavior of host cells in ways that promote the replication and spread of the bacteria. Eukaryotic pathogens such as fungi and protozoan parasites typically pass through several different forms during the course of infection; the ability to switch among these forms is usually required for these pathogens to survive in a host and cause disease. In some cases, such as malaria, parasites must pass sequentially through several host species to complete their life cycles. Unlike bacteria and eukaryotic parasites, viruses have no metabolism of their own and no intrinsic ability to produce the proteins encoded by their DNA or RNA genomes; they rely on subverting the machinery of their host cell.

CELL BIOLOGY OF PATHOGEN INFECTION

The mechanisms through which pathogens cause disease are extremely diverse. Nonetheless, all pathogens must carry out certain common tasks: they must gain access to the host, reach an appropriate growth niche, avoid host defenses, replicate, and exit from the infected host to spread to an uninfected one. In this section, we examine the cell-biological strategies that many pathogens use to accomplish these tasks. We describe how pathogens initially gain access to the host by overcoming epithelial barriers and colonizing epithelia. We then recount how extracellular pathogens disturb host cells without entering them to establish a niche and avoid host defenses. We next cover the myriad ways in which intracellular pathogens, the master manipulators of host-cell biology, enter host cells, reach an appropriate niche in the cytosol or in a membrane-bound compartment, avoid or alter membrane traffic, mobilize the cytoskeleton, manipulate autophagy, and take over metabolism. Finally, we cover how pathogen evolution shapes the immune avoidance and drug resistance.

MBOC7_ptr_ch23_1313-1352.indd 1325 02/12/21 12:22 PM

Pathogens Breach Epithelial Barriers to Infect the Host

The first step in infection is for the pathogen to gain access to the host. A thick covering of skin protects most parts of the human body from the environment. The protective boundaries of some other human tissues (eyes, nasal passages, respiratory tract, mouth, digestive tract, urinary tract, and female genital tract) are less robust. In the lungs and small intestine, for example, the barrier is just a single monolayer of epithelial cells. Nonetheless, all these epithelia serve as barriers to infection.

Wounds in barrier epithelia are one way for pathogens to gain direct access to unoccupied niches within otherwise sterile host tissues. This avenue of entry requires little in the way of pathogen specialization, and some pathogens can cause serious illness if they enter through such wounds. Staphylococci from the skin and nose and streptococci from the throat and mouth are two examples of opportunistic bacterial pathogens that can be residents of the normal microbiota (described in more detail in the final section of this chapter) in certain individuals, yet are also responsible for many serious infections resulting from breaches in epithelial barriers. The emergence of bacterial strains of *Staphylococcus* that are resistant to the antibiotics commonly used for treatment (for example, methicillinresistant *Staphylococcus aureus*, or MRSA, which can cause serious skin and tissue infections) is of particular concern. Papillomaviruses, which cause warts and cervical cancer, also take advantage of breaches in epithelial barriers.

Another efficient way for a pathogen to cross the skin is to catch a ride in the saliva of a biting arthropod. A diverse group of bacteria, viruses, and protozoa has developed the ability to survive in arthropods that they use as *vectors* for transmission to a mammalian host. Many *zoonoses*, a term that refers to diseases spread to humans from other animals, are spread in this way. As discussed earlier, the *Plasmodium* protozoan that causes malaria develops through several forms in its life cycle, including some that are specialized for survival in a human and others that are specialized for survival in a mosquito vector (see Figure 23–9). Viruses that are spread by mosquito bites also cause yellow fever, dengue fever, as well as Zika virus disease—the latter garnered worldwide attention during an epidemic in 2015–2016, and although Zika infection is often asymptomatic in adults, in pregnant women it can cause birth defects in the fetus. These three viruses replicate in both insect cells and mammalian cells, as required for their transmission by an insect vector.

The efficient spread of a pathogen via an insect vector requires that an individual insect consumes a blood meal from an infected host and transfers the pathogen to a nonimmune host. In a few striking cases, the behavior of the insect is altered by the pathogen so that its transmission to a new host is more likely. An example is the bacterium *Yersinia pestis*, which causes bubonic plague. It multiplies in the flea's foregut to form aggregated masses that physically block the digestive tract; during each repeated, but futile, attempt at feeding, some of the bacteria in the foregut are flushed into the bite site, thus transmitting plague to a new host (Figure 23–14).

Pathogens That Colonize an Epithelium Must Overcome Its Protective Mechanisms

Epithelial barriers such as the skin lining of the mouth and large intestine are densely populated by the microbiota, whereas others, including the lining of the lower lung and the bladder, are more sparsely populated. Nevertheless, these epithelial barriers have mechanisms to prevent excessive microbial colonization. A layer of protective mucus covers the respiratory epithelium, and the coordinated beating of motile cilia sweeps the mucus and trapped bacteria up and out of the lung. The epithelial lining of the bladder and the upper gastrointestinal tract also has a thick layer of mucus, and these organs are periodically flushed by urination and by peristalsis, respectively, which washes away microbes.

Pathogens that infect these epithelial surfaces, including pathogenic bacteria and eukaryotic parasites, have evolved specific features to overcome these protective mechanisms. Those that infect the urinary tract, for example, adhere

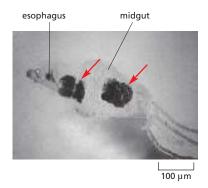

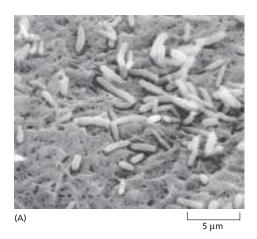

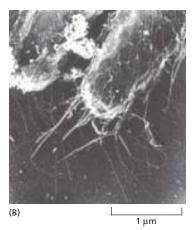

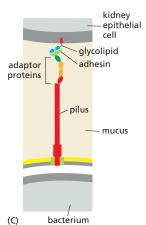

Figure 23-14 Plague bacteria within a flea. This light micrograph shows the digestive tract dissected from a flea that had dined about 2 weeks previously on the blood of an animal infected with the plague bacterium, Yersinia pestis. The bacteria multiplied in the flea gut to produce large cohesive aggregates (red arrows); the bacterial mass on the left is occluding the passage between the esophagus and the midgut. This type of blockage prevents a flea from digesting its blood meals, so that hunger causes it to bite repeatedly. disseminating the infection. (From B.J. Hinnebusch, E.R. Fischer, and T.G. Schwan, J. Infect. Dis. 178:1406-1415, 1998.)

tightly to the epithelial lining via specific **adhesins**, which are proteins or protein complexes that recognize and bind to cell-surface molecules on the epithelium. An important group of adhesins in *E. coli* strains that infect the kidney are components of *pili*—surface projections that can be several micrometers long and thus able to span the thickness of the protective mucus layer; at the tip of each pilus is an adhesin protein that binds tightly to the D-galactose-D-galactose disaccharide on glycolipids on the surface of kidney cells (**Figure 23–15**). Strains of *E. coli* that infect the bladder rather than the kidney express a second kind of pilus with a different adhesin protein that binds to D-mannose-decorated proteins on bladder epithelial cells. It is the specificity of the adhesin proteins on the tips of the two types of pili that is responsible for the bacteria colonizing different parts of the urinary tract.

The epithelial lining of the stomach is an especially hostile environment for microbes. Besides the thick layer of mucus and peristaltic washing, the acidic pH (average pH \approx 2) is lethal to almost all bacteria ingested in food. Yet, the stomach is home to resident microbial species including H. pylori, which persists for life as part of the stomach microbiota of approximately half of all humans on Earth. Although it does not cause disease in most individuals, H. pylori can cause stomach ulcers and cancers. The hypothesis that a persistent bacterial infection could cause stomach ulcers was initially met with skepticism. The young Australian doctor who made the initial discovery finally proved the point: he drank a pure culture of bacteria and developed inflammation of the stomach, which often precedes the development of ulcers. Antibiotics can now effectively cure a patient of recurrent ulcers. H. pylori has several adaptations that allow it to colonize the harsh environment in the stomach (Figure 23–16). One is to use its flagella

Figure 23-15 Pathogenic E. coli in the infected bladder of a mouse. (A) Scanning electron micrograph of uropathogenic E. coli, a common cause of bladder and kidney infections. The bacteria are attached to the surface of epithelial cells lining the infected bladder. (B) A closeup view of one of the bacteria showing the pili on its surface. (C) An E. coli pilus spans the mucus layer and has adaptor proteins on its tip that bind to alveolipids on the surface of kidney cells. (A, from G.E. Soto and S.J. Hultgren, J. Bacteriol. 181:1059-1071, 1999. With permission from the American Society for Microbiology; B, from D.G. Thanassi and S.J. Hultgren. Methods 20:111-126, 2000. With permission from Elsevier.)

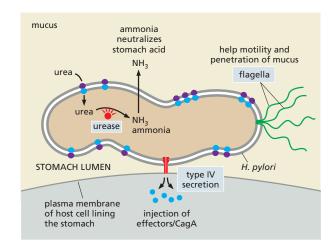

Figure 23-16 H. pylori interaction with epithelial cells in the stomach lining. These bacteria colonize the gastric epithelium by using their flagella to swim through the mucus layer lining the stomach and attach to the surface of epithelial cells. H. pylori produces the enzyme urease, which converts urea obtained from the environment into ammonia that is released and neutralizes acid surrounding the bacterium, raising the pH in its local environment. H. pylori also uses its type IV secretion system to secrete the effector protein CagA, which assists in colonization but also causes chronic disruption of hostcell pathways and prolonged inflammation, which predisposes infected individuals to gastric ulcers and cancer.

MBOC7_ptr_ch23_1313-1352.indd 1327 02/12/21 12:22 PM

for chemotactic motility, allowing it to penetrate mucus and seek out the more neutral pH near the surface of gastric epithelial cells. Another is to produce the enzyme *urease*, which converts urea to ammonia to neutralize the acid in its immediate vicinity.

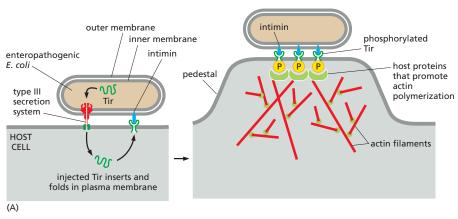

Extracellular Pathogens Use Toxins and Contact-dependent Secretion Systems to Disturb Host Cells Without Entering Them

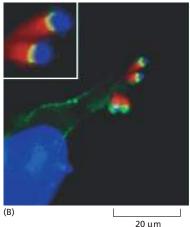

Extracellular pathogens adhere to epithelial and other surfaces without entering their underlying host cells. Many such pathogens exert effects on the host by secreting toxins that diffuse to target cells. For example, Bordetella pertussis, the bacterium that causes whooping cough, colonizes the respiratory epithelium and circumvents the normal mechanism that clears the respiratory tract by expressing adhesins that bind ciliated epithelial cells. The adherent bacteria also produce toxins that eventually kill the ciliated cells, compromising the host's ability to clear the infection. The most familiar of these is pertussis toxin, which, like the cholera toxin discussed earlier (both are shown in Figure 23-6), has an A subunit that ADP-ribosylates the α subunit of the G protein G_i , causing the G protein to remain in the inactive GDP-bound state and preventing it from inhibiting the activity of the host cell's adenylyl cyclase, thereby increasing the production of cyclic AMP. This toxin also interferes with the chemotactic pathway that neutrophils use to seek out and destroy bacteria (see Figures 16-3 and 16-81). B. pertussis colonization of the respiratory tract causes severe coughing, which helps spread the infection.

Other extracellular pathogens use contact-dependent secretion systems to directly inject bacterial effector proteins into the host cells to which they adhere. An example is *H. pylori*, which infects the stomach epithelium as described above. The *H. pylori* genome contains a pathogenicity island (see Figure 23–4A) that encodes a type IV secretion system and the effector protein CagA, which is injected by the secretion system into the host cell (Figure 23–16). CagA helps the bacterium persist in the stomach by affecting cell movement, inducing inflammation, altering host gene expression, changing cell proliferation and apoptosis, and disrupting cell–cell junctions. However, chronic alteration of these pathways is also a predisposing factor for gastric ulcers and cancer.

Another example is enteropathogenic *E. coli* (EPEC), which causes diarrhea and can be lethal to young children. EPEC uses a type III secretion system (see Figure 23–7) to deliver its own special receptor protein (called *Tir*) into the plasma membrane of a host intestinal epithelial cell (**Figure 23–17** and **Movie 23.4**). The extracellular domain of Tir binds to the bacterial surface protein *intimin*, triggering actin polymerization in the host cell that results in the formation of a unique cell-surface protrusion called a *pedestal*; this pushes the tightly adherent bacteria up about 1–5 µm from the host-cell membrane, thereby promoting bacterial

Figure 23-17 Interaction of enteropathogenic E. coli (EPEC) with host intestinal epithelial cells. (A) When EPEC contacts an epithelial cell in the lining of the human gut, it delivers a bacterial protein called Tir into the host cell through a type III secretion system. Tir then inserts into the plasma membrane of the host cell, where it functions as a receptor for the bacterial adhesin protein intimin. Next, a host-cell protein tyrosine kinase phosphorylates the intracellular domain of Tir on tyrosines. Phosphorylated Tir recruits host-cell proteins [including an adaptor protein, a nucleation-promoting factor (NPF), and the Arp2/3 complex] that trigger actin polymerization (see Figure 16-12). Consequently, a branched network of actin filaments assembles underneath the bacterium, forming an actin pedestal (see Movie 23.4). (B) EPEC on a pedestal. In this fluorescence micrograph, the DNA of the EPEC and host cell is labeled in blue, Tir protein is labeled in green, and host-cell actin filaments are labeled in red. The inset shows a close-up view of the two upper bacteria on pedestals. (B, from D. Goosney et al., Annu. Rev. Cell Dev. Biol. 16:173-189, 2000. With permission from Annual Reviews.)

MBOC7_ptr_ch23_1313-1352.indd 1328 02/12/21 12:22 PM

movement along the cell surface by a mechanism described later for the actin-based motility of intracellular pathogens. A similar strategy is used by vaccinia virus (the virus that was used as a vaccine to eradicate smallpox) to form mobile actin-rich membrane extensions, which promote spread of the virus from cell to cell. The study of how EPEC and vaccinia virus promote actin polymerization has been of major importance in understanding how intracellular signaling pathways regulate the cytoskeleton in normal, uninfected cells (discussed in Chapter 16). Although actin mobilization promotes the spread of these pathogens, the symptoms of EPEC infection (severe diarrhea) are caused by the loss of absorptive microvilli and disruption of signaling pathways in epithelial cells, which are triggered by Tir and other secreted bacterial effector proteins.

Intracellular Pathogens Have Mechanisms for Both Entering and Leaving Host Cells

Intracellular pathogens have to cross barriers, adhere to host cells, and also enter host cells to cause disease. These include all viruses and many bacteria and protozoa. Each of these has a preferred niche for replication and survival within host cells. Bacteria and protozoa replicate either in the cytosol or within a membrane-enclosed compartment. While most RNA viruses replicate within the cytosol, most DNA viruses replicate in the nucleus (poxviruses are a notable exception). Life inside a host cell has several advantages. The pathogens are not accessible to *antibodies*, nor are they easy targets for phagocytic cells (discussed in Chapter 24); furthermore, intracellular bacteria and protozoa are bathed in a rich source of nutrients, and viruses have access to the host cell's biosynthetic machinery for their reproduction. This lifestyle, however, requires that the pathogen have mechanisms for entering host cells, for finding a suitable subcellular niche where it can replicate, and for exiting from the infected cell to spread the infection. Below we consider some of the myriad ways that individual intracellular pathogens exploit and modify host-cell biology to satisfy these requirements.

Viruses Bind to Virus Receptors at the Host-Cell Surface

The first step in infection for any intracellular pathogen is to bind to the surface of the host target cell. Viruses accomplish this by the binding of viral surface proteins to **virus receptors**, which are cell-surface proteins that perform various functions in uninfected cells and have been co-opted as binding sites for viral proteins. The first virus receptor identified was an *E. coli* surface protein that is recognized by the bacteriophage lambda; the protein normally functions to transport the sugar maltose from outside the bacterium to the inside where it is used as an energy source. Receptors need not be proteins, however: an envelope protein of herpes simplex virus, for example, binds to heparan sulfate proteoglycans (discussed in Chapter 19) on the surface of certain vertebrate host cells, and simian virus 40 (SV40) binds to a glycolipid. The specificity of virus–receptor interactions often serves as a barrier preventing the spread of a virus from one species to another. Acquiring the ability to bind to a new receptor often requires multiple changes in a virus, but it can be crucial in allowing the cross-species transmission that can result in new disease outbreaks.

Viruses that infect animal cells generally exploit cell-surface receptor molecules that are either ubiquitous [such as angiotensin-converting enzyme 2 (ACE2) used by the coronavirus SARS-CoV-2] or are found uniquely on those cell types in which the virus replicates (such as the neuron-specific proteins used by rabies virus). Although a virus usually uses a single type of host-cell receptor, some viruses use more than one type. An important example is HIV, which requires two types of receptors to enter a host cell. Its primary receptor is CD4, a cell-surface protein on helper T cells and macrophages that is involved in immune recognition (discussed in Chapter 24). It also requires a co-receptor, which is either CCR5 (a receptor for β -chemokines) or CXCR4 (a receptor for α -chemokines), depending on the particular variant of the virus; macrophages are susceptible

MBOC7_ptr_ch23_1313-1352.indd 1329 02/12/21 12:22 PM

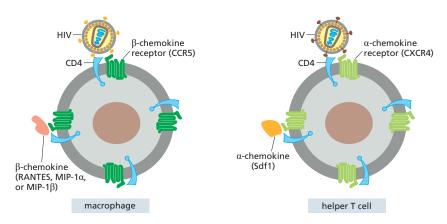

Figure 23–18 Receptor and co-receptors for HIV. All strains of HIV require the CD4 protein as a primary receptor. Early in an infection, most of the viruses use CCR5 as a co-receptor, allowing them to infect macrophages and their precursors, monocytes. As the infection progresses, mutant variants of the virus arise that now use CXCR4 as a co-receptor, enabling them to infect helper T cells efficiently. The natural ligand for the chemokine receptors (Sdf1 for CXCR4; RANTES, MIP-1 α , or MIP-1 β for CCR5) blocks co-receptor function and prevents viral invasion.

only to HIV variants that use CCR5 for entry, whereas helper T cells are most efficiently infected by variants that use CXCR4 (Figure 23–18). The viruses that are found within the first few months after HIV infection almost invariably use CCR5, which explains why individuals that carry an altered *CCR5* gene are less susceptible to HIV infection. In the later stages of infection, viruses often either switch to use CXCR4 or adapt to use both co-receptors through the accumulation of viral mutations. In this way, the virus can change the cell types it infects as the disease progresses. It may seem paradoxical that viruses would infect immune cells, as we might expect that virus binding would trigger an immune response; but invasion of an immune cell can be a useful way for a virus to weaken the immune response and travel around the body to infect other immune cells.

Viruses Enter Host Cells by Membrane Fusion, Pore Formation, or Membrane Disruption

After recognition and attachment to the host-cell surface, viruses must enter into the cell for viral replication to proceed. Entry into host cells requires that viruses overcome different challenges that depend on virus size and structure (see Figure 23–11). **Enveloped viruses** must regulate membrane fusion processes, both to ensure that their membrane envelopes fuse only with the appropriate host-cell membrane and to prevent fusion with one another. Such regulation is achieved by the coronavirus SARS-CoV-2, for example, by requiring both binding of the virus spike protein to the ACE2 receptor and cleaving of the spike protein by a host-cell protease to enable fusion with the host-cell membrane.

Some enveloped viruses, such as HIV, enter the host cell by fusing their envelope membrane at neutral pH with the plasma membrane (Figure 23–19A). In this scenario, binding to receptors or co-receptors usually triggers a conformational change in a viral envelope protein that exposes a normally buried fusion peptide (discussed in Chapter 13).

Most enveloped (and nonenveloped) viruses enter cells by activating signaling pathways in the cell that induce endocytosis, commonly via clathrin-coated pits (see Figure 13–7), leading to internalization into endosomes. Large viruses that do not fit into clathrin-coated vesicles, such as poxviruses, often enter cells by *macropinocytosis*, a process by which membrane ruffles fold over and entrap fluid into macropinosomes (see Figure 13–68).

Once inside endosomes, enveloped viruses such as influenza A virus must fuse their envelope with the endosomal membrane from the luminal side, and they frequently sense the acid environment in the late endosome as a cue to trigger a conformational change in a viral surface protein that exposes a fusion peptide (Figure 23–19B and Movie 23.5). The mechanism of membrane fusion mediated by viral spike glycoproteins has similarities with SNARE-mediated membrane fusion during normal vesicular trafficking (discussed in Chapter 13). The H⁺ pumped into the early endosome also has another effect; it enters the influenza virion through an ion channel in the viral envelope and triggers changes in the

MBOC7_ptr_ch23_1313-1352.indd 1330 02/12/21 12:22 PM

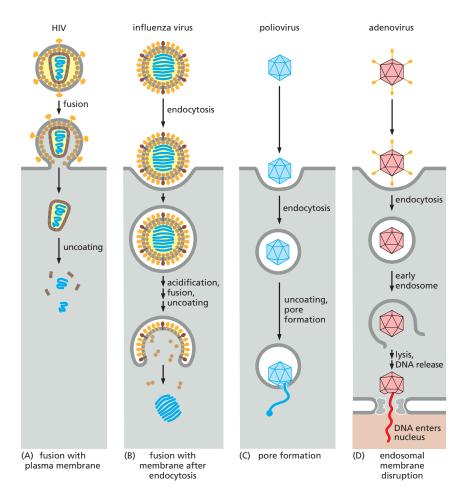

Figure 23-19 Four virus entry strategies that follow virus binding to virus receptors. (A) Some enveloped viruses, such as HIV, fuse directly with the host-cell plasma membrane to release their RNA genome (blue) and capsid proteins (brown) into the cytosol. (B) Other enveloped viruses, such as influenza virus, first bind to cell-surface receptors, triggering receptor-mediated endocytosis: when the endosome acidifies, the virus envelope fuses with the endosomal membrane. releasing the viral RNA genome (blue) and capsid proteins (tan) into the cytosol. (C) Poliovirus, a nonenveloped virus, induces receptor-mediated endocytosis and then forms a pore in the endosomal membrane to extrude its RNA genome (blue) into the cytosol. (D) Adenovirus, another nonenveloped virus, uses a more complicated strategy: it induces receptormediated endocytosis and then disrupts the endosomal membrane, releasing the capsid including its DNA genome into the cytosol. The trimmed-down virus eventually docks onto a nuclear pore and releases its DNA (red) directly into the nucleus where it is transcribed and replicated (see Movie 23.5).

viral capsid. These priming steps allow the capsids to disassemble once released into the cytosol after virus fusion with the late endosomal membrane.

Because they lack a surrounding lipid bilayer, **nonenveloped viruses** enter host cells in a fundamentally different way. Poliovirus binds to a cell-surface receptor, triggering both receptor-mediated endocytosis (see Figure 13–54) and a conformational change in the viral particle. The conformational change exposes a hydrophobic projection on one of the capsid proteins, which inserts into the endosomal membrane to form a pore. The viral RNA genome then enters the cytosol through the pore, leaving the capsid in the endosome (**Figure 23–19C**). *Adenovirus* disrupts the endosomal membrane after it is taken up by receptor-mediated endocytosis, releasing the remainder of the virus into the cytosol. During endosomal trafficking and subsequent transport within the cytosol, adenoviruses undergo multiple uncoating steps, which sequentially remove structural proteins and ready the virus particles to release their DNA into the nucleus through nuclear pore complexes (**Figure 23–19D**).

Bacteria Enter Host Cells by Phagocytosis

Bacteria are much larger than viruses—too large to be taken up either through pores or by receptor-mediated endocytosis. Instead, they enter host cells by phagocytosis, which is a normal function of phagocytes such as neutrophils, macrophages, and dendritic cells (discussed in Chapter 24). These phagocytes patrol the tissues of the body and ingest and destroy microbes; however, some intracellular bacterial pathogens such as *M. tuberculosis* use this to their advantage and have evolved to survive and multiply inside macrophages.

MBOC7_ptr_ch23_1313-1352.indd 1331 02/12/21 12:22 PM

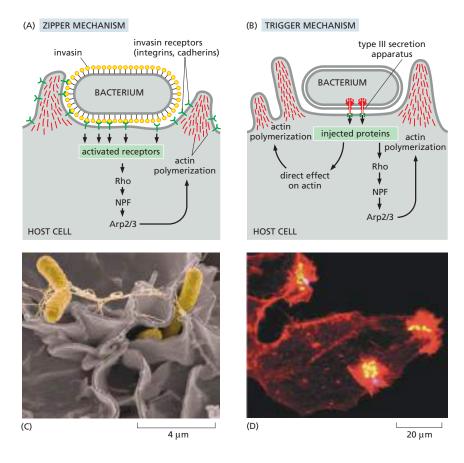

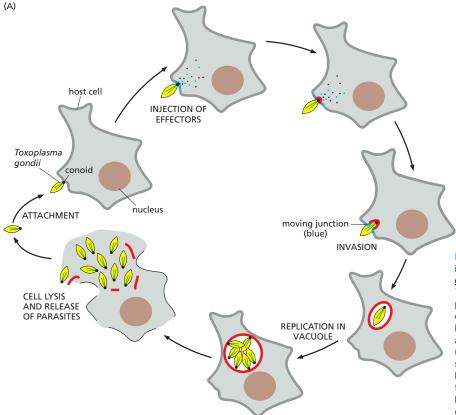

Figure 23-20 Mechanisms used by bacteria to induce phagocytosis by host cells that are normally nonphagocytic. (A) In the zipper mechanism, bacteria express an invasion protein that binds with high affinity to a host-cell receptor, which is often a cell-cell or cell-matrix adhesion protein. (B) In the trigger mechanism, bacteria inject a set of effector molecules into the host-cell cytosol through a type III secretion system called SPI1 (Salmonella pathogenicity island 1), inducing membrane ruffling. Both the zipper and trigger mechanisms cause the polymerization of actin at the site of bacterial attachment by activating Rho family small GTPases and the Arp2/3 complex. (C) A scanning electron micrograph showing Salmonella enterica invasion by the trigger mechanism. Bacteria (pseudocolored yellow) are shown surrounded by a small membrane ruffle. (D) Fluorescence micrograph showing that the large ruffles that engulf the Salmonella bacteria are actin rich. The bacteria are labeled in green and actin filaments in red; because of the color overlap, the bacteria appear vellow. (C. from Rocky Mountain Laboratories, NIAID, NIH; D, from J.E. Galán, Annu. Rev. Cell Dev. Biol. 17:53-86, 2001. With permission from Annual Reviews.)

Some bacterial pathogens can invade host cells that are normally nonphagocytic. One way they do so is by expressing an invasion protein that binds with high affinity to a host-cell receptor, which is often a cell-cell or cell-matrix adhesion protein (discussed in Chapter 19). For example, Yersinia pseudotuberculosis (a bacterium that causes diarrhea and is a close relative of the plague bacterium Y. pestis) expresses a protein called invasin that has an RGD motif that is similar to fibronectin's and which likewise is recognized by host-cell β_1 -integrins (see Figure 19-48). Listeria monocytogenes, which causes a rare but serious form of food poisoning, invades host cells by expressing a protein that binds to the cell-cell adhesion protein E-cadherin (see Figures 19-4 and 19-5). For both these bacterial species, binding of the bacterial invasion proteins to the host-cell adhesion proteins stimulates signaling through members of the Rho family of small GTPases (discussed in Chapter 16). This in turn activates NPFs and the Arp2/3 complex, leading to actin polymerization at the site of bacterial attachment. Actin polymerization, sometimes accompanied by the assembly of a clathrin coat, drives the advancement of the host cell's plasma membrane over the adhesive surface of the microbe, resulting in the phagocytosis of the bacterium—a process known as the *zipper mechanism* of invasion (Figure 23-20A).

A second pathway by which bacteria can invade nonphagocytic cells is known as the *trigger mechanism* (Figure 23–20B). It is used by various pathogens, including the food-borne pathogen *Salmonella enterica* serovar Typhimurium, and it is initiated when the bacterium injects a set of effector molecules into the host-cell cytosol through a type III secretion system (see Figure 23–7). Some of these effector molecules activate Rho family proteins, which in turn stimulate actin polymerization, as just discussed. Other bacterial effector proteins directly interact with host-cell cytoskeletal elements, nucleating and stabilizing actin filaments and causing the rearrangement of actin cross-linking proteins. The overall effect is to cause the formation of ruffles on the surface of the host cell (Figure 23–20C and D),

MBOC7_ptr_ch23_1313-1352.indd 1332 02/12/21 12:23 PM

which fold over and engulf the bacteria by a process that resembles macropinocytosis (see Figure 13–68). The appearance of cells being invaded by use of the trigger mechanism is similar to the ruffling induced by some extracellular growth factors, suggesting that the bacteria hijack normal intracellular signaling pathways.

Intracellular Eukaryotic Parasites Actively Invade Host Cells

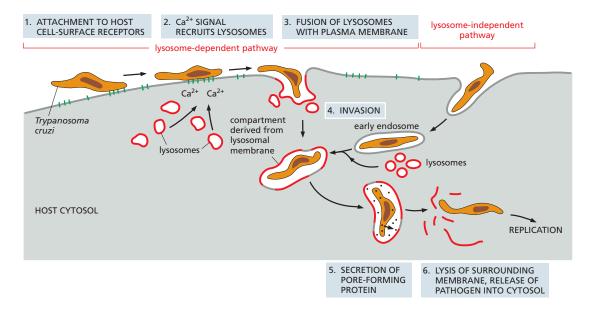

The uptake of viruses and bacteria into host cells is carried out largely by the host, with the pathogen being a relatively passive participant. In contrast, intracellular eukaryotic parasites, which are typically much larger than other types of intracellular pathogens, invade host cells through a variety of complex pathways that usually require energy expenditure by the parasite.

Toxoplasma gondii, a cat parasite that also causes occasional serious human infections in pregnant and immunocompromised individuals, is an example. T. gondii invasion involves the secretion of parasite effector proteins that target host-cell components, as well as the activities of the parasite's own cytoskeleton (Figure 23-21 and Movie 23.6). When this protozoan contacts a host cell, it protrudes an unusual microtubule-based structure called a conoid, which facilitates host-cell entry. At the point of contact, the parasite discharges effector proteins into the host cell from specialized secretory organelles. One of these effector proteins is a receptor that inserts into the host-cell plasma membrane and binds to a parasite surface protein. Other effector proteins form a ring-like moving junction through which the parasite squeezes using forces generated by its own unusual actin and myosin cytoskeleton. Remarkably, as the parasite invades it removes host transmembrane proteins from the surrounding membrane, so that it is eventually protected in a membrane-enclosed compartment, or parasitophorous vacuole, that does not fuse with lysosomes and does not participate in host-cell membrane trafficking processes. The specialized membrane is selectively porous: it allows the parasite to take up small metabolic intermediates and nutrients from

Figure 23-21 The life cycle of the intracellular parasite Toxoplasma gondii. (A) After attachment to a host cell, T. gondii uses its conoid to inject effector proteins that facilitate invasion. These effector proteins include a receptor that binds a parasite surface protein, as well as components of the moving junction (shown in blue) through which the parasite squeezes as it enters the host cell. As the host cell's plasma membrane invaginates. the parasite somehow removes the normal host-cell membrane proteins, so that the compartment (shown in red) does not fuse with lysosomes. After several rounds of replication, the parasite causes the compartment to break down and the host cell to lyse, releasing the progeny parasites to infect other host cells (see Movie 23.6). (B) Light micrograph of T. gondii replicating within a membraneenclosed compartment (a parasitophorous vacuole) in a cultured cell. (B, courtesy of Manuel Camps and John Boothroyd.)

MBOC7_ptr_ch23_1313-1352.indd 1333 02/12/21 12:23 PM

the host cell's cytosol but excludes macromolecules. Malaria parasites invade human red blood cells using a similar mechanism.

The protozoan *Trypanosoma cruzi*, which causes Chagas disease in Mexico and Central and South America, uses two alternative invasion strategies. In a *lysosome-dependent pathway*, the parasite attaches to the host's cell-surface receptors, inducing a local increase in Ca²⁺ in the host cell's cytosol. The Ca²⁺ signal recruits lysosomes to the site of parasite attachment, and the lysosomes fuse with the host cell's plasma membrane, allowing the parasites rapid access to the lysosomal compartment (Figure 23–22). In a *lysosome-independent pathway*, the parasite penetrates the host-cell plasma membrane by inducing the membrane to invaginate, without lysosome recruitment.

Some Intracellular Pathogens Escape from the Phagosome into the Cytosol

All intracellular pathogens, including viruses, bacteria, and eukaryotic parasites, face a similar problem: they must find a compartment within the host cell where they can replicate themselves. After their endocytosis by a host cell, they usually find themselves in an endosomal compartment, which normally would fuse with lysosomes (see Figure 13–67)—a dangerous place for pathogens because of the presence of many antimicrobial factors. To survive, pathogens use a variety of strategies (Figure 23–23). Some escape from the endosomal compartment before such fusion. Others remain in the endosomal compartment but modify it so that

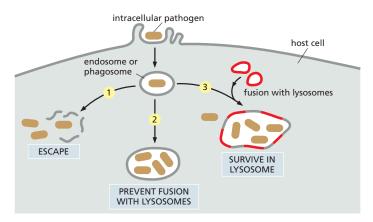

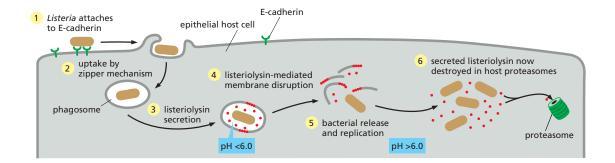

Figure 23-22 The two alternative strategies that Trypanosoma cruzi uses to invade host cells. In the lysosome-dependent pathway (left), T. cruzi recruits host-cell lysosomes to its site of attachment to the host cell. The lysosomes fuse with the invaginating plasma membrane to create an intracellular compartment constructed almost entirely of lysosomal membrane. After a brief stay in the compartment, the parasite secretes a pore-forming protein that disrupts the surrounding membrane, thereby allowing the parasite to escape into the host-cell cytosol and proliferate. In the lysosomeindependent pathway (right), the parasite induces the host plasma membrane to invaginate and pinch off without recruiting lysosomes: then, lysosomes fuse with the endosome prior to the parasite's escape into the cytosol.

Figure 23–23 Choices that an intracellular pathogen faces. After entry into a host cell, generally through phagocytosis into a membrane-enclosed compartment, intracellular pathogens can use one of three strategies to survive and replicate. Pathogens that escape into the cytosol (1) include all viruses, *Trypanosoma cruzi*, *Listeria monocytogenes*, and *Shigella flexneri*. Those that prevent fusion with lysosomes (2) include *Mycobacterium tuberculosis*, *Legionella pneumophila*, and *Toxoplasma gondii*. Those that survive in the lysosome (3) include *Salmonella enterica*, *Coxiella burnetii*, and *Leishmania*.

MBOC7_ptr_ch23_1313-1352.indd 1334 02/12/21 12:23 PM

it no longer fuses with lysosomes. Still others have evolved to weather the harsh conditions in the lysosome.

Trypanosoma cruzi uses the escape strategy by secreting a pore-forming toxin that lyses the lysosome membrane, releasing the parasite into the host cell's cytosol (see Figure 23–22). The bacterium *Listeria monocytogenes* uses a similar strategy. After phagocytosis by the zipper mechanism, it secretes a protein called *listeriolysin O*, which disrupts the phagosomal membrane, releasing the bacteria into the cytosol (Figure 23–24).

Many Pathogens Alter Membrane Traffic in the Host Cell to Survive and Replicate

Intracellular pathogens that remain in membrane-bound compartments of the host cell after invasion (see Figure 23–23) often alter these compartments to reduce their exposure to antimicrobial molecules and allow for pathogen survival and reproduction. To do so, these pathogens must alter membrane (vesicular) traffic, for example by slowing or preventing normal fusing of endosomes with lysosomes (Figure 23–25).

Different pathogens have distinct strategies for altering host-cell membrane traffic. *M. tuberculosis* prevents the maturation of the early endosome that contains the bacteria, so the endosome never acidifies or acquires the other characteristics of a late endosome or lysosome. Phagosomes containing *Salmonella enterica*, in contrast, acidify and acquire markers of late endosomes and lysosomes, but the bacteria slow the process of phagosomal maturation. They do so by injecting effector proteins through a second type III secretion system, distinct from that

Figure 23-24 Escape of Listeria monocytogenes by selective destruction of the phagosomal membrane. The bacterium attaches to E-cadherin or other receptors on the surface of host epithelial cells and induces its own uptake by the zipper mechanism (see Figure 23-20A). Within the phagosome, the bacterium secretes the protein listeriolysin O, which is activated at pH <6 and forms oligomers in the phagosome membrane, thereby creating large pores and eventually disrupting the membrane. Once in the host-cell cytosol, the bacteria begin to replicate and continue to secrete listeriolysin O; because the pH in the cytosol is >6, however, the listeriolysin O there is less active and is also rapidly degraded by proteasomes. Thus, the host cell's plasma membrane remains intact.

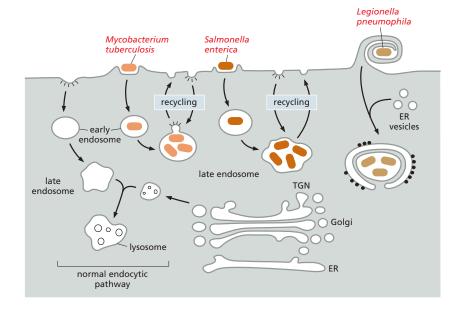

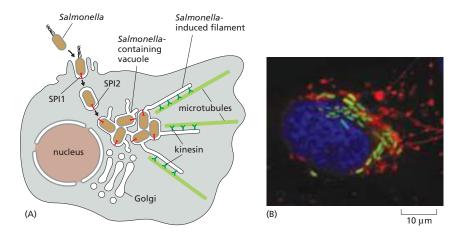

Figure 23-25 Modifications of membrane traffic in host cells by bacterial pathogens to slow or prevent normal fusing of endosomes with lysosomes. Intracellular bacterial pathogens, including Mycobacterium tuberculosis, Salmonella enterica, and Legionella pneumophila, all replicate in membrane-enclosed compartments, but the compartments differ. M. tuberculosis remains in a compartment that has early endosomal markers and continues to communicate with the plasma membrane via transport vesicles. S. enterica replicates in a compartment that has late endosomal markers. L. pneumophila replicates in an unusual compartment that is wrapped in rough endoplasmic reticulum (ER) membrane and communicates with the ER via transport vesicles. TGN = trans Golgi network.

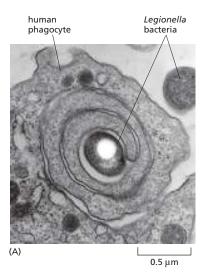

MBOC7_ptr_ch23_1313-1352.indd 1335 02/12/21 12:23 PM

involved in invasion by the trigger mechanism (see Figure 23–20). Some of these bacterial effectors activate host kinesin motor proteins to pull membrane tubules outward from the phagosome along cytoplasmic microtubules, forming a specialized compartment called the *Salmonella*-containing vacuole (Figure 23–26).

Other bacteria seem to find shelter in intracellular compartments that are distinct from those of the usual endocytic system. One example is *Legionella pneumophila*, which was first recognized as a human pathogen in 1976, when it was found to be the cause of a type of pneumonia known as **Legionnaires' disease**. *L. pneumophila* is normally a parasite of freshwater amoebae but can be spread to humans by central air-conditioning systems, which harbor infected amoebae and produce microdroplets of water that are easily inhaled. Once in the lung, the bacteria are engulfed by macrophages by an unusual process called coiling phagocytosis (**Figure 23–27A**). *L. pneumophila* uses a type IV secretion system to inject effector proteins into the phagocyte that modulate the accumulation of phosphoinositides and the activity of proteins that regulate vesicular traffic, including SNARE proteins and Rab and Arf family small GTPases (discussed in Chapter 13). The effector proteins thereby prevent the phagosome from fusing with endosomes and promote its fusion with the endoplasmic reticulum, converting the phagosome into a compartment that resembles the rough endoplasmic reticulum (**Figure 23–27B**).

Viruses can also alter membrane traffic in the host cell. Many enveloped viruses, including the coronavirus SARS-CoV-2, make use of host-cell membranes to acquire their own envelope membrane. In the simplest cases, virally encoded glycoproteins are inserted into the endoplasmic reticulum membrane and follow

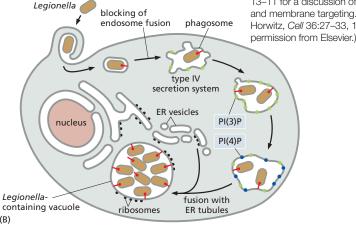

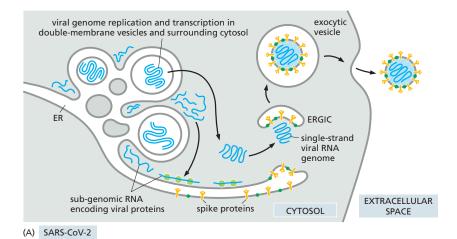

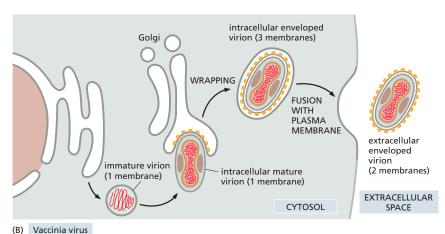

Figure 23-26 Salmonella enterica residing in a modified phagosomal compartment called the Salmonella-containing vacuole. These bacteria invade the host cell using one of two type III secretion systems to inject effector proteins that induce the trigger mechanism of microbe entry illustrated in Figure 23-20B. (A) After its engulfment into a phagosome, the bacterium inactivates the first type III secretion system and activates the second type III secretion system to inject different effector proteins, which remodel the phagosome into the specialized Salmonella-containing vacuole. One of the injected effector proteins activates host kinesin motor proteins to pull membrane tubules outward toward the plus ends of the microtubules (see Figure 16-53), forming a structure with an unusual tubulated shape that is of unknown functional significance. (B) Fluorescence micrograph showing S. enterica in a Salmonella-containing vacuole. The bacteria are stained green the microtubules red, and the nucleus blue. (B, courtesy of Stephane Meresse.)

Figure 23-27 Legionella pneumophila residing in a compartment with characteristics similar to those of the rough endoplasmic reticulum (ER). (A) Electron micrograph showing the unusual coiled structure that the Legionella pneumophila bacterium induces on the surface of a phagocyte during the invasion process. Some other pathogens, including the bacterium Borrelia burgdorferi (which causes Lyme disease), the eukaryotic pathogen Leishmania, and the yeast Candida albicans, can also invade cells using this type of coiling phagocytosis. (B) After invasion, L. pneumophila uses its type IV secretion system to secrete effector proteins that block phagosomeendosome fusion and phagosome maturation. It also secretes effector proteins that promote phosphoinositide conversion from PI(3)P to PI(4)P and the fusion of the phagosome with ER-derived vesicles, thereby converting the characteristics of the Legionella-containing vacuole from those of an endosome to those of the rough ER. See Figures 13-10 and 13-11 for a discussion of phosphoinositides and membrane targeting. (A, from M.A. Horwitz, Cell 36:27-33, 1984. With

the secretory pathway through the Golgi apparatus to the plasma membrane; the viral capsid proteins and genome assemble into nucleocapsids, which acquire their envelope as they bud off from the plasma membrane (see Figure 23–12). The process for SARS-CoV-2 is more complicated, as this virus induces the formation of convoluted double-membrane vesicles derived from the endoplasmic reticulum, which house its genome replication factories (Figure 23–28A). These

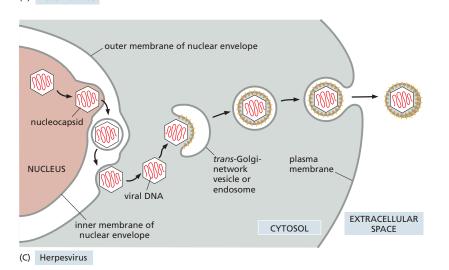

Figure 23–28 Complex strategies for viral envelope acquisition. (A) The coronavirus SARS-CoV-2 replicates its positive sense RNA genome in double membrane vesicles associated with the endoplasmic reticulum (ER). Viral genomes are released into the cytoplasm by a poorly understood mechanism that may involve passage through pores in the double membrane. Transcription of subgenomic RNAs encoding viral structural proteins occurs in the surrounding cytosol. Translation of transmembrane viral proteins, including the spike protein, occurs on the ER. These proteins are then trafficked from the ER to the ER Golgi intermediate compartment (ERGIC), where the singlestranded viral RNA genome associates with viral proteins to drive formation of virus particles in the lumen of exocytic vesicles. When these vesicles fuse with the plasma membrane, viruses are released from the cell surface. (B) Vaccinia virus assembles in "replication factories" in the cytosol, far away from the plasma membrane. The immature virion, surrounded by a single membrane, then acquires two additional membranes from the Golgi apparatus by a poorly understood wrapping mechanism, to form the intracellular enveloped virion. After fusion of the outermost membrane with the host-cell plasma membrane, the extracellular enveloped virion is released from the host cell. (C) Herpesvirus nucleocapsids assemble in the nucleus and then bud through the inner nuclear membrane into the space between the inner and outer nuclear membranes. acquiring a membrane coat. The virus particles then apparently lose this coat when they fuse with the endoplasmic reticulum membrane to escape into the cytosol. Subsequently, the nucleocapsids travel through the Golgi apparatus, acquiring two new membrane coats in the process. The virus then buds from the cell surface with a single membrane when its outer membrane fuses with the plasma membrane.

MBOC7_ptr_ch23_1313-1352.indd 1337 02/12/21 12:23 PM

may concentrate replication intermediates and sequester such intermediates from innate immune sensor molecules (see Chapter 24). Viral genomes are then released into the cytoplasm by an unknown mechanism and interact with viral structural proteins in the endoplasmic reticulum Golgi intermediate compartment (ERGIC), acquiring two new lipid bilayer membrane coats. Subsequent fusion of virus-containing exocytic vesicles with the plasma membrane leads to the release of viruses with a single membrane envelope. DNA viruses such as herpesviruses and vaccinia virus also alter membrane traffic and acquire their lipid envelopes in complex ways (Figure 23–28B and C).

Bacteria and Viruses Use the Host-Cell Cytoskeleton for Intracellular Movement

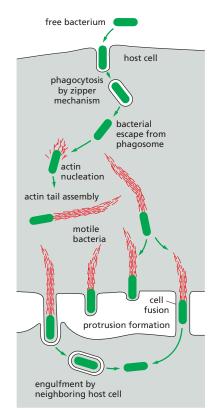

As mentioned earlier, many pathogens escape into the cytosol rather than remaining in a membrane-enclosed compartment. The cytosol of mammalian cells is extremely viscous, as it is crowded with protein complexes, organelles, and cytoskeletal filaments, all of which inhibit the diffusion of particles the size of a bacterium or a viral nucleocapsid. Thus, to reach a particular region of the host cell, a pathogen must be actively moved there. As with transport of intracellular organelles, pathogens generally use the host cell's cytoskeleton for their active movement.

Several pathogens have adopted a remarkable mechanism that depends on actin polymerization for their movement. These include the human bacterial pathogens Listeria monocytogenes, Shigella flexneri, Rickettsia rickettsii (which causes Rocky Mountain spotted fever), and Burkholderia pseudomallei (which causes melioidosis, a disease characterized by severe respiratory symptoms), as well as Ebola virus and the insect virus baculovirus. All induce the nucleation and assembly of host-cell actin filaments at one pole of the microbe. The growing filaments generate force and push the pathogens through the cytosol at rates of up to 1 μ m/min (Figure 23-29). New filaments form at the rear of each pathogen and are left behind like a rocket trail as the microbe advances; the filaments depolymerize within a minute or so as they encounter depolymerizing factors in the cytosol. For L. monocytogenes and S. flexneri, the moving bacteria collide with the plasma membrane and move outward, inducing the formation of long, thin, host-cell protrusions with the bacteria at their tip. A neighboring cell often engulfs these projections, allowing the bacteria to enter the neighbor's cytoplasm without exposure to the extracellular environment, thereby avoiding antibodies produced by the host's adaptive immune system. For B. pseudomallei, movement and collision of the bacteria with the plasma membrane promote cell-cell fusion, which serves a similar purpose of immune avoidance while aiding continued bacterial replication.

The molecular mechanisms of pathogen-induced actin assembly differ for the different pathogens, suggesting that they evolved independently (Figure 23–30). *L. monocytogenes* and baculovirus produce proteins that directly bind to and activate the Arp2/3 complex to initiate the formation of an actin tail and movement (see Figure 16–17). *S. flexneri* produces an unrelated surface protein that binds to and activates the NPF N-WASp, which then activates the Arp2/3 complex. *Rickettsia* and *Burkholderia* species produce proteins that directly polymerize actin, for example by mimicking the function of host proteins such as formins (see Figure 16–13).

Many viral pathogens rely primarily on microtubule-dependent motor proteins, rather than actin polymerization, to move within the host-cell cytosol,

Figure 23–29 The actin-based movement of bacterial pathogens within and between host cells. After invasion, bacterial pathogens such as *L. monocytogenes*, *S. flexneri*, *R. rickettsii*, and *B. pseudomallei* induce the assembly of actin-rich tails in the host-cell cytoplasm, which drives rapid bacterial movement. For most of these pathogens, the moving bacteria collide with the host-cell plasma membrane to form membrane-covered protrusions, which are engulfed by neighboring cells—spreading the infection from cell to cell. In contrast, for *B. pseudomallei*, collision with the plasma membrane promotes cell—cell fusion, creating a conduit through which bacteria can invade neighboring cells (Movie 23.7).

MBOC7_ptr_ch23_1313-1352.indd 1338 02/12/21 12:23 PM

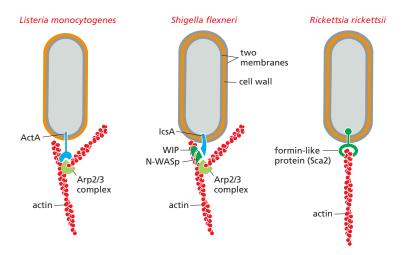

Figure 23-30 Molecular mechanisms for actin nucleation by various bacterial pathogens. L. monocytogenes and S. flexneri induce actin nucleation by recruiting and activating the host Arp2/3 complex (see Figure 16-12), although each uses a different recruitment strategy: L. monocytogenes expresses a surface protein, ActA, that directly binds to and activates the Arp2/3 complex; S. flexneri expresses a surface protein. IcsA (unrelated to ActA), that recruits the host NPF N-WASp, which in turn recruits the Arp2/3 complex, along with other host proteins, including WIP (WASp-interacting protein). R. rickettsii uses an entirely different strategy: it expresses a surface protein, Sca2, that directly nucleates actin polymerization by mimicking the activity of host formin proteins.

taking advantage of the inherent polarity of microtubules to enable directed longrange movements. Important examples are viruses that infect neurons, such as the neurotropic alphaherpesviruses, which include the virus that causes chickenpox (Figure 23-31). These virions enter sensory neurons at the tips of their axons and move by retrograde ("backward") axonal transport along the axon toward the microtubule minus end. The transport is mediated by attachment of viral capsid proteins to the motor protein dynein. These viruses then establish either productive or latent infection in the nuclei of neurons of the peripheral nervous system. After replication or reactivation, virions are then carried by anterograde ("forward") axonal transport along microtubules to the axon tips, with the transport being mediated by the attachment of a different viral capsid protein to a kinesin motor protein. Many other viruses associate with either dynein or kinesin motor proteins to move along microtubules at some stage in their replication, and some even alter the dynamic assembly and disassembly of microtubules. As microtubules serve as oriented tracks for vesicular transport in all cell types, not just neurons, it is not surprising that many viruses have independently evolved the ability to exploit them for their own transport.

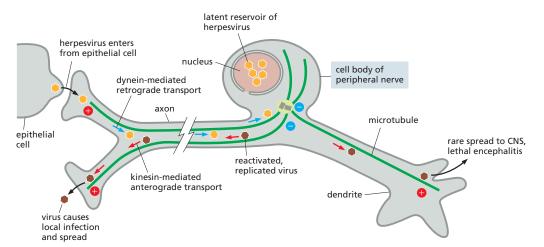

Figure 23-31 Microtubule-based movement of viruses. Neurotropic alphaherpesviruses infect peripheral nerve cells from neighboring epithelial cells in the skin. Virus particles are then transported along microtubules in the nerve-cell axon toward the microtubule minus ends in the cell body (retrograde transport), a process that is driven by dynein motor proteins. Upon reaching the cell body, viruses can establish a latent reservoir in the nucleus. After reactivation (for example, following stress or immune suppression) or upon replication, virus particles are again transported along microtubules in the axon, this time toward the microtubule plus ends at the nerve terminal (anterograde transport), where they are released to enable local reinfection and spread. In rare instances, viruses can instead spread to the central nervous system (CNS), which can cause encephalitis.

MBOC7_ptr_ch23_1313-1352.indd 1339 02/12/21 12:23 PM

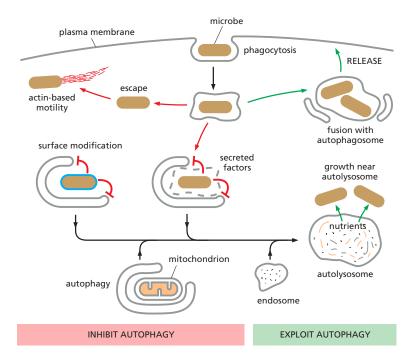

Figure 23–32 Microbial manipulation of autophagy. Microbial pathogens have various mechanisms for avoiding antimicrobial autophagy (red lines), which include modifying their surface to avoid autophagy initiation or secreting factors and initiating actin-based motility to avoid enclosure in autophagosomes. Microbes can also exploit autophagy (green arrows), for example by recruiting and fusing with autophagosomes to gain nutrients and lipids or by growing near autolysosomes for nutrient acquisition.

Many Microbes Manipulate Autophagy

Whether a microbe lives within the cytosol or inside a membrane-bound compartment, it must contend with the host cell's defenses, which include the *autophagy* pathway (see Figure 13–67). Autophagy is the process through which organelles or other cytoplasmic cargoes become surrounded by a double-membrane autophagosome that fuses with lysosomes to promote degradation (see Figure 13–71). It has recently become apparent that targeting of intracellular microbes for destruction by autophagy is an important pathway in the innate immune defense against infection (see Chapter 24). When this occurs, the process is called *antimicrobial autophagy*, or *xenophagy*. Not surprisingly, pathogens have evolved various strategies either to avoid antimicrobial autophagy or to manipulate autophagy pathways for their own benefit (Figure 23–32).

One strategy for avoiding antimicrobial autophagy is to deploy a protective shield that prevents detection of the microbe by the host cell. *Francisella tularensis*, which causes the zoonosis tularemia, or rabbit fever, uses this scheme. Once it escapes from the phagosome into the cytosol, it shields its surface by producing a variant of its outer membrane LPS that is not recognized by the host cell's autophagy initiation machinery. Other strategies to subvert autophagy, employed by *L. monocytogenes*, are to secrete bacterial enzymes and harness actin-based movement, both of which enable bacteria to avoid enclosure by autophagosomes. On the other hand, some pathogens take the opposite strategy of activating and then exploiting autophagy. *Coxiella burnetii*, which causes the zoonosis Q fever, replicates in a membrane-bound compartment that recruits and fuses with autophagosomes to deliver nutrients as well as lipids for compartment expansion. Poliovirus makes use of autophagy for the alternative effect of promoting virus trafficking to the plasma membrane and release from the host cell.

Viruses Can Take Over the Metabolism of the Host Cell

Viruses use basic host-cell machinery for most aspects of their reproduction: they depend on host-cell ribosomes to produce their proteins, and many use host-cell DNA and RNA polymerases for their own replication and transcription. Many viruses encode proteins that modify the host transcription or translation apparatus to favor the synthesis of viral RNAs and proteins over those of the host

MBOC7_ptr_ch23_1313-1352.indd 1340 02/12/21 12:23 PM

cell, shifting the synthetic capacity of the cell toward the production of new virus particles. Poliovirus, for example, encodes a protease that specifically cleaves the TATA-binding component of TFIID (see Figure 6–15), shutting off transcription of most of the host cell's protein-coding genes. Influenza virus produces a protein that blocks both the splicing and the polyadenylation of host-cell RNA transcripts, preventing their export into the cytosol (see Figure 6–39), but does not affect viral RNA transcripts.

Viruses also alter translation by the host. Translation initiation for most host-cell mRNAs depends on recognition of their 5' cap by translation initiation factors (see Figure 6–40). This initiation process is often inhibited during viral infection, so that the host-cell ribosomes can be used more efficiently for the synthesis of viral proteins. Some viral genomes encode endonucleases that cleave off the 5' cap from host-cell mRNAs; some go even further by using the liberated 5' caps as primers to synthesize viral mRNAs, a process called *cap snatching*. Several other viral RNA genomes encode proteases that cleave certain translation initiation factors; these viruses rely on 5' cap-independent translation of their own RNA, using internal ribosome entry sites (IRESs; see Figure 7–72).

DNA viruses that replicate in the nucleus use host-cell DNA polymerase to replicate their genome. Because DNA polymerase is expressed at high levels only during S phase of the cell cycle, adenovirus has evolved a mechanism to drive the host cell into S phase, so that the cell produces large amounts of active DNA polymerase, which then replicates the viral genome. To accomplish this, the adenovirus genome also encodes proteins that inactivate both Rb (see Figure 17–59) and p53 (see Figure 17–60), two key suppressors of cell-cycle progression. As might be expected for any mechanism that encourages unregulated DNA replication, these viruses can promote, under some circumstances, the development of cancer.

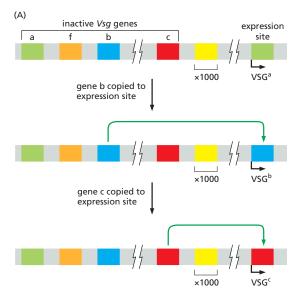

Animal RNA viruses encode their own replication proteins because most animals lack polymerase enzymes that use RNA as a template (such as the RNA-dependent RNA polymerases used in RNA interference; see Chapter 7). For RNA viruses with a single-stranded genome, the replication strategy depends on whether the RNA is a positive [+] strand, which contains translatable information like mRNA does, or a complementary negative [-] strand. When the RNA genome is a positive [+] strand (such as for the coronavirus SARS-CoV-2), the incoming viral genome is translated to produce the viral RNA polymerase and viral proteins; the viral polymerase is then used to replicate the viral RNA and to generate mRNAs for the production of more viral proteins. For viruses with a negative [-] strand RNA genome (such as influenza and measles virus), an RNA polymerase enzyme is packaged as a structural protein of the incoming viral capsids.

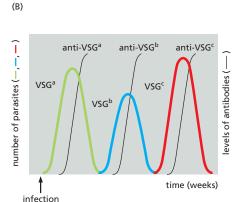

Retroviruses such as HIV, which have a positive [+] strand RNA genome, are a special class of RNA virus because they carry with them a viral *reverse transcriptase* enzyme. After entry to the host cell, the reverse transcriptase uses the viral RNA genome as a template to synthesize a double-stranded DNA copy of the viral genome, which enters into the nucleus and integrates into the host cell's chromosomes (see Figure 5–61). It is later transcribed by the cell's DNA-dependent RNA polymerase to produce viral genomes and proteins.

Pathogens Can Evolve Rapidly by Antigenic Variation

The complexity and specificity of the interplay between pathogens and their host cells might suggest that virulence would be difficult to acquire by random mutation. Yet, new pathogens are constantly emerging, and old pathogens are constantly changing in ways that make familiar infections more difficult to prevent or treat. Pathogens have two advantages that enable them to evolve rapidly. First, they replicate very quickly, providing a great deal of mutational variation for natural selection to work with. Whereas humans and chimpanzees have acquired a 2% difference in genome sequences over about 8 million years of divergent evolution, poliovirus manages a 2% change in its genome in 5 days—about the time it takes the virus to pass from the human mouth to the gut. Second, selective pressures act rapidly on this genetic variation. The host's adaptive immune

MBOC7_ptr_ch23_1313-1352.indd 1341 02/12/21 12:23 PM

system and modern microbicidal drugs, both of which destroy pathogens that fail to change, are the main sources of these selective pressures.

An example of an adaptation to the selective pressure imposed by the adaptive immune system is the phenomenon of antigenic variation. An important adaptive immune response against many pathogens is the host's production of antibodies that recognize specific molecules (antigens) on the pathogen's surface (discussed in Chapter 24). Many pathogens have evolved mechanisms that change these antigens during the course of an infection, enabling them to stay one step ahead of the antibody response. Some eukaryotic parasites, for example, undergo programmed rearrangements of the genes encoding their surface antigens (Figure 23-33). A striking example occurs in Trypanosoma brucei, a protozoan parasite that causes African sleeping sickness and is spread by tsetse flies. (T. brucei is a relative of T. cruzi—see Figure 23-22—but it replicates extracellularly rather than intracellularly.) T. brucei is covered with a single type of glycoprotein, called variant-specific glycoprotein (VSG), which elicits in the host an antibody response that rapidly clears most of the parasites. The trypanosome genome, however, contains about 1000 different inactive Vsg genes (or pseudogenes), each encoding a VSG with a distinct amino acid sequence. Only one Vsg gene is expressed at any one time, from one of approximately 20 possible expression sites in the genome. Gene rearrangements that copy different inactive Vsg genes into expression sites repeatedly change the VSG protein displayed on the surface of the pathogen. In this way, a few trypanosomes with an altered VSG escape the initial antibody-mediated clearance, replicate, and cause the disease to recur, leading to a chronic cyclic infection.

Bacterial pathogens can also rapidly change their surface antigens. Species of the genus *Neisseria* are champions at this. These Gram-negative cocci can cause sexually transmitted disease, in the case of *Neisseria gonorrhoeae*, or meningitis, in the case of *Neisseria meningitidis*. They undergo genetic recombination very similar to that just described for eukaryotic pathogens, which enables them to vary the pilin protein they use to attach to host cells. By inserting one of the multiple silent copies of variant *pilin* genes into a single expression locus, they can express many slightly different versions of the protein and repeatedly change the amino acid sequence over time. *Neisseria* bacteria are also extremely adept at taking up DNA from their environment by natural transformation and incorporating it into their genomes, further contributing to their extraordinary variability. The end result of this considerable variation is a plethora of different surface protein compositions with which to bewilder the host adaptive immune system. It is therefore not surprising that it has been difficult to develop an effective vaccine against *N. gonorrhoeae* infections, although there are now several that protect

Figure 23-33 Antigenic variation in trypanosomes. (A) There are about 1000 distinct Vsg genes in Trypanosoma brucei, and they are expressed one at a time from approximately 20 expression sites in the genome. To be expressed, an inactive gene is copied and the copy is moved into an expression site through DNA recombination. Each Vsg gene encodes a different surface protein (antigen). These switching events allow the trypanosome to repeatedly change the surface antigen it expresses. (B) A person infected with trypanosomes expressing VSGa mounts an antibody response against this particular antigen, which clears most of the VSGaexpressing parasites. However, a few of the trypanosomes will have spontaneously switched to expression of VSGb, which can now proliferate until anti-VSGb antibodies are made. By that time, however, some parasites will have switched to VSGc, and so the cycle continues.

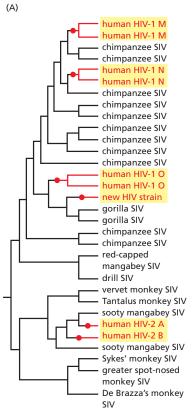

MBOC7_ptr_ch23_1313-1352.indd 1342 02/12/21 12:23 PM

against N. meningitidis, due to the much smaller number of variants of its surface polysaccharide capsule.

Error-prone Replication Dominates Viral Evolution

In contrast to the DNA rearrangements in bacteria and parasites, viruses rely on an error-prone replication mechanism for antigenic variation. Retroviral genomes, for example, acquire on average one point mutation every replication cycle, because the viral reverse transcriptase (see Figure 5-61) needed to produce DNA from the viral RNA genome lacks the proofreading activity of DNA polymerases. A typical, untreated HIV infection may eventually produce HIV genomes with every possible point mutation. By a process of mutation and selection within each host, most HIV viruses change over time—from a form that is most efficient at infecting macrophages to one more efficient at infecting T cells, as described earlier (see Figure 23-18). Similarly, once a patient is treated with an antiviral drug, the viral genome can quickly mutate and be selected for its resistance to the drug. Remarkably, only about one-third of the nucleotide positions in the coding sequence of the viral genome are invariant (because mutations at these positions would be detrimental to the virus), and nucleotide sequences in some parts of the genome, such as the Env gene (see Figure 7-66), can differ by as much as 30% from one HIV isolate to another. This extraordinary genomic plasticity greatly complicates attempts to develop vaccines against HIV.

The rapid evolution of HIV by error-prone replication has also led to the swift emergence and spread of new HIV strains. Nucleotide sequence comparisons between various strains of HIV and the very similar simian immunodeficiency virus (SIV) isolated from a variety of monkey species suggest that the most virulent type of HIV, HIV-1, may have jumped from primates to humans multiple independent times, starting as long ago as 1908 (Figure 23–34A). Sequence

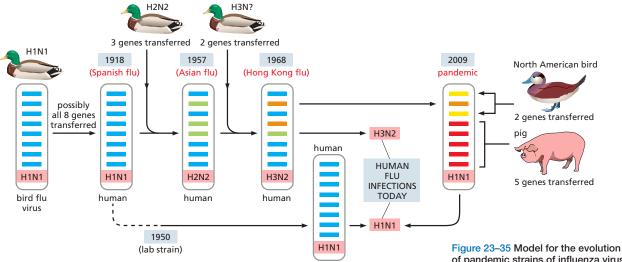

Figure 23–34 Diversification of HIV-1, HIV-2, and related strains of SIV. (A) HIV comprises different viral families, all descended from SIV (simian immunodeficiency virus). On three separate occasions, SIV was passed from a chimpanzee to a human, resulting in three HIV-1 groups: major (M), outlier (O), and non-M non-O (N). HIV-1 M is the most common and is primarily responsible for the global AIDS epidemic. On two separate occasions, SIV was passed from a sooty mangabey monkey to a human, resulting in the two pandemic HIV-2 groups A and B. In 2009, a new strain of HIV was discovered that appears to have resulted from SIV passage from a gorilla to a human. (B) Geography and timing of HIV-1 spread from Africa to other parts of the world.

MBOC7_ptr_ch23_1313-1352.indd 1343 02/12/21 12:23 PM

1977

(Russian flu)

comparisons between human HIV strains has further enabled a reconstruction of the evolutionary and geographic history of the current pandemic of HIV-1 group M (major). The pandemic strain is thought to have originated in Kinshasa, Democratic Republic of the Congo, in the 1920s. Virus spread increased in Africa in the 1960s due to changing sexual behaviors and emerging transportation networks (Figure 23–34B). It then crossed the Atlantic to Haiti in the late 1960s and spread to New York and other locations in the United States in the 1970s, eventually giving rise to a worldwide pandemic.

An important exception to the rule that error-prone replication dominates viral evolution is the influenza viruses. Although they accumulate point mutations as they replicate, they differ from other viruses in that their genome consists of several (usually eight) strands of RNA, each of which codes for different proteins. When two strains of influenza infect the same host, the RNA strands of the two strains can reassort to form a new type of influenza virus. In normal years, influenza is a mild disease in healthy adults, although it can be life-threatening in the very young and very old. Different influenza strains infect fowl such as ducks and chickens, but only a subset of these strains can infect humans, and transmission from fowl to humans is rare. In 1918, however, a particularly virulent variant of avian influenza crossed the species barrier to infect humans, triggering the catastrophic pandemic of 1918 called the Spanish flu, which killed 20-50 million people worldwide. Subsequent influenza pandemics have been triggered by genome reassortment, in which a new RNA segment from an avian form of the virus replaced one or more of the viral RNA segments from the human form (Figure 23-35). In 2009, a new H1N1 swine virus emerged that derived genes from pig, avian, and human influenza viruses. Such recombination events allowed the new virus to replicate rapidly and spread through an immunologically naïve human population. Generally, within 2 or 3 years, the human population develops immunity to a new recombinant strain of virus, and the infection rate drops to a steady-state level. Because the recombination events are unpredictable, it is not possible to know when the next influenza pandemic will occur or how severe it might be.

Drug-resistant Pathogens Are a Growing Problem

The development of drugs that cure rather than prevent infections has had a major impact on human health. **Antibiotics**, which are either bactericidal (they kill bacteria) or bacteriostatic (they inhibit bacterial growth without killing), are the most successful class of such drugs. Penicillin was one of the first antibiotics

of pandemic strains of influenza virus by recombination. Influenza A virus is a natural pathogen of birds, particularly waterfowl, and it is always present in wild bird populations. In 1918, a particularly virulent form of the virus crossed the species barrier from birds to humans and caused a devastating worldwide epidemic. This strain was designated H1N1, referring to the specific forms of its main antigens. hemagglutinin (H) and neuraminidase (N). Changes in the virus, rendering it less virulent, and the rise of adaptive immunity in the human population prevented the pandemic from continuing in subsequent seasons, although H1N1 influenza strains continued to cause serious disease every year in very young and very old people. In 1957, a new pandemic arose when three genes were replaced by equivalent genes from a different avian virus (green bars); the new strain (designated H2N2) was not effectively cleared by antibodies in people who had previously contracted only H1N1 forms of influenza. In 1968, another pandemic was triggered when two genes were replaced from yet another avian virus; the new virus was designated H3N2. In 1977, there was a resurgence of H1N1 influenza, which had previously been almost completely replaced by the N2 strains. Molecular sequence information suggests that this minor pandemic may have been caused by an accidental release of an influenza strain that had been held in a laboratory since about 1950 or by the use of this strain in a vaccine study. In 2009. a new H1N1 swine virus emerged that had derived five genes from pig influenza viruses, two from avian influenza viruses, and one from a human influenza virus. As indicated, most human influenza todav is caused by H1N1 and H3N2 strains.

MBOC7_ptr_ch23_1313-1352.indd 1344 02/12/21 12:23 PM

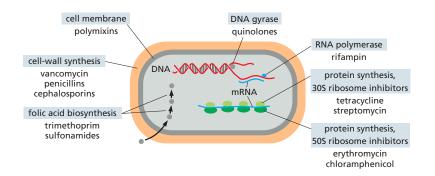

Figure 23–36 Antibiotic targets. Although there are many antibiotics in clinical use, they have a narrow range of targets, which are highlighted in *blue*. A few representative antibiotics in each class are listed. Nearly all antibiotics used to treat human infections fall into one of these categories. The vast majority inhibit either bacterial protein synthesis or bacterial cell-wall synthesis. The illustration example is a Gram-positive bacterium

used to treat infections in humans, just in time to prevent tens of thousands of deaths from infected battlefield wounds in World War II. Because bacteria (see Figure 1–9) are not closely related evolutionarily to the eukaryotes they infect, much of their basic machinery for cell-wall synthesis, DNA replication and transcription, RNA translation, and metabolism differs from that of their host. These differences enable us to develop antibacterial drugs that exhibit *selective toxicity*, in that they specifically inhibit these processes in bacteria without disrupting them in the host. Most of the antibiotics that we use to treat bacterial infections are small molecules that inhibit macromolecular synthesis in bacteria by targeting bacterial enzymes that either are distinct from their eukaryotic counterparts or are involved in pathways such as cell-wall biosynthesis that are absent in animals (Figure 23–36; see also Table 6–4).

However, bacteria continually evolve and strains resistant to antibiotics rapidly develop, often within a few years of the introduction of a new drug. Similar drug resistance also arises rapidly when treating viral infections with antiviral drugs. The virus population in an HIV-infected person treated with the reverse transcriptase inhibitor azidothymidine (AZT), for example, will acquire complete resistance to the drug within a few months. The current protocol for treatment of HIV infections involves the simultaneous use of three drugs, which helps to minimize the acquisition of resistance for any one of them. Even eukaryotic pathogens rapidly evolve resistance. The malaria parasite *Plasmodium falciparum* is now generally resistant to the heavily used drug chloroquine, which was introduced in the 1930s, and resistance to the newer drug artemisinin is emerging.

There are three general strategies by which a pathogen can develop drug resistance: (1) it can alter the molecular target of the drug so that it is no longer sensitive to the drug; (2) it can produce an enzyme that modifies or destroys the drug; or (3) it can prevent the drug's access to the drug target by, for example, actively pumping the drug out of the pathogen (Figure 23–37).

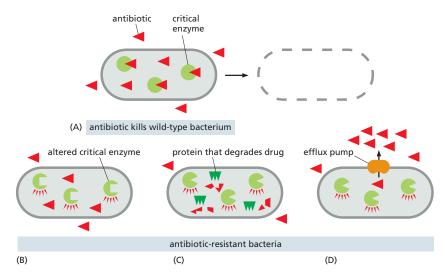

Figure 23-37 Three general mechanisms of antibiotic resistance. (A) A nonresistant wild-type bacterial cell bathed in a drug (red triangles) that binds to and inhibits an essential enzyme (light green) will be killed because of enzyme inhibition. (B) A bacterium that has altered the drug's target enzyme so that the drug no longer binds to the enzyme will survive and proliferate. In many cases, a single point mutation in the gene encoding the target protein can generate resistance. (C) A bacterium that expresses an enzyme (dark green) that either degrades or covalently modifies the drug will survive and proliferate. Some resistant bacteria, for example, make $\beta\text{-lactamase}$ enzymes, which cleave penicillin and similar molecules. (D) A bacterium that expresses or up-regulates an efflux pump that ejects the drug from the bacterial cytoplasm (using energy derived from either ATP hydrolysis or the electrochemical gradient across the bacterial plasma membrane) will survive and proliferate. Some efflux pumps, such as the TetR efflux pump, are specific for a single drug (in this case, tetracycline). whereas others, called multidrug resistance (MDR) efflux pumps, are capable of exporting a wide variety of structurally dissimilar drugs. Up-regulation of an MDR pump can render a bacterium resistant to a very large number of different antibiotics in a single step.

MBOC7_ptr_ch23_1313-1352.indd 1345 02/12/21 12:23 PM

Once a pathogen has chanced upon an effective drug-resistance strategy, the newly acquired or mutated genes that confer the resistance are frequently spread throughout the pathogen population by horizontal gene transfer. They may even spread between pathogens of different species. The highly effective but expensive antibiotic *vancomycin*, for example, is used as a treatment of last resort for many severe, hospital-acquired, Gram-positive bacterial infections that are resistant to most other known antibiotics. Vancomycin prevents one step in bacterial cell-wall synthesis—the cross-linking of peptidoglycan chains in the bacterial cell wall (see Figure 23–3B). Resistance can arise if the bacterium synthesizes a cell wall using different subunits that do not bind vancomycin. The most devastating form of vancomycin resistance depends on the acquisition of a transposon (see Figure 5–58) containing seven genes, the products of which work together to sense the presence of vancomycin, shut down the normal pathway for bacterial cell-wall synthesis, and produce a different type of cell wall.

Drug-resistance genes acquired by horizontal transfer frequently come from environmental microbial reservoirs. Nearly all antibiotics used to treat bacterial infections today are based on natural products produced by fungi or bacteria. Penicillin, for example, is made by the mold *Penicillium*, and more than 50% of the antibiotics currently used in the clinic are made by Gram-positive bacteria of the genus *Streptomyces*, which reside in the soil. It is believed that microorganisms produce antimicrobial compounds, many of which have probably existed on Earth for hundreds of millions of years, as weapons in their competition with other microorganisms in the environment. Surveys of bacteria taken from soil samples that have never been exposed to antibiotic drugs used in modern medicine reveal that there are bacteria already resistant to about seven or eight of the antibiotics widely used in clinical practice. When pathogenic microorganisms are faced with the selective pressure provided by antibiotic treatments, they can apparently draw upon the immense source of genetic material in environmental microbial reservoirs to acquire resistance.

Like most other aspects of infectious disease, human behavior has exacerbated the problem of drug resistance. Many patients take antibacterial antibiotics for symptoms that are typically caused by viruses (flu-like illnesses, colds, and sore throats), and these drugs have no effects. Persistent and chronic misuse of antibiotics can eventually result in antibiotic-resistant microbes, which can then transfer the resistance to pathogens. Antibiotics are also misused in the livestock industry, where they are commonly employed as food additives to promote the growth and health of farm animals. An antibiotic closely related to vancomycin was commonly added to cattle feed in Europe; the resulting resistance in the microbiota of these animals is widely believed to be one of the original sources for vancomycin-resistant bacteria that now threaten the lives of hospitalized patients.

Summary

All pathogens share the ability to interact with host cells in diverse ways that promote pathogen replication and spread. Pathogens often colonize the host by adhering to or invading the epithelial surfaces that line the respiratory, gastrointestinal, and urinary tracts, as well as the other body surfaces in direct contact with the environment. Intracellular pathogens, including all viruses and many bacteria and protozoa, invade host cells by one of several mechanisms. Viruses rely largely on receptor-mediated endocytosis, whereas bacteria exploit cell adhesion and phagocytic pathways; in both cases, the host cell provides the machinery and energy for the invasion. Protozoa, by contrast, employ unique invasion strategies that usually require significant energy expenditure on the part of the invader. Once inside, intracellular pathogens seek out a cell compartment that is favorable for their survival and replication, frequently altering host membrane traffic, exploiting the host-cell cytoskeleton for intracellular movement, and manipulating autophagy. Pathogens evolve rapidly, so that new infectious diseases frequently emerge, and old pathogens acquire new ways to evade our attempts at prevention, treatment, and eradication.

MBOC7_ptr_ch23_1313-1352.indd 1346 02/12/21 12:23 PM

THE HUMAN MICROBIOTA 1347

Because the acquisition of drug resistance is almost inevitable, it is crucial that we take measures to delay the onset of resistance and develop innovative new drug treatments.

THE HUMAN MICROBIOTA

Although pathogens can cause disease in otherwise healthy humans, it is now appreciated that our bodies are colonized by many microbes that normally cause no harm. These microbes compose the so-called microbiota. Recent estimates suggest that the human body contains about 3×10^{13} human cells, as well as approximately 4×10^{13} resident microbial cells. As detailed below, we now appreciate that the microbiota is a complex microbial community that makes important contributions to human biology.

The Human Microbiota Is a Complex Ecological System

The human microbiota is usually confined to specific locations of the body (Figure 23–38), including the skin, mouth, digestive tract, and vagina, with distinct communities of species inhabiting each body part. Of the resident microbes, bacterial cells make up the vast majority by sheer numbers (>99%), whereas there are smaller numbers of archaeal, fungal, and protozoan cells. The concentrations and total numbers of microbial cells differ vastly between body locations (Figure 23–38), with the large intestine containing by far the most microbial residents.

The microbiota of an individual person consists of thousands of different microbial species. The species composition varies considerably between individual humans, even between close relatives or identical twins. Different body sites also have different degrees of species diversity. The digestive tract, for example, contains between 500 and 1000 species, most belonging to only a few phyla of bacteria. The microbiota of the digestive tract also provides an interesting illustration of how the diversity and composition of microbial species can change over time, from birth through adulthood. The digestive tract of human infants is colonized by environmental microbes during birth, and the mode of birth (vaginal delivery versus cesarean section) can influence species composition. During the first year of life, the microbiota consists of fewer species that vary considerably over time and between individuals, whereas species diversity increases and composition stabilizes at 1–2 years of age. Thereafter, the microbiota of an individual is generally consistent over time but is influenced by a variety of factors, including age, pregnancy, diet, health status, hygiene, and antibiotic use.

To appreciate the contributions of the microbiota to human biology, it is helpful to consider the various ecological terms that are used to classify relationships between microbes and their host. For the pathogens discussed earlier in this chapter, the microbe benefits to the detriment of the host, a situation referred to as **parasitism**. In contrast, most constituents of the microbiota exhibit less sinister ecological relationships with the host. Some exhibit **commensalism**, which describes the circumstance in which the microbe benefits but has no known beneficial or harmful effects on the host. In **mutualism**, both the microbe and host benefit. It is sometimes difficult to draw a line between these categories.

Figure 23–38 Sites in the human body that harbor the microbiota include the skin, mouth, and digestive tract. An estimate of the total number of microbes in each location is indicated.

MBOC7_ptr_ch23_1313-1352.indd 1347 02/12/21 12:23 PM

Some constituents of the microbiota that exhibit commensalism or mutualism under normal circumstances can also act as parasites or opportunistic pathogens that can cause disease if our immune systems are weakened or if they gain access to a normally sterile part of the body.

The Microbiota Influences Our Development and Health

It is increasingly recognized that many constituents of the human microbiota exhibit a mutualistic relationship with our bodies by supporting metabolism, development, and immunity (Figure 23-39). The anaerobic bacteria that inhabit our intestines, for example, gain shelter and a nutrient supply but also contribute to the digestion of our food and produce important metabolites. One reason for the beneficial influence of the microbiota on our metabolism is that the combined genomes of the various microbial species, called the microbiome, contain 100 times more genes than the number in the human genome itself. A consequence of this genomic diversity is that the microbiota expands the range of biochemical activities available to humans by producing small-molecule metabolites of different chemical composition or in greater abundance than that produced by our own cells. An example is the production of abundant short-chain fatty acids by the microbiota in the digestive tract, which may contribute to metabolism and may also signal to our cells to influence human physiology.

The microbiota is also important for normal development, most notably of the epithelial tissue and immune system in the digestive tract. Studies comparing mice with and without a gastrointestinal microbiota (so-called germ-free mice) show that the microbiota affects properties of the intestinal lining including villus geometry, stem-cell proliferation, blood vessel density, and mucus thickness (Figure 23-39). The mucosal immune system that is associated with the mucus-containing surface of the intestinal epithelium is also strongly influenced by the microbiota. The mucosal immune system must be fine-tuned to be nonresponsive to beneficial microbes in the microbiota, yet responsive to pathogens and microbes that inappropriately penetrate into the epithelial layer. The microbiota plays an important role in the development of lymphoid tissues and in the appropriate differentiation of various immune cell types to control the overall number, species composition, and location of microbes in the digestive tract (Figure 23-39).

There is increasing evidence that an imbalance in the community of microbes that constitute the microbiota, referred to as dysbiosis, is correlated with various human diseases. These include autoimmune and allergic diseases, obesity,

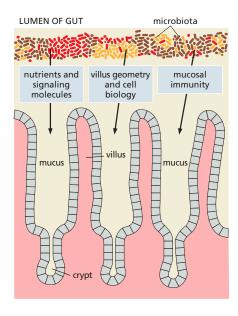

Figure 23-39 Influences of the microbiota on metabolism and development. The microbiota (not drawn exactly to scale) produces nutrients as well as signaling molecules that affect host-cell biology and physiology and also influences the development of the intestinal epithelium and the mucosal immune system.

MBOC7_ptr_ch23_1313-1352.indd 1348 02/12/21 12:23 PM THE HUMAN MICROBIOTA 1349

inflammatory bowel disease, and diabetes, and the list is expanding rapidly. A common example of a disease caused by dysbiosis is colitis, which occurs in response to antibiotic treatment that kills off beneficial microbes in the digestive tract, resulting in overgrowth of the bacterial pathogen *Clostridium difficile*. Although first-line treatment for colitis is an additional course of antibiotics, recurrent colitis has been successfully treated by the transfer of the microbiota from a healthy individual to someone suffering from the disease.

As research intensifies into the influences of the microbiota on human health and disease, a future challenge will be to shift scientific inquiry from investigation of correlations and associations between the presence of certain microbes and health status to investigation of whether there are causal relationships between the composition of the microbiota and its molecular products and health or disease. An impediment to making this shift is the sheer number of variables that must be considered when studying a community consisting of hundreds of microbial species that produce thousands of proteins and small molecules. One path forward may be to search for clear instances in which individual microbes or molecules exert strong effects on human physiology. As microbiomes with defined composition are developed and genetic tools are improved, we may begin to understand how individual microbial species or even individual microbial genes influence human development and health, and we may be able to harness the microbiome to treat human disease.

Summary

Humans are colonized by a community of microbes, collectively called the microbiota, that consists of roughly the same number of microbial cells as there are human cells in the body and is located primarily on the skin, in the mouth, and in the digestive tract. The microbiota as a whole is thought to exhibit a mutualistic ecological relationship with the human host, meaning that both microbes and humans benefit from their interactions. The microbiota produces nutrients that aid in metabolism, as well as molecules that influence tissue and immune system development and function. However, it has been difficult to establish causal relationships between individual microbes or their molecular products and human health. Knowledge of the microbiota is expanding rapidly, and advances promise to enhance our understanding of human biology and result in new disease treatments.

PROBLEMS

Which statements are true? Explain why or why not.

- 23–1 Pathogens must enter host cells to cause disease.
- **23–2** Viruses replicate their genomes in the nucleus of the host cell.
- **23–3** You should not take antibiotics for diseases caused by viruses.
- **23–4** Our adult bodies harbor about 10 times more resident microbial cells than human cells.
- **23–5** The microbiomes from healthy humans are all very similar.

Discuss the following problems.

- **23–6** In order to survive and multiply, a successful pathogen must accomplish five tasks. Name them.
- **23–7** What are the three general mechanisms for horizontal gene transfer?
- 23–8 John Snow is widely regarded as the father of modern epidemiology. Most famously, he investigated an outbreak of cholera in London in 1854 that killed more than 600 people before it was finished. Snow recorded where the victims lived and plotted the data on a map, along with the locations of the water pumps that served as the source of water for the public (Figure Q23–1). He concluded that the disease was most likely spread in the water, although he could find nothing suspicious-looking

Figure Q23–1 A map of where the victims of the 1854 cholera outbreak lived, superimposed on a modern map of the area (Problem 23–8). The locations of the victims' houses are indicated by the small red rectangles. Stacks of rectangles indicate multiple cases occurring in the same house. Public water pumps are shown as blue squares. (Adapted from Wellcome Library, London/Google Maps.)

in it. His conclusion ran counter to the then-current belief that cholera was from "miasmas" in bad air. Very few believed his theory during the next 50 years, with the "bad air" theory persisting until at least 1901. What do you suppose Snow saw in the data that led him to his conclusion? Why do you think most scientists remained skeptical for so long?

The Gram-negative bacterium Yersinia pestis, the causative agent of the plague, is extremely virulent. Upon infection, Y. pestis injects a set of effector proteins into macrophages that suppresses their phagocytic behavior and also interferes with their innate immune responses. One of the effector proteins, YopJ, acetylates serines and threonines on various MAP kinases, including the MAP kinase kinase (MAPKKK) TAK1, which controls a key signaling step in the innate immune response pathway. To determine how YopJ interferes with TAK1, you transfect human cells with catalytically active YopJ (YopJWT) or inactive YopJ (YopJ^{C172A}) and with FLAG-tagged active TAK1 (TAK1WT) or inactive TAK1 (TAK1K63W) and assay for total TAK1 and for phosphorylated TAK1, using antibodies against the FLAG tag or against phosphorylated TAK1 (Figure 023-2). How does YopJ block the TAK1 signaling pathway? How do you suppose the serine/ threonine acetylase activity of YopJ might interfere with TAK1 activation?

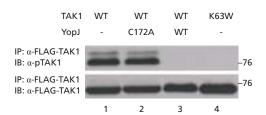

Figure Q23–2 Effects of YopJ on TAK1 phosphorylation (Problem 23–9). TAK1 was immunoprecipitated (IP) using antibodies against the FLAG tag (α -FLAG-TAK1). Total TAK1 in the immunoprecipitation was assayed by immunoblot (IB) using the same antibody. Phosphorylated TAK1 was assayed by IB using antibodies specific for phospho-TAK1 (α -pTAK1). A marker of protein molecular mass is shown at *right* in kilodaltons. (From N. Paquette et al., *Proc. Natl. Acad. Sci. USA* 109:12710–12715, 2012. With permission from National Academy of Sciences.)

23–10 The intracellular bacterial pathogen *Salmonella enterica* serovar Typhimurium, which causes gastroenteritis, injects effector proteins to promote its invasion into nonphagocytic host cells by the trigger mechanism. *S. enterica* serovar Typhimurium first stimulates membrane ruffling to promote invasion, and then suppresses membrane ruffling once invasion is complete. This behavior is mediated in part by injection of two effector proteins: SopE, which promotes membrane ruffling and invasion, and SptP, which blocks the effects of SopE. Both effector proteins target the monomeric GTPase, Rac, which in its active form promotes membrane ruffling. How do you

REFERENCES 1351

suppose SopE and SptP affect Rac activity? How do you suppose the effects of SopE and SptP are staggered in time if they are injected simultaneously?

23–11 Several negative-strand viruses carry their genome as a set of discrete RNA segments. Examples include influenza virus (eight segments), Rift Valley fever virus (three segments), hantavirus (three segments), and Lassa virus (two segments), to name a few. Why does segmentation of the genome provide a strong evolutionary advantage for these viruses?

23–12 Influenza epidemics account for 250,000–500,000 deaths globally each year. These epidemics are markedly seasonal, occurring in temperate climates in the Northern and Southern Hemispheres during their respective winters. By contrast, in the tropics, there is significant influenza activity year round, with a peak in the rainy season (Figure Q23–3). Can you suggest some possible explanations for the patterns of influenza epidemics in temperate zones and the tropics?

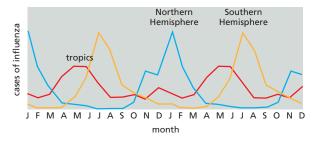

Figure Q23–3 Seasonal patterns of influenza epidemics (Problem 23–12). Cases of influenza at different times of the year are shown for the Northern Hemisphere (blue), the Southern Hemisphere (orange), and the tropics (red).

23–13 Avian influenza viruses readily infect birds but are transmitted to humans very rarely. Similarly, human influenza viruses spread readily to other humans but have never been detected in birds. The key to this specificity lies in the viral capsid protein, hemagglutinin, which binds to sialic acid residues on cell-surface glycoproteins, triggering virus entry into the cell (Movie 23.8). Hemagglutinin on human viruses recognizes sialic acid in a 2,6 linkage with galactose, whereas avian hemagglutinin recognizes sialic acid in a 2,3 linkage with galactose. Humans make carbohydrate chains that have only the 2,6 linkage between sialic acid and galactose; birds make only the 2,3 linkage; but pigs make carbohydrate chains with both linkages. How does this situation make pigs ideal hosts for generating new strains of human influenza viruses?

23–14 The majority of antibiotics used in the clinic are made as natural products by bacteria. Why do you suppose bacteria make the very agents we use to kill them?

23–15 In the early days of penicillin research, it was discovered that bacteria in the air could destroy the penicillin, a big problem for large-scale production of the drug. How do you suppose this occurs?

23–16 When the Oxford team of Ernst Chain and Norman Heatley had laboriously collected their first two grams of penicillin (probably no more than 2% pure!), Chain injected two normal mice with 1 g each of this preparation and waited to see what would happen. The mice survived with no apparent ill effects. His boss, Howard Florey, was furious at what he saw as a waste of good antibiotic. Why was this experiment important?

The Innate and Adaptive Immune Systems

CHAPTER

As we discussed in Chapter 23, all living organisms serve as hosts for other species, usually in relationships that are benign or even mutually helpful. But all organisms, and all cells in a multicellular organism, need to defend themselves against infection by harmful invaders, collectively called **pathogens**, which can be microbes (bacteria, viruses, or fungi) or larger parasites. The first line of defense against pathogens is provided by the **innate immune responses**, which can include protective barriers, toxic molecules, and phagocytic cells that ingest and destroy the invading pathogen. These and other innate immune defenses are not pathogen specific, but they usually can prevent or halt an infection early; if they fail to do so, some organisms, including all vertebrates and some bacteria and archaea (see Figure 7–81), can activate more sophisticated, powerful, and pathogen-specific *adaptive immune responses*. In this chapter, we mainly discuss the innate and adaptive immune systems of humans.

The diverse cells of our innate immune system can respond directly to a pathogen, and some of them can then help activate adaptive immune responses. The innate and adaptive immune responses then work together to help eliminate the pathogen (Figure 24–1). Unlike the innate responses, our adaptive responses are highly specific to the particular pathogen that induced them, and they depend on white blood cells called B and T lymphocytes. B lymphocytes (B cells) secrete antibodies that bind specifically to the pathogen. T lymphocytes (T cells) can either directly kill cells infected with the pathogen (Figure 24–2) or produce secreted or cell-surface signal proteins that stimulate other host cells to help destroy the pathogen. Whereas innate immune responses are generally brief, the adaptive responses provide long-lasting protection: a person who recovers from measles or is vaccinated specifically against it, for example, is protected for life against measles by the adaptive immune system, although not against other common viruses, such as those that cause mumps or chickenpox.

Both the innate and adaptive immune systems have evolved sensing mechanisms that enable the systems to recognize pathogens and their harmful products, and distinguish them from both the host's own cells and molecules and from harmless or beneficial foreign organisms and their molecules. The innate system relies on various sensor proteins to distinguish self from nonself by recognizing particular types or patterns of molecules that are common to microbes but are absent or sequestered in the host. Our adaptive system, by contrast, uses unique genetic mechanisms to produce a virtually limitless diversity of related proteins—receptors on T and B cells and secreted antibodies—that, among them, can bind almost any foreign molecule. This remarkable strategy enables our adaptive immune system to react specifically against any pathogen, even if we never encountered it before. However, it also requires that the system learn not to react against self molecules or harmless foreign ones; if these learning mechanisms fail, harmful autoimmune or allergic responses result.

In this chapter, we focus mainly on features of our immune responses that distinguish them from other kinds of human cell and tissue responses. We begin with innate immune defenses and then discuss the highly specialized properties of our adaptive immune system.

IN THIS CHAPTER

The Innate Immune System

Overview of the Adaptive Immune System

B Cells and Immunoglobulins

T Cells and MHC Proteins

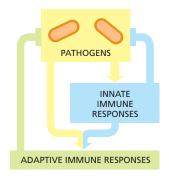

Figure 24–1 Innate and adaptive immune responses. Innate immune responses are activated directly by pathogens and defend all multicellular organisms against infection. In vertebrates, pathogens, together with the innate immune responses they activate, also stimulate adaptive immune responses, which then work together with innate immune responses to help fight the infection. Whereas adaptive responses are specific to a particular pathogen, innate responses are not.

MBOC7_ptr_ch24_1353-1404.indd 1353 02/12/21 12:22 PM

THE INNATE IMMUNE SYSTEM

Our adaptive immune responses are slow to develop when we first encounter a new pathogen. This is because the specific B cells and T cells that can respond to a particular pathogen are initially few in number and must be stimulated to proliferate and differentiate before they can mount effective adaptive immune responses, which can take days. By contrast, a single bacterium that divides every hour can generate almost 20 million progeny in a single day, producing a full-blown infection. We therefore rely on our **innate immune system** to defend us against infection during the first critical hours and days of exposure to a new pathogen.

In this section, we consider some of the strategies our innate immune system uses to recognize pathogens and to provide a first line of defense against them.

Epithelial Surfaces Serve as Barriers to Infection

Our first encounters with infectious organisms are typically at the epithelial surfaces that form our skin and line our respiratory, digestive, and genitourinary tracts. These epithelia provide both physical and chemical barriers to invasion by pathogens: tight junctions between epithelial cells bar entry between the cells, and a variety of substances secreted by the cells discourage the attachment and entry of pathogens. The keratinized epithelial cells of the skin, for example, form a thick physical barrier, and the sebaceous glands in the skin secrete fatty acids and lactic acid, which inhibit bacterial growth. In addition, epithelial cells in all tissues, including those in plants and invertebrates, secrete antimicrobial molecules called **defensins**. Defensins are positively charged, amphipathic peptides that bind to and disrupt the membranes of many pathogens, including enveloped viruses, bacteria, fungi, and parasites.

The epithelial cells that line internal organs such as the respiratory and digestive tracts also secrete slimy mucus, which sticks to the epithelial surface and makes it difficult for pathogens to adhere. The beating of cilia on the surface of the epithelial cells lining the respiratory tract and the peristaltic action of the intestine also discourage the adherence of pathogens. Moreover, as we discuss in Chapter 23, healthy skin and gut are normally populated by enormous numbers of harmless (and often helpful) *commensal* microbes, collectively called the *flora*, which compete for nutrients with pathogens; some also produce antimicrobial peptides that actively inhibit pathogen proliferation. Commensal microbes also bring other benefits to their host: some of those in the gut, for example, help digest food and make several vitamins; some are also needed for the normal development of the gut's innate and adaptive immune systems.

Pattern Recognition Receptors (PRRs) Recognize Conserved Features of Pathogens

Pathogens do occasionally breach the epithelial barricades, in which case underlying nonepithelial cells of the innate immune system provide the next line of defense. These cells sense the presence of pathogens largely through the use of receptor proteins that recognize microbe-associated molecules that are either not present or are sequestered in the host organism. Because these microbial molecules often occur in repeating patterns, they are called **pathogen-associated molecular patterns**, or **PAMPs** (because the molecular patterns are shared with commensal microbes, they are also called microbe-associated molecular patterns, or MAMPs). PAMPs are present in various microbial macromolecules, including nucleic acids, lipids, polysaccharides, and proteins.

The diverse receptor proteins that recognize PAMPs are collectively called **pattern recognition receptors (PRRs)**, which not only bind to PAMPs but can also activate intracellular signaling pathways that lead to the production and secretion of various signal molecules that help fight the pathogen, as we discuss shortly. Some PRRs are transmembrane proteins on the surface of many types of host cells, where they recognize extracellular pathogens. On specialized phagocytic cells (phagocytes) such as *macrophages* and *neutrophils*, for example, they

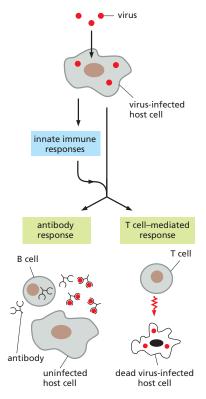

Figure 24–2 Two classes of vertebrate adaptive immune responses.

Lymphocytes carry out both classes, shown here as responses to a viral infection. In one class, B cells secrete antibodies that specifically bind to and neutralize an extracellular virus, thereby preventing the virus from infecting host cells. In the other, T cells mediate the response; in this example, they kill the virus-infected host cells. In both cases, innate immune responses help activate the adaptive immune responses through pathways that we discuss later.

MBOC7_ptr_ch24_1353-1404.indd 1354 02/12/21 12:22 PM

THE INNATE IMMUNE SYSTEM 1355

Figure 24–3 A scanning electron micrograph of a mutant fruit fly that died from a fungal infection. The fly is covered with fungal hyphae, as it lacked Toll receptors, which help protect *Drosophila* from fungal infections. (From B. Lemaitre et al., *Cell* 86:973–983, 1996. With permission from Elsevier.)

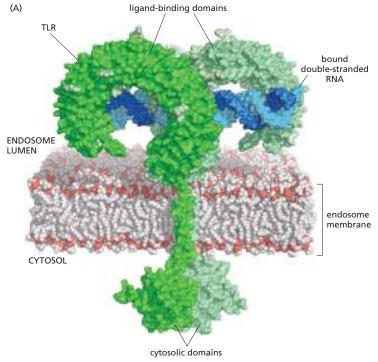

can help mediate the uptake of the pathogens into phagosomes, which then fuse with lysosomes to form *phagolysosomes*, where the pathogens are destroyed. Other PRRs are located intracellularly, where they can detect intracellular pathogens such as viruses; these PRRs are either free in the cytosol or associated with the membranes of the endolysosomal system (discussed in Chapter 13). Still other PRRs are secreted and bind to the surface of extracellular pathogens, marking them for destruction by either phagocytes or blood proteins that are part of the *complement system* (discussed later).

There Are Multiple Families of PRRs

The first PRR identified was the *Toll receptor* in *Drosophila*, which was already well known for its role in fly development (see Figure 21–16). It was later discovered to be required also for the production of antimicrobial peptides that protect the fly against fungal infections (Figure 24–3). Toll is a transmembrane glycoprotein with a large extracellular domain that contains a series of leucine-rich repeats. Soon it was discovered that both plants and animals have a variety of Toll-like receptors (TLRs) that function as PRRs in innate immune responses against various pathogens. A human makes at least 10 different TLRs, each recognizing distinct ligands: TLR3, for example, recognizes double-stranded viral RNA in the endosomal lumen (Figure 24–4); TLR4 recognizes lipopolysaccharide (LPS) on the outer membrane of Gram-negative bacteria; TLR5 recognizes the protein that forms the bacterial flagellum; TLR7 and TLR8 recognize single-stranded viral RNA; and TLR9 recognizes short, unmethylated sequences of bacterial, viral, or protozoan DNA, called CpG motifs, which are uncommon in vertebrate DNA

In addition to TLRs, humans use several other families of PRRs to detect pathogens. One is the large family of NOD-like receptors (NLRs). Like TLRs, NLRs have leucine-rich repeat motifs, but they are exclusively cytoplasmic and recognize a distinct set of bacterial molecules. Individuals who are homozygous for an inactivating mutation in the NLR gene NOD2 have a greatly increased risk of developing Crohn's disease, a chronic inflammatory disease of the small intestine, thought to involve chronic immune responses against harmless commensal gut microbes. Another family of PRRs consists of RIG-like receptors (RLRs), which are members of the RNA helicase family of proteins. They are also exclusively cytoplasmic and detect viral pathogens. A fourth family of PRRs consists of C-type lectin receptors (CLRs), which are transmembrane cell-surface proteins that recognize carbohydrates (which is why they are called lectins) on various microbes; they are called C-type because the binding to carbohydrate is dependent on Ca²⁺. Table 24-1 summarizes some PRRs and their ligands and locations in cells. Collectively, these and other PRRs act as an alarm system to alert the innate and adaptive immune systems that an infection is brewing (Movie 24.1).

MBOC7_ptr_ch24_1353-1404.indd 1355 02/12/21 12:22 PM

When a cell-surface or intracellular PRR binds a PAMP, it stimulates the cell to secrete a variety of cytokines and other extracellular signal molecules. Some of these inhibit viral replication, but most induce a local inflammatory response that helps eliminate the pathogen, as we now discuss.

Activated PRRs Trigger an Inflammatory Response at Sites of Infection

When a pathogen invades a tissue, it activates PRRs on or in various cells of the innate immune system, resulting in an inflammatory response at the site of infection. Resident macrophages are usually the first cells to respond, and

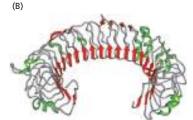

Figure 24–4 A Toll-like receptor.

(A) The structure of human TLR3 is shown (green), bound to a double-stranded RNA molecule (dsRNA; blue). The receptor is a transmembrane homodimer in the membrane of endosomes. The binding of dsRNA to the two horseshoe-shaped domains on the lumenal side of the endosome brings the two cytosolic domains together, allowing adaptor proteins in the cytosol to assemble into a large signaling complex, leading to the production of antivirus cytokines (not shown, but discussed later). (B) The crystal structure of a lumenal domain of the transmembrane receptor, which contains 23 conventional leucine-rich repeats, each of which contributes a β strand to the continuous β sheet (red) that lines the concave surface of the structure. (A, adapted from L. Liu et al., Science 320:379-381, 2008; B, adapted from J. Choe et al., Science 309:581-585, 2005. Both with permission from AAAS. PDB code: 1ZIW.)

TABLE 24–1 Some Pattern Recognition Receptors (PRRs)			
Receptor	Location	Ligand	Origin of ligand
Toll-like receptors (TLRs)			
TLR3	Endolysosomal system	Double-stranded RNA	Viruses

Dectin1	Plasma membrane	β-Glucan	Fungi

MBOC7_ptr_ch24_1353-1404.indd 1356 02/12/21 12:22 PM they orchestrate the subsequent responses by secreting short-range signal molecules that recruit other cells of the innate immune system. The inflammatory response involves changes in local blood vessels and is characterized clinically by local pain, redness, heat, and swelling. The blood vessels dilate and become permeable to fluid and proteins, leading to local swelling and an accumulation of blood proteins, including some that aid in defense against pathogens. At the same time, the endothelial cells lining the local blood vessels are stimulated to express cell adhesion proteins, which promote the attachment and escape of white blood cells, or *leukocytes* (see Figure 19–28), adding to the local swelling; initially neutrophils escape, followed later by lymphocytes and monocytes (the blood-borne precursors of macrophages—see Figure 22–12).

The activation of PRRs results in the production of a large variety of extracellular signal molecules that mediate the inflammatory response at the site of an infection. These include both lipid signal molecules, such as prostaglandins, and protein (or peptide) signal molecules called **cytokines**, which mainly influence nearby cells. Some of the most important **pro-inflammatory cytokines** are *tumor necrosis factor-* α (*TNF* α), *interferon-* γ (*IFN* γ), a variety of *chemokines* that recruit leukocytes, and various *interleukins* (*ILs*) that we discuss later, including IL1 β , IL6, IL12, IL17, and IL18. In addition, a secreted PRR (mannose-binding lectin) activates the complement system when the PRR binds to a pathogen; fragments of complement proteins released during complement activation stimulate an inflammatory response (discussed shortly; see Figure 24–7).

When activated by PAMPs, most cell-surface and intracellular PRRs stimulate the production of multiple pro-inflammatory cytokines by activating intracellular signaling pathways that switch on transcription regulators, including NF κ B, to induce the transcription of the relevant cytokine genes (see Figure 15–63). Some PRRs, however, can also stimulate pro-inflammatory cytokine production by a different mechanism: when activated, several cytoplasmic NLRs assemble with adaptor proteins and specific proteases of the caspase family (discussed in Chapter 18) to form **inflammasomes**, in which the pro-inflammatory cytokines such as IL1 β and IL18 are cleaved from their inactive precursor proteins by caspase-1. These cytokines are then released from the cell by unconventional secretion pathways. Inflammasomes closely resemble *apoptosomes* in their assembly and structure, but, in apoptosomes, caspases are activated to initiate an intracellular, proteolytic, caspase cascade that leads to apoptotic cell death (see Figure 18–8).

NLR-dependent inflammasome assembly can also be triggered in the absence of infection if cells are damaged or stressed. Such cells produce *damage-associated molecular patterns* (*DAMPs*), including those on altered or misplaced self molecules, which can activate the relevant NLRs: the arthritis caused by uric acid crystals formed in the joints of individuals with gout, who have abnormally high uric acid levels in their blood, is a painful example.

The inflammatory response is amplified by various positive feedback loops. Activated macrophages, for example, secrete IL1 β , which acts back on macrophages to increase their production of more precursor of IL1 β ; at the same time, other cytokines increase the assembly of inflammasomes that produce yet more IL1 β by cleaving its precursor. As another example, activated macrophages secrete chemokines that recruit leukocytes that also secrete chemokines that recruit more leukocytes, some of which are monocytes that mature into macrophages, which can be become activated to drive more rounds of this positive feedback cycle.

Besides their local effects, pro-inflammatory cytokines can produce wide-spread changes in the body. IL1 β , IL6, and TNF α , for example, can act on the brain hypothalamus, muscle cells, and fat cells to increase body temperature, producing a fever that helps some immune cells fight infection. These cytokines can also stimulate the liver to secrete acute-phase proteins, such as C-reactive protein, which binds to the surface of various pathogens, where it

MBOC7_ptr_ch24_1353-1404.indd 1357 02/12/21 12:22 PM

recruits complement components that stimulate phagocytosis of the pathogen (discussed shortly). Because it increases several hundredfold, the increase in C-reactive protein is widely used clinically as a test for infection, inflammation, and tissue damage.

Phagocytic Cells Seek, Engulf, and Destroy Pathogens

In all animals, the recognition of a microbial invader is usually quickly followed by its engulfment by a phagocytic cell. In humans, these are usually macrophages, which are long-lived cells that are resident in most tissues and are therefore the first phagocytes to respond. Neutrophils, by contrast, are short-lived and, although they are the most numerous leukocytes in blood, they are not present in other healthy tissues. They are rapidly recruited from the blood to sites of infection by various attractive molecules, including formylmethionine-containing peptides (which are released by microbes but are not made by mammalian cells), chemokines secreted by activated macrophages, and peptide fragments produced from cleaved, activated complement proteins. The recruited neutrophils phagocytose the pathogens and secrete their own pro-inflammatory cytokines, thereby amplifying the local inflammatory response.

In addition to their PRRs, macrophages and neutrophils display a variety of cell-surface receptors that recognize antibodies or fragments of complement proteins bound to the surface of a pathogen. The binding of such a coated pathogen to these receptors leads to its rapid phagocytosis (Figure 24-5) and the mounting of a ferocious attack on the pathogen once it is inside a phagolysosome. Both macrophages and neutrophils possess an impressive armory of weapons to kill ingested invaders, including enzymes such as lysozyme and acid hydrolases that can degrade the pathogen's cell wall. The cells assemble NADPH oxidase complexes on the phagolysosomal membrane, where the complexes catalyze the production of highly toxic oxygen-derived compounds, including superoxide (O2-), hydrogen peroxide, and hydroxyl radicals. A transient increase in oxygen consumption by the phagocytic cells, called the respiratory burst, helps power the production of these toxic compounds. Whereas macrophages generally survive this killing frenzy and live to kill again, neutrophils do not: they are programmed to die by apoptosis (discussed in Chapter 18) after they have destroyed their prey and are then phagocytosed by macrophages; some neutrophils die by a form of cell necrosis, releasing decondensed chromatin that forms extracellular nets, which are thought to trap and kill pathogens. Dead and dying neutrophils are a major component of the pus that forms in acute wounds infected with bacteria.

If a pathogen is too large to be successfully phagocytosed (if it is a large parasite such as a worm, for example), a group of macrophages, neutrophils, or eosinophils (another type of leukocyte—see Figure 22–11) will gather around the invader. They secrete defensins and other damaging agents and release the oxygen-derived toxic products of the respiratory burst. This barrage is often sufficient to destroy the pathogen (Figure 24–6).

Complement Activation Targets Pathogens for Phagocytosis or Lysis

The blood and other extracellular fluids contain numerous proteins with antimicrobial activity, some of which are produced in response to an infection, while others are produced constitutively. The most important of these are components of the **complement system**, which consists of more than 30 interacting soluble proteins that are mainly made continually by the liver and are inactive until an infection or another trigger activates them. They were originally identified by their ability to amplify and thereby "complement" the action of antibodies made by B cells, but some are also secreted PRRs, which directly recognize PAMPs on microbes.

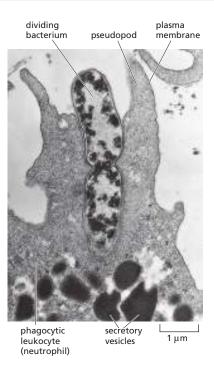

Figure 24–5 Phagocytosis of an antibody-coated pathogen. Electron micrograph of a neutrophil phagocytosing an antibody-coated bacterium, which is in the process of dividing. The process in which antibody (or complement) coating of a pathogen increases the efficiency with which the pathogen is phagocytosed is called *opsonization*. (Courtesy of Dorothy F. Bainton, from R.C. Williams, Jr., and H.H. Fudenberg, Phagocytic Mechanisms in Health and Disease. New York: Intercontinental Medical Book Corporation, 1971.)

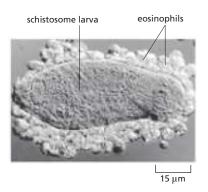

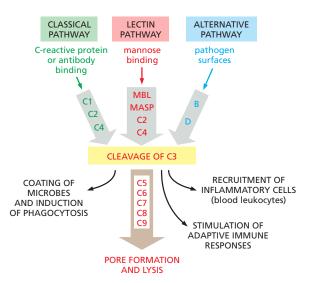

Figure 24–6 Eosinophils attacking a parasite. Phagocytes cannot ingest large parasites such as the schistosome larva shown here. When such a parasite is coated with antibody or complement components, however, eosinophils (and other leukocytes) can recognize it and collectively kill it by secreting a large variety of toxic molecules. THE INNATE IMMUNE SYSTEM 1359

The *early complement components* consist of three sets of proteins, belonging to three distinct pathways of complement activation—the *classical pathway*, the *lectin pathway*, and the *alternative pathway*. The early components of all three pathways act locally to cleave and activate C3, which is the pivotal complement component (Figure 24–7); individuals with a C3 deficiency are subject to repeated severe infections. The early components are proenzymes, which are activated sequentially by proteolytic cleavage. The cleavage of each proenzyme in the series activates the next component to generate a serine protease, which cleaves the next proenzyme in the series, and so on. Because each activated enzyme cleaves many molecules of the next proenzyme in the chain, the activation of the early components consists of an amplifying *proteolytic cascade*.

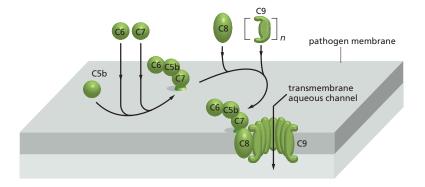

Many of these protein cleavages liberate a biologically active small fragment, which can attract neutrophils, plus a membrane-binding larger fragment. The binding of the large fragment to a cell membrane, usually the surface of a pathogen, helps stimulate the next reaction in the sequence. In this way, complement activation is largely kept confined to the cell surface where it began. In particular, the large fragment of C3, called C3b, binds covalently to the surface of the pathogen. Here, it recruits protein fragments produced by cleavage of other early complement components to form proteolytic complexes that catalyze the subsequent steps in the complement cascade. The early events in complement activation have diverse functions: C3b-binding receptors on phagocytic cells enhance the ability of these cells to phagocytose the pathogen, and similar receptors on B cells enhance the ability of these cells to make antibodies against various microbial molecules on C3b-coated pathogens. The smaller fragment of C3 (called C3a), as well as small fragments of C4 and C5, act independently as diffusible signals to promote an inflammatory response by recruiting leukocytes to the site of infection.

As indicated in Figure 24–7, C-reactive protein or antibodies bound to the surface of a pathogen activate the *classical pathway*. *Mannose-binding lectin*, mentioned earlier, is a secreted PRR that initiates the *lectin pathway* of complement activation when it recognizes bacterial or fungal glycolipids and glycoproteins bearing terminal mannose and fucose sugars in a particular spatial conformation. These initial binding events in the classical and lectin pathways cause the recruitment and activation of the early complement components. Because molecules on the surface of pathogens can directly activate the *alternative pathway*, it is usually the first complement pathway activated at the start of an infection.

Membrane-immobilized C3b, produced by any of the three pathways, triggers a further cascade of reactions that leads to the assembly of the *late complement*

Figure 24-7 The principal stages in complement activation by the classical, lectin, and alternative pathways. In all three pathways, the reactions of complement activation usually take place on the surface of an invading microbe, such as a bacterium, and lead to the cleavage of C3 and the various consequences shown. As indicated, the complement proteins C1 to C9, mannose-binding lectin (MBL), MBL-associated serine protease (MASP). and factors B and D are the central components of the complement system. The early components are shown within gray arrows, while the late components are shown within a brown arrow. The black arrows indicate the functions of the protein fragments produced during complement activation. The various complement proteins that regulate the system are omitted. C-reactive protein is a secreted PRR protein that is made by the liver; it increases in the blood during an infection (and other inflammatory conditions) and binds to the surface of some bacteria.

MBOC7_ptr_ch24_1353-1404.indd 1359 02/12/21 12:22 PM

components to form membrane attack complexes. These protein complexes assemble in the pathogen membrane near the site of C3 activation, forming aqueous pores through the membrane (Figure 24–8). For this reason, and because they perturb the structure of the lipid bilayer in their vicinity, they make the membrane leaky and can, in some cases, cause the microbe to lyse.

The self-amplifying, inflammatory, and destructive properties of the complement cascade make it essential that the cascade is tightly controlled, which is achieved in various ways. One way is that key activated components are unstable and rapidly inactivate after they are generated, unless they bind immediately to either the next component in the cascade or to a nearby membrane. In addition, specific inhibitor proteins in the blood or on the surface of host cells abort the cascade by inactivating certain complement components once the components have been activated by proteolytic cleavage. One such inhibitor protein in the blood is recruited to sialic acid on host-cell glycoproteins and glycolipids (see Figure 10–16); because pathogens generally lack sialic acid, they are singled out for complement-mediated phagocytosis and destruction, while host cells are spared. Some pathogens, including the bacterium *Neisseria gonorrhoeae* that causes the sexually transmitted disease gonorrhea, coat themselves with a layer of sialic acid to effectively hide from the complement system.

Virus-infected Cells Take Drastic Measures to Prevent Viral Replication

A common way for a host-cell PRR to recognize the presence of an infecting virus is to detect unusual elements of the viral genome, such as the double-stranded RNA (dsRNA) that is an intermediate in the life cycle of many viruses and is recognized by several PRRs, including the Toll-like receptor TLR3 (see Figure 24–4A). In addition, DNA virus genomes frequently contain significant amounts of the CpG motifs mentioned earlier, which can be recognized by TLR9 (see Table 24–1, p. 1356).

Mammalian cells are particularly adept at recognizing the presence of dsRNA, which activates intracellular PRRs that induce the host cell to produce and secrete two antiviral cytokines: interferon- α (IFN α) and interferon- β (IFN β). These interferons are referred to as *type I interferons* to distinguish them from IFN γ , which is a type II interferon and has different functions, as we discuss later. A type I interferon acts in both an autocrine fashion on the infected cells that produced it and a paracrine fashion on uninfected neighbors. Type I interferons bind to a common cell-surface receptor, which activates the JAK-STAT intracellular signaling pathway (see Figure 15–57) to stimulate the transcription of many specific genes and thereby promote the production of hundreds of proteins, including many cytokines, reflecting the complexity of the cell's acute response to a viral infection.

The production of type I interferons appears to be a general response of our cells to a viral infection, and viral components other than dsRNA and CpG motifs

Figure 24–8 Assembly of the late complement components to form a membrane attack complex in the membrane of a pathogen. The cleavage of the early complement components (shown within gray arrows in Figure 24-7) results in the formation of C3b-containing proteolytic complexes on the pathogen membrane (not shown). These then cleave the first of the late components. C5. to produce C5a (not shown) and C5b. As illustrated, C5b rapidly assembles with C6 and C7 to form C567, which then binds firmly via C7 to the pathogen membrane. One molecule of C8 binds to the complex to form C5678. The binding of a molecule of C9 to C5678 induces a conformational change in C9 that exposes a hydrophobic region and causes C9 to insert into the target membrane. This starts a chain reaction in which the altered C9 binds a second molecule of C9, which can then bind another molecule of C9, and so on. In this way, a ring of C9 molecules forms a large, transmembrane aqueous channel in the pathogen membrane.

MBOC7_ptr_ch24_1353-1404.indd 1360 02/12/21 12:22 PM

in viral DNA can trigger it. The type I interferons help block viral replication in multiple ways. They activate a latent ribonuclease, for example, that nonspecifically degrades single-stranded RNAs of both the virus and host cell. They also indirectly activate a protein kinase that phosphorylates and inactivates the protein synthesis initiation factor eIF2 (discussed in Chapter 6), thereby shutting down most protein synthesis in the infected host cell. Apparently, by destroying most of its own RNA and transiently halting most of its protein synthesis, the host cell inhibits viral replication without killing itself. If these measures fail, the cell takes an even more extreme step to prevent the virus from replicating: it kills itself by undergoing apoptosis, often with the help of immune killer cells that are activated by type I interferons, as we discuss next.

Natural Killer Cells Induce Virus-infected Cells to Kill Themselves

An indirect way that type I interferons block viral replication is by enhancing the activity of **natural killer cells (NK cells)**. These lymphocyte-like leukocytes are part of the innate immune system. They are recruited early to sites of inflammation by cytokines secreted by activated resident macrophages; once there, they secrete cytokines that further activate macrophages to increase their ability to ingest and destroy pathogens and secrete cytokines—yet another positive feedback loop that amplifies the inflammatory response. Like *cytotoxic T cells* of the adaptive immune system (discussed later), NK cells also directly destroy virus-infected cells by inducing the infected cells to kill themselves by undergoing apoptosis. Thus NK cells help defend us against both extracellular and intracellular pathogens. We consider later how NK cells induce apoptosis when we discuss how cytotoxic T cells do it (see Figure 24-43). Although the two types of killer cells kill in the same ways, the means by which they distinguish the surface of virus-infected cells from that of uninfected cells are different (Movie 24.2).

Both cytotoxic T cells and NK cells recognize the same special class of cellsurface proteins on a host cell to help determine if the cell is virus-infected, but they use distinct receptors to do so. The special cell-surface proteins recognized are called *class I MHC proteins*. As we discuss in detail later, *MHC proteins* are so called because they are encoded by a cluster of genes in the major histocompatibility complex. Class I MHC proteins are present on almost all nucleated cells in vertebrates, and cytotoxic T cells use specific T cell receptors (TCRs) to recognize peptide fragments of viral proteins bound to these MHC proteins on the surface of virus-infected host cells to induce the cells to undergo apoptosis (discussed later). By contrast, NK cells have a variety of cell-surface inhibitory receptors that monitor the level of class I MHC proteins on the surface of other host cells: the high levels of these MHC proteins normally present on healthy host cells engage these receptors and thereby inhibit the killing activity of the NK cells. The NK cells thus focus primarily on host cells expressing abnormally low levels of class I MHC proteins and induce the cells to kill themselves; these are mainly virus-infected cells and some cancer cells (Figure 24-9). NK-cell killing activity is stimulated when various activating receptors on the NK cell surface recognize specific proteins that are greatly increased on the surface of virus-infected cells and some cancer cells.

The reason that class I MHC protein levels are often low on virus-infected cells is that many viruses have developed a variety of mechanisms to inhibit the expression of these proteins on the surface of the host cells they infect, in order to avoid detection by cytotoxic T cells: some viruses encode proteins that block class I MHC gene transcription; others block the intracellular assembly of peptide–MHC complexes; still others block the transport of these complexes to the cell surface. By evading recognition by cytotoxic T cells in these ways, however, a virus incurs the wrath of NK cells, which recognize the infected cells as being different—both because the infected cells express little class I MHC protein and because they express large amounts of other

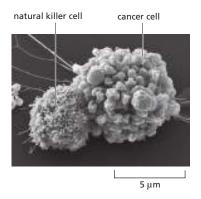

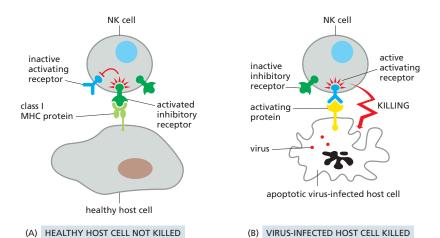

Figure 24–9 A natural killer (NK) cell attacking a cancer cell. This scanning electron micrograph was taken shortly after the NK cell attached to the cancer cell, causing the cancer cell to undergo apoptosis. The blebbing of the cancer cell's plasma membrane is characteristic of cells dying in this way (discussed in Chapter 18; see Movie 18.1). (From Eye of Science/ Science Source.)

MBOC7_ptr_ch24_1353-1404.indd 1361 02/12/21 12:22 PM

of activating and inhibitory receptors on its surface, and the decision to kill or not kill a host cell depends on the sum of interactions between these receptors and the molecules they recognize on the host cell. One simplified example is shown here. (A) The high levels of class I MHC proteins found on healthy host cells activate inhibitory receptors on the NK cell, suppressing the NK cell's killing activity. (B) In contrast, the high levels of activating proteins and abnormally low level of class I MHC proteins on infected cells stimulate the NK cell to kill the virus-infected host cell by inducing the host cell to kill itself by undergoing apoptosis.

Figure 24–10 How an NK cell recognizes its target. An NK cell displays a variety

cell-surface proteins that are recognized by the activating receptors on the NK cells (Figure 24–10).

NK cells belong to a large class of lymphocyte-like cells of the innate immune system, collectively called *innate lymphoid cells* (*ILCs*); although these cells share some characteristics with T cells, they lack TCRs. Besides NK cells, the ILCs include more recently discovered cell types with diverse distributions and functions: some promote the early development of lymphoid tissues; some secrete various cytokines during innate immune responses to a wide variety of pathogens; others promote the repair of damaged tissues; and some help prevent adaptive immune responses against commensal microbes in the gut. And new ILCs and functions are still being discovered.

Dendritic Cells Provide the Link Between the Innate and Adaptive Immune Systems

Dendritic cells are crucially important components of the innate immune system. Like macrophages, they are made in the bone marrow, are resident in most of our tissues, express a large variety of PRRs that enable them to recognize and phagocytose invading pathogens or their products, and they become activated during the encounter with pathogens. But, unlike macrophages, which kill the pathogens they ingest, dendritic cells act indirectly to fight the pathogens they ingest by activating T cells of the adaptive immune system to join the fight.

As discussed later, an activated dendritic cell cleaves the proteins of the ingested pathogen or its products into peptide fragments, which bind to newly synthesized MHC proteins that then carry the fragments to the dendritic-cell surface. The activated cells then migrate to a nearby lymphoid organ such as a lymph node (also called a lymph gland), where they present the peptide-MHC complexes to T cells, activating the T cells to proliferate and help fight the specific pathogen (Figure 24–11).

In addition to the complexes of MHC proteins and microbial peptides displayed on their cell surface, activated dendritic cells also display cell-surface *co-stimulatory proteins* that help activate T cells (see Figure 24–11). The activated dendritic cells also secrete a variety of cytokines that influence the type of T cell response induced, ensuring that it is appropriate to fight the particular pathogen. In these ways, dendritic cells serve as crucial links between the innate immune system, which provides a rapid first line of defense against invading pathogens, and the adaptive immune system, which mounts slower but more powerful and highly specific responses to attack a particular invader, as we discuss next.

Summary

All multicellular organisms possess innate immune defenses against invading pathogens; these defenses include physical and chemical barriers and various defensive cell responses that are not specific to a particular pathogen. In vertebrates,

MBOC7_ptr_ch24_1353-1404.indd 1362 02/12/21 12:22 PM

THE INNATE IMMUNE SYSTEM 1363

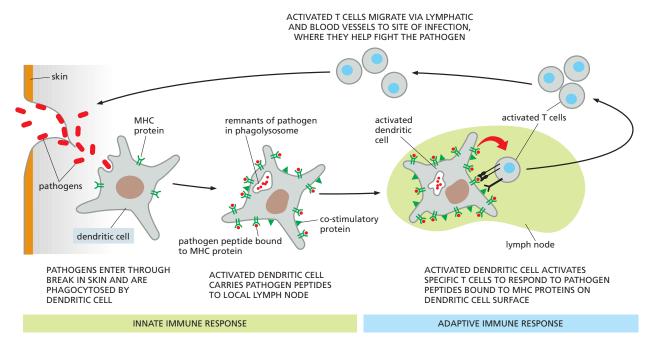

Figure 24–11 Dendritic cells as functional links between the innate and adaptive immune systems. Dendritic cells pick up invading pathogens or their products at the site of an infection. The pathogen PAMPs activate the dendritic cells to express co-stimulatory proteins and increased amounts of MHC proteins on their surface and to migrate via lymphatic vessels to a nearby lymph node. In the lymph node, the activated dendritic cells activate T cells that express appropriate receptors for the co-stimulatory proteins and the pathogen peptides bound to MHC proteins on the dendritic-cell surface. The activated T cells proliferate, and some of their progeny migrate via lymphatic and blood vessels to the original site of infection, where they help eliminate the pathogen, either by activating local macrophages to engulf and kill the pathogen or by directly killing infected host cells (not shown). In addition, some of the activated T cells help stimulate specific B cells in the lymph node to secrete antibodies against the pathogen (not shown).

A crucial feature of dendritic-cell activation is that the pathogen provides an individual dendritic cell with both the peptides for presentation to T cells and the PAMP signals that activate the dendritic cell to express co-stimulatory proteins. In this way, the individual dendritic cell has all it needs to activate specific T cells that recognize the peptide–MHC complexes on its surface (Movie 24.3).

these innate immune responses can also recruit more powerful adaptive immune responses, which are pathogen-specific and help fight the infection. Innate immune responses rely on the ability of host cells to recognize characteristic features of microbial molecules called pathogen-associated molecular patterns, or PAMPs, which can be associated with a pathogen's proteins, lipids, sugars, or nucleic acids. PAMPs are mainly recognized by a variety of pattern recognition receptors (PRRs), including the Toll-like receptors (TLRs) found on or in both plant and animal cells. In vertebrates, some PRRs are secreted and can activate complement when they bind to PAMPs on the pathogen surface. The complement system, which can also be activated by antimicrobial antibodies bound to pathogens, consists of a group of blood proteins that are activated in sequence to help fight infections by disrupting the pathogen's membrane, stimulating an inflammatory response, or, most important, by targeting the microbe for phagocytosis-mainly by macrophages and neutrophils. The phagocytes use a combination of hydrolytic enzymes, antimicrobial peptides, and oxygen-derived toxic molecules to kill invading pathogens; in addition, they secrete various signal molecules that help trigger an inflammatory response.

Cells infected by a virus produce and secrete type I interferons (IFN α and IFN β), which induce a complex set of host-cell responses that inhibit viral replication. The interferons also enhance the killing activity of natural killer (NK) cells. An NK cell kills infected host cells because they express large amounts of surface proteins that activate the NK cell; the killing is especially efficient when infected cells express reduced amounts of class I MHC proteins, which, when present in normal amounts on the surface of a healthy host cell, inhibit the killing activity of NK cells.

MBOC7_ptr_ch24_1353-1404.indd 1363 02/12/21 12:22 PM

Dendritic cells of the innate immune system functionally link innate immune responses to adaptive immune responses. They become activated when their PRRs recognize pathogens and the products of pathogens at sites of infection and phagocytose them. The activated dendritic cells cleave the pathogen proteins into peptide fragments, which bind to newly made MHC proteins, which transport the fragments to the dendritic-cell surface. The activated cells then carry the peptide–MHC complexes to a lymph organ, where they activate appropriate T cells to make pathogen-specific adaptive immune responses against the invading microbes.

OVERVIEW OF THE ADAPTIVE IMMUNE SYSTEM

A dramatic "big bang" in the evolution of animal immune defense mechanisms occurred when jawed vertebrates acquired an adaptive immune system. This sophisticated defense system depends on B and T lymphocytes (B and T cells), which, during their development, rearrange specific DNA sequences in various combinations so that, together, the cells can produce an almost limitless variety of B and T cell receptors and secreted antibodies. Collectively, these cell-surface and secreted proteins can bind to essentially any molecule—operationally referred to as an antigen—including small chemicals, carbohydrates, lipids, and proteins. Individually, the receptors and antibodies can distinguish between antigens that are very similar—such as between two proteins or peptides that differ in only a single amino acid or between two optical isomers of the same small molecule. By this strategy, the adaptive immune system can recognize and respond specifically to any pathogen, including new mutant forms. However, because the genetic rearrangement processes involved produce receptors that can bind to self molecules as well as receptors that can bind to foreign molecules, vertebrates have had to evolve special mechanisms to ensure that B and T cells do not react against the host's own molecules and cells—a process called *immunological self-tolerance*.

Moreover, many harmless foreign substances enter the body, for example, as food or inhaled material, and it would be pointless and potentially dangerous to mount adaptive immune responses against them. Such inappropriate responses are normally avoided because innate immune responses are required to call adaptive immune responses into play and do so only when the innate cells' PRRs recognize microbial PAMPs, as we discussed earlier. One can trick the adaptive immune system into responding to a harmless foreign molecule, such as a foreign protein, by co-injecting a molecule (often of microbial origin) called an *adjuvant*, which activates PRRs. This trick is called **immunization**, and it can be exploited in vaccination (discussed later).

There are two broad classes of adaptive immune responses—antibody responses and T cell-mediated immune responses—and most pathogens induce both classes of responses. In **antibody responses**, B cells are activated to secrete antibodies, which are proteins that circulate in the bloodstream and permeate other body fluids, where they can bind specifically to the foreign antigen that stimulated their production. Binding of antibody can neutralize extracellular viruses (see Figure 24–2) and microbial toxins (such as tetanus toxin or cholera toxin) by blocking their ability to bind to receptors on host cells. Antibody binding can also mark invading pathogens for destruction, both by making it easier for phagocytes of the innate immune system to ingest and destroy them and by activating the complement system by the classical pathway (see Figure 24–7).

In **T cell-mediated immune responses**, T cells recognize foreign antigens that are bound to MHC proteins on the surface of host cells such as dendritic cells, which are specialized for presenting antigen to T cells and are therefore often referred to as "professional" *antigen-presenting cells* (*APCs*). Because MHC proteins carry fragments of pathogen proteins from inside a host cell to the cell surface, T cells can detect pathogens hiding inside a host cell and either kill the infected cell (see Figure 24–2) or stimulate phagocytes or B cells to help eliminate the pathogens.

In this section, we discuss the origins and general properties of B and T cells. In later sections, we consider the specific properties and functions of these cells.

MBOC7_ptr_ch24_1353-1404.indd 1364 02/12/21 12:22 PM

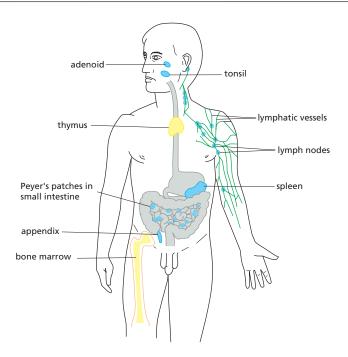

Figure 24-12 Human lymphoid organs. Lymphocytes develop from lymphoid progenitor cells in the thymus and bone marrow (yellow), which are therefore called central (or primary) lymphoid organs. Newly formed lymphocytes migrate from these primary organs to peripheral (or secondary) lymphoid organs (blue), where B and T cells respond to foreign antigen. Only some of the peripheral lymphoid organs and lymphatic vessels (green) are shown; many lymphocytes, for example, are found in the skin and respiratory tract. As we discuss later, the lymphatic vessels ultimately empty into the bloodstream (not shown).

B Cells Develop in the Bone Marrow, T Cells in the Thymus

There are about 2×10^{12} lymphocytes in the human body, making the immune system comparable in cell mass to the liver or the brain. They occur in large numbers in the blood and lymph (the colorless fluid in the lymphatic vessels, which connect the lymph nodes in the body to each other and to the bloodstream). They are also concentrated in **lymphoid organs**, such as the thymus, lymph nodes, and spleen (**Figure 24–12**), and many are also found in other organs, including skin, lung, and gut.

T cells and B cells derive their names from the organs in which they develop: T cells develop in the *thymus*, and B cells, in adult mammals, develop in the *bone marrow*. Both types of cells develop from *lymphoid progenitor cells* that are produced from multipotent *hematopoietic stem cells*, which, in adults, are found mainly in the bone marrow (Figure 24–13). The hematopoietic stem cells give rise

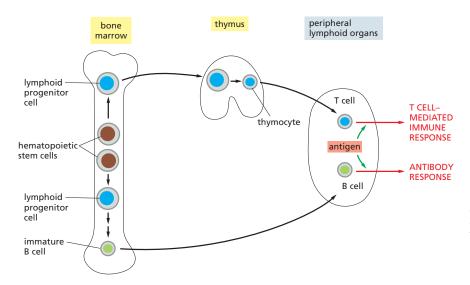

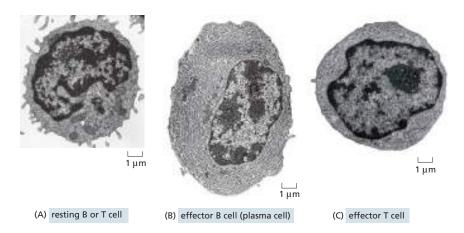

Figure 24-13 The development of B and T cells in adult humans. The central lymphoid organs, where lymphocytes develop from lymphoid progenitor cells, are labeled in yellow boxes. The lymphoid progenitor cells develop from multipotent hematopoietic stem cells in the bone marrow. Some lymphoid progenitor cells develop locally in the bone marrow into immature B cells, while others migrate via the bloodstream to the thymus where they develop into thymocytes (developing T cells). Foreign antigens activate B cells and T cells mainly in peripheral lymphoid organs, such as lymph nodes and the spleen.

MBOC7_ptr_ch24_1353-1404.indd 1365 02/12/21 12:22 PM

to more than just lymphocytes: as discussed in Chapter 22, they produce all of the cells of the hematopoietic system, including erythrocytes, leukocytes, and platelets (see Figure 22–12).

Because they are sites where B and T lymphocytes (as well as innate lymphoid cells, such as NK cells) develop from lymphoid progenitor cells, the thymus and bone marrow are referred to as **central**, **or primary**, **lymphoid organs** (see Figure 24–12). Here, lymphocytes differentiate and then migrate via the blood to the **peripheral**, **or secondary**, **lymphoid organs**—mainly the lymph nodes, spleen, and epithelium-associated lymphoid tissues in the gastrointestinal tract, respiratory tract, and skin. It is in these peripheral lymphoid organs that foreign antigens activate B and T cells (see Figure 24–13).

B and T cells become morphologically distinguishable from each other only after antigen has activated them: resting B and T cells look very similar, even in an electron microscope (Figure 24–14A). After activation by an antigen, both B and T cells proliferate and mature into *effector cells*. Effector B cells secrete antibodies; in their most mature form, called *plasma cells*, they are filled with an extensive rough endoplasmic reticulum that is busily making antibodies (Figure 24–14B). In contrast, effector T cells (Figure 24–14C) contain very little endoplasmic reticulum and secrete a variety of cytokines rather than antibodies. Whereas B cell-derived antibodies are widely distributed by the bloodstream, T cell-derived cytokines mainly act locally, on cells the T cell contacts or on noncontacted neighboring cells, although some are carried via the blood and act on distant host cells.

Immunological Memory Depends on Both Clonal Expansion and Lymphocyte Differentiation

The most remarkable feature of the adaptive immune system is that it can respond to millions of different foreign antigens in a highly specific way. Human B cells, for example, collectively can make more than 1012 different antibody molecules that react specifically with the antigen that induced their production. How can B cells and T cells respond specifically to such an enormous diversity of foreign antigens? The answer for both B and T cells is the same. As each lymphocyte develops in a central lymphoid organ, it becomes committed to react with a particular antigen before ever being exposed to it. The cell expresses this commitment in the form of cell-surface receptors that specifically bind the antigen. When a lymphocyte encounters its antigen in a peripheral lymphoid organ, the binding of the antigen to the receptors, with help from co-stimulatory signals (see Figure 24-11, and discussed later), activates the lymphocyte; this causes the lymphocyte to proliferate, thereby producing many more cells with the same antigen-specific receptors—a process called clonal expansion. The encounter with antigen also causes some of the cells to differentiate into effector cells. An antigen therefore selectively stimulates those cells that express complementary antigen-specific receptors and are

Figure 24-14 Electron micrographs of resting and effector B and T cells. (A) This resting lymphocyte could be either a B cell or a T cell, as these cells are difficult to distinguish morphologically until antigen activates them to become effector cells. (B) An effector B cell (a plasma cell). It is filled with an extensive rough endoplasmic reticulum (ER), which is distended with antibody molecules that are secreted in large amounts. (C) An effector T cell, which has relatively little rough ER but is filled with free ribosomes; it secretes cytokines, but in relatively small amounts. The three cells are shown at the same magnification. (A and B. from D. Zucker-Franklin et al., Atlas of Blood Cells: Function and Pathology, 2nd ed. Philadelphia: Lea & Febiger, 1988. Figure 24-15 Clonal selection. An antigen activates only those B and T cells that are already committed to respond to it. The committed cell expresses cell-surface receptors that specifically recognize the antigen. The human adaptive immune system consists of many millions of different B and T cell clones, with cells within a clone expressing the same unique antigen receptor. Before its first encounter with antigen, a clone would usually contain only one or a small number of cells. A particular antigen may activate hundreds of different clones, each expressing a different antigen receptor that binds either a different part of the antigen or the same part with a different binding affinity. Although only B cells are shown here, T cells are selected in a similar way. Note that the antigen receptors on the B cells labeled BB in this diagram have the same antigen-binding site as the antibodies secreted by the effector $B\beta$ cells. As we discuss later, B cells require co-stimulatory signals from T cells to become activated by antigen to proliferate and differentiate into antibody-secreting cells (not shown).

thus already committed to respond to it (Figure 24–15). This arrangement, called clonal selection, provides an explanation for immunological memory, whereby we develop longlasting immunity to many common infectious diseases after our initial exposure to the pathogen—either through natural infection or vaccination.

It is easy to demonstrate such immunological memory in experimental animals. If an animal is immunized once with antigen A, an adaptive immune response (antibody, T cell-mediated, or both) can be detected after several days; the response rises rapidly and exponentially, and then, more gradually, declines. This is the characteristic course of a **primary immune response**, occurring on an animal's first exposure to an antigen. If, after some weeks, months, or even years have elapsed, the animal is immunized again with antigen A, it will usually produce a **secondary immune response** that differs from the primary response: the lag period is shorter, because there are now many more preexisting B or T cells (or both) with specificity for antigen A, and the response is greater and more efficient. These differences indicate that the animal has "remembered" its first exposure to antigen A. If the animal is given a different antigen (for example, antigen B) instead of a second immunization with antigen A, the response is typical of a primary, and not a secondary, immune response. The secondary response therefore reflects antigen-specific immunological memory for antigen A (**Figure 24–16**).

Immunological memory depends on both lymphocyte proliferation and differentiation. In an adult animal, the peripheral lymphoid organs contain a mixture of B and T cells in at least three stages of maturation: *naïve cells, effector cells,* and *memory cells*. When **naïve cells** encounter their specific foreign antigen for the first time, the antigen stimulates some of them to proliferate and differentiate into **effector cells**, which then carry out an immune response: effector B cells secrete antibody, whereas effector T cells either kill infected cells (see Figure 24–2) or influence the response of other immune cells—by secreting cytokines, for example. Whereas most of the effector cells die after the pathogen has been eliminated,

MBOC7_ptr_ch24_1353-1404.indd 1367 02/12/21 12:22 PM

a long-lived population of **memory cells** usually persists, which can more easily and more quickly be induced to become effector cells by a later encounter with the same antigen: like naïve cells, when memory cells encounter their antigen, they give rise to effector cells and more memory cells (Figure 24–17).

Thus, during the primary response, clonal expansion and differentiation creates many antigen-specific memory cells, some of which can persist as a population for the lifetime of the animal, even in the absence of their specific antigen, thereby providing lifelong protection against the pathogen. Whereas many newly formed memory T and B cells join the pool of T and B cells that continually recirculate through peripheral lymphoid organs (discussed shortly), some memory T cells remain permanently at the site of pathogen entry as *tissue-resident memory T cells*, which provide long-term local protection against reinfection. In addition, a small proportion of the plasma cells produced in a primary B cell response in a peripheral lymphoid organ migrate to the bone marrow, where they can survive for years and continue to secrete their specific antibodies into the bloodstream, contributing to long-term immunological memory.

Most B and T Cells Continually Recirculate Through Peripheral Lymphoid Organs

Pathogens generally enter the body through an epithelial surface, usually through the skin, gut, or respiratory tract. To induce an adaptive immune response, pathogenic microbes or their products must travel from these entry points to a peripheral lymphoid organ such as a lymph node, where B and T cells become activated (see Figure 24–11). The route and destination depend on the site of entry. Lymphatic vessels carry antigens that enter through the skin or respiratory tract to local lymph nodes; antigens that enter through the gut end up in gut-associated peripheral lymphoid organs such as Peyer's patches; and the spleen filters out antigens that enter the blood (see Figure 24–12). As discussed earlier (see Figure 24–11), in many cases, activated dendritic cells will carry the antigen from the site of infection to the peripheral lymphoid organ, where they play a crucial part in activating T cells, as we discuss later.

But only a tiny fraction of naïve B and T cells can recognize a particular microbial antigen in a peripheral lymphoid organ, a reasonable estimate being between 1/10,000 and 1/1,000,000 of each class of lymphocyte, depending on the antigen. How do these rare cells find an antigen-presenting cell displaying their specific antigen? The answer is that the lymphocytes continually recirculate between one peripheral lymphoid organ and another via the lymph and blood. In a lymph node, for example, lymphocytes continually leave the bloodstream by squeezing out between specialized endothelial cells lining small veins called *postcapillary venules*. After percolating through the node, they accumulate in small lymphatic vessels that leave the node and connect with other lymphatic vessels that pass through other lymph nodes downstream (see Figure 24–12). Passing into larger

Figure 24-16 Immunological memory: primary and secondary antibody responses. The secondary response induced by a second exposure to antigen A is faster and greater than the primary response and is specific for A, indicating that the adaptive immune system has specifically remembered its previous encounter with antigen A. The same type of immunological memory is observed in T cell-mediated responses (not shown). As we discuss later, the types of antibodies produced in the secondary response are different from those produced in the primary response, and these antibodies bind the antigen more tightly.

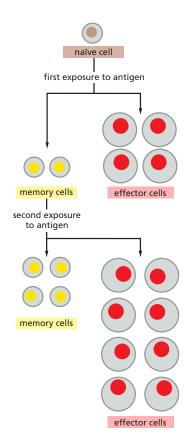

Figure 24-17 Clonal expansion and production of memory cells as the cellular basis of immunological memory. When stimulated by their specific antigen and co-stimulatory signals, both naïve B and T cells proliferate and differentiate, producing both effector cells and memory cells. In principle, memory cells could form either directly from naïve cells, as shown here, or from "retired" effector cells (not shown); for some types of T cells, at least, effector cells can become memory cells. When exposed to the same antigen in the presence of co-stimulatory signals, memory cells respond more readily, rapidly, and efficiently than do naïve cells.

and larger vessels, the lymphocytes eventually enter the main lymphatic vessel (the *thoracic duct*), which carries them back into the blood (Figure 24–18).

The continual recirculation of a lymphocyte between the blood and lymph ends only if its specific antigen activates it in a peripheral lymphoid organ. In that case, the lymphocyte remains in the peripheral lymphoid organ, where it proliferates and differentiates to produce effector and memory T and B cells. Many of the effector T cells leave the lymphoid organ via the lymph and migrate through the blood to the site of infection (see Figure 24–11), whereas others stay in the lymphoid organ and help activate B cells to differentiate into antibody-secreting cells and undergo further maturation (discussed later). Some effector B cells (including some of the most mature, plasma cells) remain in the peripheral lymphoid organ and secrete antibodies into the blood and undergo further maturation (discussed later). Many of the memory B and T cells produced in a peripheral lymphoid organ join the recirculating pool of naïve and memory lymphocytes.

Lymphocyte recirculation depends on specific interactions between the lymphocyte cell surface and the surface of the endothelial cells lining the blood vessels in the peripheral lymphoid organs. Lymphocytes that enter a lymph node via the blood, for example, adhere weakly to specialized endothelial cells lining the postcapillary venules via *homing receptors* that belong to the *selectin* family of cell-surface lectins that bind to specific sugar groups on the endothelial cell surface (see Figure 19–28). The lymphocytes roll slowly along the surface of the endothelial cells until another, much stronger adhesion system, dependent on an integrin protein, is called into play by chemokines secreted by the endothelial cells. Now, the lymphocytes stop rolling, and they crawl out of the blood vessel into the lymph node by using yet another cell adhesion protein called CD31 (Figure 24–19). Although B and T cells initially enter the same region of a lymph node, different chemokines guide them to separate regions of the node—B cells to *lymphoid follicles* and T cells to the *paracortex* (Figure 24–20).

Unless they encounter their antigen, both B and T cells soon leave the lymph node via efferent lymphatic vessels. If they encounter their antigen, however, they are stimulated to display adhesion receptors that trap the cells in the node; the cells accumulate at the junction between the B cell and T cell areas, where the

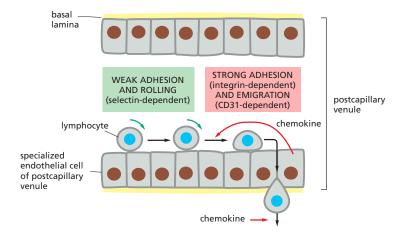

Figure 24–19 Migration of a lymphocyte out of the bloodstream into a lymph node. A recirculating lymphocyte adheres weakly to the surface of the specialized endothelial cells lining a postcapillary venule in a lymph node (see Figure 24–18). This initial adhesion is mediated by L-selectin (discussed in Chapter 19) on the lymphocyte surface. The adhesion is sufficiently weak to enable the lymphocyte, pushed by the flow of blood, to roll along the surface of the endothelial cells. Stimulated by chemokines secreted by specialized endothelial cells in the node (curved red arrow), the lymphocyte rapidly activates a stronger adhesion system, mediated by an integrin protein. This strong adhesion enables the cell to stop rolling. The lymphocyte then uses an immunoglobulin-like cell adhesion protein (CD31) to bind to the junctions between adjacent endothelial cells and migrate out of the venule. The subsequent migration of the lymphocyte in the lymph node is directed by chemokines produced within the node (straight red arrow). The migration of other types of leukocytes out of the bloodstream into sites of infection occurs in a similar way (see Figure 19–28 and Movie 19.2).

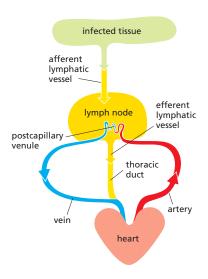

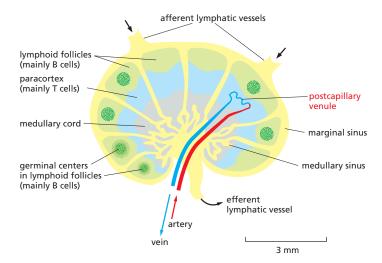

Figure 24-18 The path followed by lymphocytes that continually recirculate between the lymph and blood. The circulation through a lymph node (yellow) is shown here. Microbial antigens are usually carried into the lymph node by activated dendritic cells (not shown), which enter the node via afferent lymphatic vessels draining an infected tissue (green). B and T cells, by contrast, enter via the blood, migrating out of the bloodstream into the lymph node through postcapillary venules. Unless they encounter their antigen, the B and T cells leave the lymph node via efferent lymphatic vessels, which eventually join the thoracic duct. The thoracic duct empties into a large vein carrying blood to the heart, completing the recirculation cycle for T and B cells. A typical recirculation cycle for these lymphocytes takes about 12-24 hours.

MBOC7_ptr_ch24_1353-1404.indd 1369 02/12/21 12:22 PM

rare antigen-specific B and T cells can interact, leading to their proliferation and differentiation into either effector cells or memory cells. Many of the effector cells leave the node, expressing different chemokine receptors that help guide them to their new destinations—effector plasma cells to the bone marrow, for example, and effector T cells to sites of infection.

Immunological Self-tolerance Ensures That B and T Cells Do Not Attack Normal Host Cells and Molecules

As discussed earlier, cells of the innate immune system use PRRs to distinguish microbial molecules from self molecules made by the host. The adaptive immune system has the far more difficult recognition task of responding specifically to an almost unlimited number of foreign molecules while not responding to the large number of self molecules. How does it accomplish this feat? It helps that self molecules normally do not induce the innate immune reactions required to activate adaptive immune responses. But even when an infection or tissue injury triggers innate reactions, the vast majority of self molecules normally still fail to induce an adaptive immune response. Why?

One important reason is that the adaptive immune system "learns" not to respond to self molecules. Normal mice, for example, cannot mount an immune response against one of their own protein components of the complement system called C5 (see Figure 24–7). However, mutant mice that lack the gene encoding C5 but are otherwise genetically identical to normal mice of the same strain can make a strong immune response to this blood protein when immunized with it. The **immunological self-tolerance** exhibited by normal mice persists only for as long as the self molecule remains in the body: if a self molecule such as C5 is experimentally removed from an adult mouse, the animal gains the ability to respond to it after a few weeks or months, as new B and T cells develop in the absence of C5. Thus, the adaptive immune system is genetically capable of responding to self molecules but deploys multiple strategies to avoid doing so.

Self-tolerance depends on a number of distinct mechanisms, including the following (Figure 24–21):

- 1. In *receptor editing*, developing B cells that recognize self molecules change their antigen receptors so that the cells no longer do so.
- 2. In *clonal deletion*, large numbers of developing, potentially self-reactive B and T cells die by apoptosis when they encounter their particular self molecule.
- 3. In *clonal inactivation* (also called clonal anergy), self-reactive B and T cells become functionally inactivated when they encounter their self molecule.

Figure 24-20 A simplified drawing of a human lymph node. B cells are mainly found in lymphoid follicles, whereas T cells are found mainly in the paracortex. Some of the lymphoid follicles contain germinal centers, where B cells, activated by their specific antigen (with the help of activated T cells), proliferate rapidly and differentiate into memory and effector cells (as discussed later). Chemokines attract resting B and T cells into the lymph node from the blood via postcapillary venules (see Figure 24-19), after which the two cell types migrate to their respective areas, attracted by different chemokines. If they do not encounter their specific antigen, both B and T cells then migrate to the medullary sinus and leave the node via the efferent lymphatic vessel, which carries the lymph away from the node to a downstream lymph node (not shown). After traveling from node to node, the lymph enters a large lymphatic vessel, the thoracic duct, that empties into the bloodstream to begin another cycle of B and T cell circulation through peripheral lymphoid organs (see Figure 24-18).

MBOC7_ptr_ch24_1353-1404.indd 1370 02/12/21 12:22 PM

 In clonal suppression, self-reactive regulatory T cells (discussed later) suppress the activity of other types of potentially self-reactive lymphocytes.

As we discuss later, some of these mechanisms—especially the first two, receptor editing in B cells and clonal deletion of B and T cells—operate in central lymphoid organs when self-reactive developing B and T cells first encounter their self molecules, and they are largely responsible for the process called *central tolerance*. Clonal inactivation and clonal suppression, by contrast, operate mainly when mature B and T cells encounter their self molecules in peripheral lymphoid organs, and they are largely responsible for the process called *peripheral tolerance*. Clonal deletion, however, can also operate peripherally, and clonal inactivation can also operate centrally.

Why does the binding of a self molecule lead to tolerance rather than activation? The answer is still not completely known. As we discuss later, the activation of a B or T cell by its antigen in a peripheral lymphoid organ requires more than just antigen binding: it requires co-stimulatory signals, which are provided by a helper T cell in the case of a B cell and by an activated dendritic cell in the case of a naïve T cell. The production of such signals is usually triggered by exposure to a pathogen, but a self-reactive lymphocyte normally encounters its self antigen in the absence of such signals. Under these conditions, the lymphocyte will not only fail to be activated, it will often be rendered tolerant—being killed (deleted), or inactivated, or suppressed by a regulatory T cell (see Figure 24–21). In peripheral lymphoid organs, both T cell tolerance and activation usually occur through interactions with a dendritic cell, although the type or state of the dendritic cell is different in the two cases.

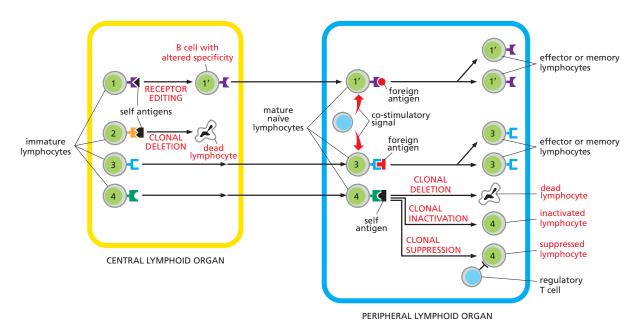

Figure 24–21 Mechanisms of immunological self-tolerance. When a potentially self-reactive immature B cell recognizes a specific self antigen in the central lymphoid organ (the bone marrow) where the cell is produced, it may alter its antigen receptor so that it no longer recognizes the self antigen (cell 1); this process is called receptor editing. Alternatively, when either a potentially self-reactive developing B or T cell recognizes a specific self antigen in a central lymphoid organ, it may die by apoptosis, a process called clonal deletion (cell 2). Because these two forms of tolerance (shown on the left) occur in central lymphoid organs, they are called *central tolerance*.

When a potentially self-reactive developing B or T cell escapes tolerance in the central lymphoid organ and binds its specific self antigen in a peripheral lymphoid organ (cell 4) or in a nonlymphoid peripheral tissue (not shown), it will generally not be activated, because the binding usually occurs in the absence of sufficient co-stimulatory signals; instead, the cell may die by apoptosis (often after a period of proliferation), be inactivated, or be suppressed by a regulatory T cell. These forms of tolerance (shown on the right) are called *peripheral tolerance*. As discussed later, the cells providing the co-stimulatory signals are T lymphocytes for B cells and usually dendritic cells for T cells (not shown).

MBOC7_ptr_ch24_1353-1404.indd 1371 02/12/21 12:22 PM

For reasons that are usually unknown, self-tolerance mechanisms sometimes fail, causing T or B cells (or both) to react against the animal's own molecules. *Myasthenia gravis* is an example of such an **autoimmune disease**. Most of the affected individuals make antibodies against the acetylcholine receptors on their own skeletal muscle cells; these receptors are required for the muscle to contract normally in response to nerve stimulation, which releases acetylcholine (see Figure 11–39). The antibodies interfere with the normal functioning of the receptors so that the individuals become weak and may die because they cannot breathe. Similarly, in *juvenile* (type 1) diabetes, adaptive immune reactions against insulin-secreting β cells in the pancreas kill these cells, leading to severe insulin deficiency.

Summary

The human adaptive immune system is composed of many millions of B and T cell clones, with the cells in each clone sharing a unique cell-surface receptor that enables them to bind a particular pathogen antigen. The binding of antigen to these receptors, with the help of membrane-bound co-stimulatory signals, activates the lymphocyte to proliferate and differentiate into an effector cell that helps eliminate the pathogen. Effector B cells secrete antibodies, which can act over long distances to help eliminate extracellular pathogens and to neutralize their toxins. Effector T cells, by contrast, produce cell-surface co-stimulatory molecules and secreted cytokines, which act locally to help other immune cells eliminate the pathogen; in addition, some T cells induce infected host cells to kill themselves.

During a primary adaptive immune response to an antigen, B and T cells that recognize the antigen proliferate, so there are more of them to respond the next time, during a secondary response to the same antigen. Moreover, although most effector cells produced during a primary response die after the pathogen is eliminated, some of the lymphocytes activated during the primary response become long-lived memory cells, which can respond faster and more efficiently the next time the same pathogen invades. These two mechanisms-clonal expansion and differentiation into memory cells-are largely responsible for immunological memory. Both B and T cells circulate continually between one peripheral lymphoid organ and another via the blood and lymph; only if they encounter their specific foreign antigen in a peripheral lymphoid organ do they stop migrating, proliferate, and differentiate into effector cells and memory cells. B and T cells that would react against self molecules either alter their receptors (in the case of B cells) or are eliminated, inactivated, or suppressed by regulatory T cells. These mechanisms collectively are responsible for immunological self-tolerance, which helps ensure that the adaptive immune system normally avoids attacking the molecules and cells of the host.

B CELLS AND IMMUNOGLOBULINS

We would die of infection if we were unable to make antibodies. Antibodies are secreted proteins that defend us against extracellular pathogens in several ways. They bind to viruses and microbial toxins, thereby preventing them from binding to host cells (see Figure 24–2). When bound to an extracellular pathogen or its products, antibodies also recruit some of the components of the innate immune system, including various types of leukocytes and components of the complement system, which work together to inactivate or eliminate the invaders.

Antibodies are synthesized exclusively by B cells. They are produced in billions of different varieties, each with a unique antigen-binding site formed by one or more unique amino acid sequences. They belong to the class of proteins called **immunoglobulins** (abbreviated as **Igs**) and are among the most abundant protein components in the blood. In this section, we discuss the structure and function of immunoglobulins and how each of us can make them with so many different antigen-binding sites.

MBOC7_ptr_ch24_1353-1404.indd 1372 02/12/21 12:22 PM

B Cells Make Immunoglobulins (Igs) as both Cell-Surface Antigen Receptors and Secreted Antibodies

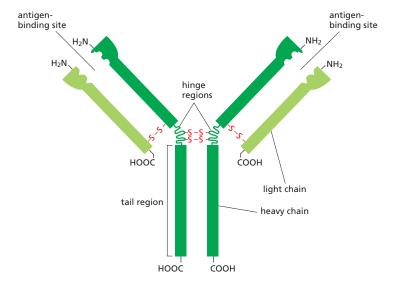

The first Igs made by a developing B cell are not secreted but are instead inserted into the plasma membrane, where they serve as receptors for antigen. They are called B cell receptors (BCRs), and each B cell has approximately 10^5 of them on its surface. Each BCR is stably associated with invariant transmembrane proteins that activate intracellular signaling pathways when antigen binds to the BCR; we discuss these invariant proteins later, when we consider how B cells are activated with the assistance of *helper T cells*.

Each B cell clone produces a single species of BCR, with a unique antigen-binding site. When an antigen and a helper T cell activate a naïve or a memory B cell, the B cell proliferates and differentiates into an effector cell, which then produces and secretes large amounts of soluble (rather than membrane-bound) Ig. The secreted Ig is now called an antibody, and it has the same unique antigen-binding site as the BCR (Figure 24–22; and see Figure 24–15).

A typical Ig molecule is bivalent, with two identical antigen-binding sites. It consists of four polypeptide chains—two identical *light chains* and two identical *heavy chains*. The N-terminal parts of both light and heavy chains usually cooperate to form the antigen-binding surface, while the more C-terminal parts of the heavy chains form the tail of the Y-shaped protein (Figure 24–23). The tail mediates many of the activities of antibodies, and antibodies with the same antigen-binding sites can have any one of a number of different tail regions, each of which gives the antibody different functional properties, such as the ability to activate complement or to bind to receptor proteins on various immune cells that bind a specific type of antibody tail.

Mammals Make Five Classes of Igs

We can make five major *classes* of Igs, each of which mediates a characteristic biological response after antigen binding to an antibody: IgA, IgD, IgE, IgG, and IgM, each with its own class of heavy chain (α , δ , ϵ , γ , and μ , respectively). IgA molecules have α chains, IgG molecules have γ chains, and so on. Moreover, there are four IgG subclasses (IgG1, IgG2, IgG3, and IgG4), with γ_1 , γ_2 , γ_3 , and γ_4 heavy chains, respectively, and there are two IgA subclasses. In addition to the various classes and subclasses of heavy chains, we make two types of light chains, κ and λ , which seem to be functionally indistinguishable. Either type of light chain can be associated with any of the heavy chains, but an individual Ig molecule always contains identical light chains and identical heavy chains: an IgG molecule, for instance, can have either κ or λ light chains, but not one of each. As a result, an Ig's antigen-binding sites are always identical (see Figures 24–22 and 24–23).

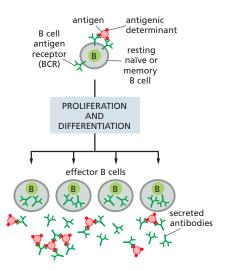

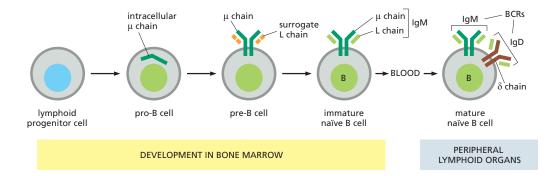

Figure 24-22 Activation of a B cell by antigen. The binding of an antigen to the B cell receptors (BCRs) on either a naïve or a memory B cell (together with co-stimulatory signals provided by helper T cells—not shown) activates the cell to proliferate and differentiate into antibodysecreting, effector B cells. The effector cells produce and secrete antibodies with a unique antigen-binding site, which is the same as that of the cell-surface BCRs. Because typical antibodies have two identical antigen-binding sites, they can cross-link antigens, as shown for an antigen with multiple, identical, antigenic determinants—the parts of an antigen an antibody or antigen receptor binds to.

Figure 24–23 A schematic drawing of a bivalent antibody molecule. The distal ends of the light and heavy chains together form the two antigen-binding sites. The two heavy chains each have a hinge region (not present in all classes of heavy chains), which, because of its flexibility, improves the efficiency with which the antibody can cross-link antigens (see Figure 24–22). The two heavy chains also form the tail of the antibody, which determines the functional properties of the antibody. The heavy and light chains are held together by a combination of covalent S–S bonds (red) and noncovalent bonds (not shown).

MBOC7_ptr_ch24_1353-1404.indd 1373 02/12/21 12:22 PM

All classes of human Ig can be made in a membrane-bound BCR form, as well as in a soluble, secreted antibody form. The two forms differ only in the C-terminus of their heavy chain. The heavy chains of membrane-bound Ig molecules (BCRs) have a transmembrane hydrophobic C-terminus, which anchors them in the lipid bilayer of the B cell's plasma membrane. The heavy chains of secreted antibody molecules, by contrast, have instead a hydrophilic C-terminus, which allows them to escape from the cell. The switch in the character of the Ig molecules made occurs because the activation of B cells by antigen and helper T cells induces a change in the way in which the heavy-chain RNA transcripts are made and processed in the nucleus (see Figure 7–62).

The various Ig heavy chains give a distinctive conformation to the tail region of secreted antibodies, so that each class (and subclass) has characteristic properties of its own. **IgM** is always the first class of Ig that a developing B cell in the bone marrow makes. It forms the BCRs on the surface of *immature naïve B cells*. After these cells leave the bone marrow, they start to produce **IgD** BCRs as well, with the same antigen-binding site as the IgM BCRs. These cells are now called *mature naïve B cells*, as they can now respond to their specific foreign antigen if they encounter it in a peripheral lymphoid organ (**Figure 24–24**). IgM is also the major class of antibody secreted into the blood in the early stages of a primary antibody response on first exposure to an antigen. In its secreted form, IgM is a wheel-like pentamer composed of five four-chain units, giving it a total of 10 antigen-binding sites that allow it to bind strongly to pathogens; in its antigen-bound form, IgM is highly efficient at activating complement, which is important in early antibody responses to pathogens.

IgM and IgD are the only classes of Igs made before a B cell is activated by antigen, at which stage they are made only as BCRs. All the other Ig classes are made only after antigen stimulation, as both BCRs and antibodies. **IgG** antibodies are four-chain monomers (see Figure 24–23), and they are secreted into the blood in especially large quantities during secondary antibody responses to most antigens. The tail region of some subclasses of IgG antibodies that are bound to antigen can activate complement and also bind to specific receptors on macrophages and neutrophils. Largely by means of such **Fc receptors** (so named because antibody tails are called Fc regions), these phagocytic cells bind, ingest, and destroy infecting microorganisms that have become coated with the IgG antibodies produced in response to the infection (see Figure 24–5); the activated Fc receptors also signal the phagocyte to secrete pro-inflammatory cytokines (Movie 24.4).

IgE antibodies are produced in response to parasites and, in genetically susceptible individuals, to otherwise harmless environmental antigens (allergens) such as pollen, foods, and drugs. The IgE tail region binds to another class of Fc receptors on the surface of *mast cells* in tissues and of *basophils* in the blood (see Figures 22–11 and 22–12). Because antigen-free IgE antibodies bind with high affinity to such Fc receptors, the antibodies act as acquired antigen receptors on these cells. Antigen binding to the bound antibodies activates the Fc receptors and stimulates the cells to secrete a variety of cytokines and biologically active amines, especially *histamine*, which causes blood vessels to dilate and become leaky; this helps leukocytes, antibodies, and complement components to enter sites

Figure 24-24 Stages of B cell development. All of the stages shown occur before the B cells bind their specific foreign antigen. The first cells in the B cell lineage that make Ig are called pro-B cells; they make u heavy chains, which remain in the membrane of the endoplasmic reticulum until a special type of light (L) chain is made, called a surrogate light chain. The surrogate light chains substitute for genuine light chains and assemble with u chains to form a temporary receptor molecule that is delivered to the plasma membrane. The cells are now called pre-B cells. Signaling from this pre-B cell receptor allows the cells to make bona fide light chains, which combine with u chains to form four-chain IgM molecules that serve as antigen-specific, cell-surface BCRs on immature naïve B cells. After these cells leave the bone marrow (labeled in yellow shading), they start to express IgD BCRs as well. which have the same antigen-binding sites as the IaM BCRs: it is this mature naïve B cell that reacts with its specific foreign antigen in peripheral lymphoid organs (labeled in blue shading).

Binds to mast cells and basophils	-	-	+ (IgG1 and IgG3)	_	+	

where mast cells have been activated. The release of amines from mast cells and basophils is largely responsible for the symptoms of such *allergic reactions* as hay fever, asthma, and hives. In addition, mast cells secrete factors that attract and activate *eosinophils* (see Figures 22–11 and 22–12), which also have Fc receptors that bind IgE molecules and can kill extracellular parasitic worms, especially if the worms are coated with IgE antibodies (see Figure 24–6).

IgA is the principal antibody class in secretions, including saliva, tears, milk, and respiratory and intestinal tract secretions. Yet another class of Fc receptors, located on the relevant epithelial cells, guides the secretion by binding antigen-free IgA dimers and transporting them from the extracellular fluid across the epithelium by the process of transcytosis (see Figure 13–56). Some of this IgA is directed against commensal microbes and keeps them in check by preventing them from binding to mucosal epithelial cells. The properties of the various classes of antibodies in humans are summarized in Table 24–2.

Ig Light and Heavy Chains of Antibodies Consist of Constant and Variable Regions

Both the light and heavy chains of antibodies have a variable amino acid sequence at their N-terminal ends but a constant sequence at their C-terminal ends. Whereas the **constant region** and **variable region** of a light chain are the same size, the constant region of a heavy chain is about three or four times longer than its variable region, depending on the class (**Figure 24–25**).

The variable regions of the light and heavy chains come together to form the antigen-binding sites, and the variability of their amino acid sequences provides the structural basis for the diversity of these binding sites. The greatest diversity

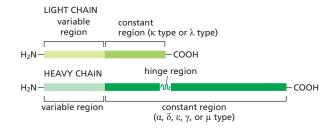

Figure 24-25 Constant and variable regions of antibody chains. The variable regions of both the light and heavy chains form the antigen-binding sites, while the constant regions of the heavy chains determine the other functional properties of an antibody molecule. The different subclasses of IgG antibodies have different γ-chain constant regions. An individual Ig protein has either κ or λ light chains but not both. Note that the heavy chain of the BCR form of each class of Ig has an additional, transmembrane domain at its C-terminus (not shown), and the constant regions of the μ and ϵ heavy chains do not have a hinge region (not shown).

MBOC7_ptr_ch24_1353-1404.indd 1375 02/12/21 12:22 PM

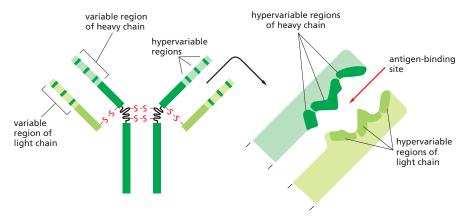

Figure 24–26 Ig hypervariable regions. Highly schematized drawing of how the three hypervariable regions in each light and heavy chain together form each antigen-binding site of an Ig protein.

occurs in three small **hypervariable regions** in the variable regions of both light and heavy chains. Only about 5–10 amino acids in each hypervariable region form the actual antigen-binding site (**Figure 24–26**). As a result, the size of the **antigenic determinant** that an Ig molecule recognizes is generally small: it can consist of fewer than 10 amino acids on the surface of a globular protein, for example (see Figure 24–22).

Both light and heavy chains are made up of repeating segments—each about 110 amino acids long and each containing one intrachain disulfide bond. Each repeating segment folds independently to form a compact functional unit called an **immunoglobulin (Ig) domain**. As shown in **Figure 24–27A**, a light chain consists of one variable (V_L) and one constant (C_L) domain, whereas a heavy chain

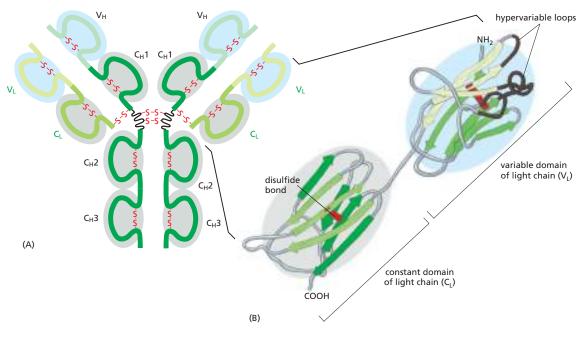

Figure 24–27 Ig domains. (A) The light and heavy chains in an Ig protein are each folded into similar repeating domains. The variable domains (shaded in blue) of the light and heavy chains (V_L and V_H) make up the antigen-binding sites, while the constant domains (shaded in gray) of the heavy chains (mainly C_H2 and C_H3) determine the other functional properties of the protein. The heavy chains of IgM and IgE do not have a hinge region and have an extra constant domain (C_H4 —not shown). Hydrophobic interactions between domains on adjacent chains help hold the chains together in the Ig molecule: V_L binds to V_H , V_L binds to V_H , V_L binds to V_H , and so on. (B) X-ray crystallography—based structures of the Ig domains of a light chain (Movie 24.5). The variable and constant domains have a similar overall structure, consisting of two β sheets joined by a disulfide bond (red). Note that all the hypervariable regions (black) form loops at the far end of the variable domain, where they come together to form part of the antigen-binding site. All Igs are glycosylated on their C_H2 domains (not shown); the attached oligosaccharide chains vary from Ig to Ig and can greatly influence the functional properties of the protein, mainly by affecting its binding to Fc receptors on immune cells.

MBOC7_ptr_ch24_1353-1404.indd 1376 02/12/21 12:22 PM

has one variable and three or four constant domains: the variable domains of the light and heavy chains pair to form the antigen-binding region. Each Ig domain has a very similar three-dimensional structure, consisting of a sandwich of two β sheets held together by a disulfide bond; the variable domains are unique in that each has its particular set of hypervariable regions, which are arranged in three hypervariable loops that cluster together at the ends of the variable domains to form the antigen-binding site (Figure 24–27B).

Ig Genes Are Assembled from Separate Gene Segments During B Cell Development

Prior to antigen stimulation, the human **primary Ig repertoire** is probably composed of more than 10^{12} different BCRs. This repertoire consists of IgM and IgD proteins and is apparently large enough to ensure that there will be an antigen-binding site to fit almost any potential antigenic determinant, albeit with low affinity ($K_a \approx 10^5 - 10^7$ liters/mole). After stimulation by antigen and helper T cells, B cells can switch from making IgM and IgD to making other classes of Ig—a process called *class switching*. In addition, the binding affinity of these Igs for their antigen progressively increases over time—a process called *affinity maturation*. Thus, antigen stimulation generates a **secondary Ig repertoire**, with a greatly increased affinity (K_a up to 10^{11} liters/mole) and a greater diversity of both Ig classes and antigen-binding sites.

How can each of us make so many different Igs? The problem is not quite as formidable as it might first appear. Recall that the variable regions of the Ig light and heavy chains usually combine to form the antigen-binding site. Thus, if we had 1000 genes encoding light chains and 1000 genes encoding heavy chains, we could, in principle, combine their products in 1000×1000 different ways to make 10^6 different antigen-binding sites. Nonetheless, we have evolved special genetic mechanisms to enable our B cells to generate an almost unlimited number of different light and heavy chains in a remarkably economical way. We do so in two steps. First, before antigen stimulation, developing B cells join together separate *gene segments* in DNA to create the genes that encode the primary repertoire of low-affinity IgM and IgD proteins. Second, after antigen stimulation, the assembled *Ig genes* can undergo two further changes—point mutations that can increase the affinity of their antigen-binding site and DNA rearrangements that switch the class of Ig made. Together, these changes produce the secondary repertoire of high-affinity IgG, IgE, and IgA proteins.

We produce our primary Ig repertoire by joining separate **Ig gene segments** together during B cell development. Each type of Ig chain— κ light chains, λ light chains, and heavy chains—is encoded by a separate locus on a separate chromosome. Each locus contains a large number of gene segments encoding the V region of an Ig chain and one or more gene segments encoding the C region. During the development of a B cell in the bone marrow, a complete coding sequence for each of the two Ig chains to be synthesized is assembled by site-specific genetic recombination (discussed in Chapter 5). Once a V-region coding sequence is assembled next to a C-region sequence, it can then be co-transcribed and the resulting RNA transcript processed to produce an mRNA molecule that codes for the complete Ig polypeptide chain.

Each light-chain V region, for example, is encoded by a DNA sequence assembled from two gene segments—a long **V** gene segment and a short *joining segment*, or **J** gene segment (Figure 24–28). Each heavy-chain V region is similarly constructed by combining gene segments, but here an additional *diversity segment*, or **D** gene segment, is also required (Figure 24–29). In addition to bringing together the separate gene segments of the Ig gene, these rearrangements also activate transcription from the gene promoter through changes in the relative positions of the *cis*-regulatory DNA sequences acting on the gene. Thus, a complete Ig chain can be synthesized only after the DNA has been rearranged.

The large number of inherited V, J, and D gene segments available for encoding Ig chains contributes substantially to Ig diversity, and the combinatorial joining of

MBOC7_ptr_ch24_1353-1404.indd 1377 02/12/21 12:22 PM

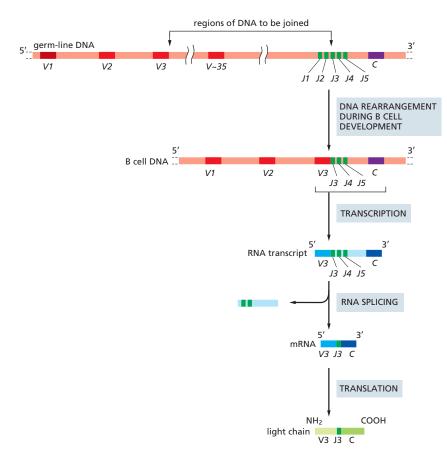

Figure 24–28 The V–J joining process involved in making a human κ light chain. In the "germ-line" DNA (where the Ig gene segments are not rearranged and are therefore not being expressed), the cluster of five J gene segments (green) is separated from the C-region coding sequence (purple) by a short intron and from the 35 or so functional V gene seaments (red) by thousands of nucleotide pairs. During the development of a B cell, a randomly chosen V gene segment (V3 in this case) is moved to lie precisely next to one of the J gene segments (J3 in this case). The "extra" J gene segments (J4 and J5) and the intron sequence are transcribed (along with the joined V3 and J3 gene segments and the C-region coding sequence) and then removed by RNA splicing to generate mRNA molecules with contiguous V3, J3, and C sequences, as shown. These mRNAs are then translated into κ light chains. A J gene segment encodes the 15 or so C-terminal amino acids of the V region, and a short sequence containing the V-J segment junction encodes the third hypervariable region, which is the most variable part of the light-chain V region.

these segments (called *combinatorial diversification*) greatly increases this contribution. Any of the 35 or so functional V segments in our κ light-chain locus, for example, can be joined to any of the 5 J segments (see Figure 24–28), so that this locus can encode at least 175 (35 \times 5) different κ -chain V regions. Similarly, any of the 40 V segments in the human heavy-chain locus can be joined to any of the 23 or so D segments and to any of the 6 J segments to encode at least 5520 (40 \times 23 \times 6) different heavy-chain V regions. By this mechanism alone, called V(D)J recombination, a human can produce 295 different V_L regions (175 κ and 120 λ) and 5520 different V_H regions. In principle, these could then be combined to make more than 1.6×10^6 (295 \times 5520) different antigen-binding sites.

V(D)J recombination is mediated by an enzyme complex called V(D)J recombinase, which recognizes recombination signal sequences in the DNA that flanks each gene segment to be joined. Although the process ensures that only appropriate gene segments recombine, a variable number of nucleotides are often lost from the ends of the recombining gene segments, and one or more randomly chosen nucleotides are also inserted. This random loss and gain of nucleotides at joining sites is called **junctional diversification**, and it greatly increases the diversity of V-region coding sequences created by V(D)J recombination (between 10^7 -fold and 10^8 -fold), specifically in the third hypervariable region. This increased diversification comes at a price, however. In many cases, it shifts the reading frame to produce a nonfunctional gene, in which case the developing B cell fails to make a functional Ig molecule and consequently dies in the bone marrow by apoptosis. Once a B cell makes a functional heavy chain and light chain that form an

Figure 24–29 The human heavy-chain locus. There are 40 V segments, about 23 D segments, 6 J segments, and an ordered cluster of C-region coding sequences, each cluster encoding a different class of heavy chain. The D segment (and part of the J segment) encodes amino acids in the third hypervariable region, which is the most variable part of the heavychain V region. The genetic mechanisms involved in producing a heavy chain are the same as those shown in Figure 24-28 for light chains, except that two DNA rearrangement steps are required instead of one: first a D segment joins to a J segment, and then a V segment joins to the rearranged DJ segment. The rearrangements lead to the production of a VDJC mRNA that encodes a complete Ig heavy chain. The figure is not drawn to scale: the total length of the heavychain locus is more than 2 megabases. Moreover, a number of details are omitted; for example, the exons encoding each C-region Ig domain and the hinge region (see Figure 24-27) and the different subclasses of C_v-coding segments are not shown.

MBOC7_ptr_ch24_1353-1404.indd 1378 02/12/21 12:22 PM

antigen-binding site, it turns off the V(D)J recombination process, thereby ensuring that the cell makes Ig of only one antigen-binding specificity.

B cells making BCRs that bind strongly to self antigens in the bone marrow would be dangerous. Such B cells are signaled by the self-binding to maintain expression of an active V(D)J recombinase and undergo a second round of V(D)J recombination in a light-chain locus, thereby changing the specificity of its BCR—in the process of **receptor editing** discussed earlier; self-reactive B cells that fail to change their specificity die by apoptosis, in the process of clonal deletion (see Figure 24–21).

Antigen-driven Somatic Hypermutation Fine-Tunes Antibody Responses

As mentioned earlier, with the passage of time after an infection or vaccination, there is usually a progressive increase in the affinity of the antibodies produced against the pathogen. This phenomenon of **affinity maturation** is due to the accumulation of point mutations in both heavy-chain and light-chain V-region coding sequences. The mutations occur long after the coding regions have been assembled. After B cells have been stimulated by both antigen and helper T cells in a peripheral lymphoid organ, some of the activated B cells proliferate rapidly in some lymphoid follicles and form *germinal centers* (see Figure 24–20). Here, the B cells mutate at the rate of about one mutation per V-region coding sequence per cell generation. Because this is about a million times greater than the spontaneous mutation rate in other genes and occurs in somatic cells rather than germ cells, the process is called **somatic hypermutation**.

Very few of the altered Igs generated by hypermutation will have an increased affinity for the antigen. However, the antigen will stimulate preferentially those few B cells that do make BCRs with increased affinity for the antigen. Clones of these altered B cells will preferentially survive and proliferate, especially as the amount of antigen decreases to very low levels late in the response. Most other B cells in the germinal center will die by apoptosis. Thus, as a result of repeated cycles of somatic hypermutation followed by antigen-driven proliferation of selected clones of effector and memory B cells, BCRs and antibodies of increasingly higher affinity become abundant during an adaptive immune response, providing progressively better protection against the pathogen (Movie 24.6).

A breakthrough in understanding the molecular mechanism of somatic hypermutation came with the identification of an enzyme that is required for the process. It is called **activation-induced deaminase (AID)** because it is expressed specifically in activated B cells and deaminates cytosine (C) to uracil (U) during transcription of V-region coding DNA. The deamination produces U:G mismatches in the DNA double helix, and the repair of these mismatches produces various types of mutations, depending on the repair pathway used. Somatic hypermutation affects only actively transcribed DNA, both because AID works only on single-stranded DNA (which is transiently exposed during transcription) and because proteins involved in the transcription of V-region coding sequences are required to recruit the AID enzyme. AID is also required for activated B cells to switch from IgM and IgD production to the production of the other classes of Ig, as we now discuss.

B Cells Can Switch the Class of Ig They Make

After a developing B cell leaves the bone marrow, but before it interacts with antigen, it expresses both IgM and IgD BCRs on its surface, both with the same antigen-binding sites (see Figure 24–24). Stimulation by antigen and helper T cells in a peripheral lymphoid organ activates many of these mature naïve B cells to become IgM-secreting effector cells, so that IgM antibodies dominate the primary antibody response. Later in the immune response, however, when the activated B cells are undergoing somatic hypermutation in germinal centers, the combination of antigen and cytokines derived from helper T cells (discussed later)

MBOC7_ptr_ch24_1353-1404.indd 1379 02/12/21 12:22 PM

stimulates many of the B cells to switch from making membrane-bound IgM and IgD to making IgG, IgE, or IgA, in the process of **class switching**. Some of these cells become memory cells that express the corresponding class of Ig as BCRs on their surface, while others become effector cells that secrete the Ig molecules as antibodies. The IgG, IgE, and IgA molecules initially retain their original antigen-binding sites, which can then undergo affinity maturation in the germinal centers. These class-switched Igs are collectively referred to as *secondary classes* of Igs, because they are produced only after antigen stimulation, dominate secondary antibody responses, and make up the secondary Ig repertoire.

As discussed earlier, the constant region of an Ig heavy chain determines the class of the Ig and hence the Ig's functional properties. Thus, the ability of B cells to switch the class of Ig they make without changing their antigen specificity implies that the same assembled V_H -region coding sequence (which specifies the antigen-binding part of the heavy chain) can sequentially associate with different C_H -coding sequences. This has important functional implications. It means that, in an individual animal, a particular antigen-binding site that has been selected by environmental antigens can be distributed among the various classes of antibodies, thereby acquiring the different functional properties of each class. In this way, antipathogen antibodies harness a variety of effector mechanisms to help clear the pathogen, including activation of the complement system and Fc receptors on phagocytes and other innate immune cells (see Table 24–2).

When a B cell switches from making IgM and IgD to one of the secondary classes of Ig, an irreversible change occurs in the DNA—a process called **class switch recombination**. It entails the deletion of all the C_H-coding sequences between the assembled VDJ-coding sequence and the particular C_H-coding sequence that the cell is destined to express. Class switch recombination differs from V(D)J recombination in several ways. (1) It happens after antigen stimulation, mainly in germinal centers, and depends on helper T cells. (2) It uses different recombination signal sequences, called *switch sequences*, which flank the different C_H-coding segments. (3) It involves cutting and joining the switch sequences, which are noncoding sequences, and leaves the assembled V_H-region coding sequence unchanged (**Figure 24–30**). (4) Most important, the molecular mechanism is different. It depends on AID, which is also involved in somatic hypermutation, rather than on the V(D)J recombinase. The cytokines that activate class switching induce the production of transcription regulators that activate transcription from the relevant switch sequences, allowing the recruitment of

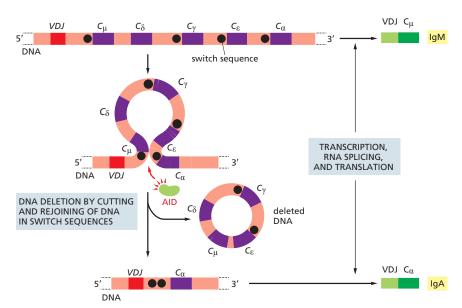

Figure 24-30 An example of the DNA rearrangement that occurs in class switch recombination. A B cell making IgM (and IgD-not shown) molecules with the same heavy-chain V region encoded by a particular assembled VDJ DNA sequence is stimulated to switch to making IgA molecules with the same heavy-chain V region. In the process, it deletes the DNA between the VDJ sequence and the C_{α} -coding sequence. Specific DNA sequences (switch sequences) located upstream of each C_H-coding sequence (except C_{δ} , as B cells don't switch from C_{μ} to C_{δ}) can recombine with one another, with the deletion of the intervening DNA, as shown here. As discussed in the text. the recombination process depends on AID, the same enzyme that is involved in somatic hypermutation. When switching from IgM and IgD to IgG or IgE, the C-region coding sequences downstream of C_{ν} or C_{ϵ} , which remain after the DNA deletion, are removed during RNA splicing.

MBOC7_ptr_ch24_1353-1404.indd 1380 02/12/21 12:22 PM

AID to these sites. Once bound, AID initiates switch recombination by deaminating some cytosines to uracil in the vicinity of these switch sequences. Excision of these uracils is thought to lead to double-strand breaks in the participating switch regions, which are then joined by a form of nonhomologous end joining (discussed in Chapter 5).

Thus, whereas the primary Ig repertoire in humans (and mice) is generated by V(D)J joining mediated by V(D)J recombinase, the secondary antibody repertoire is generated by somatic hypermutation and class switch recombination, both of which are mediated by AID. Figure 24–31 lists the main mechanisms for diversifying Igs that we have discussed in this chapter.

Summary

Each B cell clone makes Ig molecules with a unique antigen-binding site. Initially, the Ig molecules are inserted into the plasma membrane and serve as B cell receptors (BCRs) for antigen. Antigen binding to the BCRs, together with co-stimulatory signals from helper T cells, activate the B cells to proliferate and differentiate into antibody-secreting effector cells or memory cells. The effector cells secrete large amounts of antibodies with the same antigen-binding site as the BCRs.

A typical Ig molecule is composed of four polypeptide chains—two identical heavy chains and two identical light chains. Parts of both the heavy and light chains form the two identical antigen-binding sites. There are multiple classes of Ig (IgA, IgD, IgE, IgG, and IgM), each with a distinctive heavy chain, which determines the functional properties of the Ig class. Each light and heavy chain is composed of a number of similarly folded Ig domains. The amino acid sequence variation in the variable domains of both light and heavy chains is concentrated in several small hypervariable regions, which form loops at one end of these domains to form the antigen-binding site.

Igs are encoded by loci on three different chromosomes, each of which is responsible for producing a different polypeptide chain— $a \kappa$ light chain, $a \lambda$ light chain, or a heavy chain. Each locus contains separate gene segments that encode different parts of the variable region of the particular Ig chain. Each light-chain locus contains one or more constant (C)-region coding sequences and sets of variable (V) and joining (J) gene segments. The heavy-chain locus contains sets of C-region coding sequences and sets of V, diversity (D), and J gene segments.

During B cell development in the bone marrow, before foreign antigen stimulation, separate gene segments are brought together by site-specific recombination mediated by V(D)J recombinase. A V_L gene segment recombines with a J_L gene segment to produce a DNA sequence coding for the V region of a light chain, and a V_H gene segment recombines with a D and a J_H gene segment to produce a DNA sequence coding for the V region of a heavy chain. Each of the newly assembled V-region coding sequences is then co-transcribed with the appropriate C-region sequence to produce an RNA molecule that codes for the complete J_L golypeptide chain.

By randomly combining inherited gene segments that code for the variable regions during B cell development, we can make hundreds of different light chains and thousands of different heavy chains. Because the antigen-binding site is formed where the hypervariable loops of the V_L and V_H domains come together in the final Ig molecule, the heavy and light chains can potentially pair to form Igs with more than a million different antigen-binding sites. A loss or gain of nucleotides at the site of gene-segment joining increases this number enormously. The Igs made by such V(D) recombination before antigen stimulation are IgMs and IgDs with low affinity for binding antigen, and they constitute the primary Ig repertoire.

Igs are further diversified after antigen stimulation in peripheral lymphoid organs by the AID-mediated and helper T cell-dependent processes of somatic hypermutation and class switch recombination, which together produce the high-affinity IgG, IgE, and IgA Igs that constitute the secondary Ig repertoire. The process of class switching allows the same antigen-binding site to be incorporated into antibodies that have different tails and therefore different functional properties.

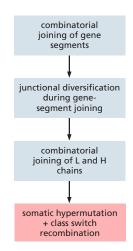

Figure 24–31 The main mechanisms of Ig diversification in mice and humans. Those shaded in gray occur during B cell development in the bone marrow, whereas the two mechanisms shaded in red occur when B cells are stimulated by foreign antigen and helper T cells in germinal centers in peripheral lymphoid organs, either late in a primary response or in a secondary response.

T CELLS AND MHC PROTEINS

Like antibody responses, T cell-mediated immune responses are exquisitely antigen specific, and they are at least as important as antibodies in defending vertebrates against infection. Indeed, most adaptive immune responses, including most antibody responses, require helper T cells for their initiation. Most important, unlike B cells, T cells can help eliminate pathogens that have entered the interior of host cells, where they are invisible to B cells and antibodies. Much of the rest of this chapter is concerned with how T cells accomplish this feat.

T cell responses differ from B cell responses in at least two crucial ways. First, a T cell is activated by foreign antigen to proliferate and differentiate into effector cells only when the antigen is displayed on the surface of an *antigen-presenting cell (APC)*, usually a dendritic cell in a peripheral lymphoid organ. One reason T cells require APCs for activation is that the form of antigen they recognize is different from that recognized by the Igs produced by B cells. Whereas Igs can recognize antigenic determinants on the surface of pathogens and soluble folded proteins, for example, T cells can only recognize fragments of protein antigens that have been produced by partial proteolysis inside a host cell. As mentioned earlier, newly formed *MHC proteins* capture these peptide fragments and carry them to the surface of the host cell, where T cells can recognize them.

The second difference is that, once activated, effector T cells act mainly at short range, usually contacting the cells they influence, either within a secondary lymphoid organ or after they have migrated to a site of infection. Effector B cells, by contrast, secrete antibodies that can act far away. Effector T cells interact directly with another host cell in the body, which they either kill (if it is an infected host cell, for example) or signal in some way (if it is a B cell or macrophage, for example). We will refer to such host cells as *target cells*. As is the case with APCs, target cells must display an antigen bound to an MHC protein on their surface for a T cell to recognize them.

There are three main classes of T cells—cytotoxic T cells, helper T cells, and regulatory T cells. When activated, they develop into effector cells, each class having its own distinct activities. Effector *cytotoxic T cells* directly kill cells that are infected with an intracellular pathogen. Effector *helper T cells* help stimulate the responses of other immune cells—mainly macrophages, dendritic cells, and B cells; as we will see, there are various functionally distinct subtypes of effector helper T cells. Effector *regulatory T cells* suppress the activity of other immune cells. After functioning, some effector T cells become memory T cells.

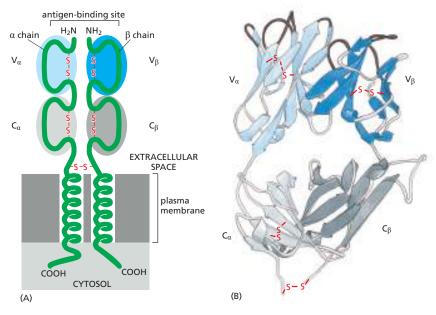

In this section, we discuss how T cells recognize foreign antigens on the surface of APCs or target cells and the crucial part played by MHC proteins in the recognition process. We describe the different classes and subclasses of T cells and their respective functions and how T cells start their development in the thymus. We begin by considering the cell-surface receptors that T cells use to recognize antigen.

T Cell Receptors (TCRs) Are Ig-like Heterodimers

T cell receptors (TCRs), unlike Igs made by B cells, exist only in membrane-bound form. They are composed of two transmembrane, disulfide-linked polypeptide chains, each of which contains two Ig-like domains—one variable and one constant. On most T cells, the TCRs have one α chain and one β chain (Figure 24–32).

The genetic loci that encode the α and β chains are located on different chromosomes. Like an Ig heavy-chain locus (see Figure 24–29), the TCR loci contain separate V, D, and J gene segments (or just V and J gene segments in the case of the α -chain locus), which are brought together by site-specific recombination during T cell development in the thymus. With one exception, T cells use the same mechanisms to generate antigen-binding-site diversity of their TCRs as B cells use to generate antigen-binding-site diversity of their Igs, and they use the same V(D)J recombinase; thus, humans or mice deficient in this recombinase cannot make functional B or T cells. The mechanism that does not operate in TCR diversification is antigen-driven somatic hypermutation. Therefore, the affinities

MBOC7_ptr_ch24_1353-1404.indd 1382 02/12/21 12:22 PM

of TCRs tend to be low ($K_a \approx 10^5$ - 10^7 liters/mole). Various co-receptors and cellcell adhesion proteins, however, greatly strengthen the binding of a T cell to an APC or target cell. TCRs also do not diversify by class switching.

Instead of making TCR α and β chains, a minority of T cells makes a different but related type of TCR heterodimer, composed of γ chains and δ chains. Although these $\gamma\delta$ *T cells* normally make up only 5–10% of the T cells in human blood, they can be the dominant T cell population in epithelia such as the skin. They differ from conventional $\alpha\beta$ T cells in other important ways: their surface receptors have restricted diversity and generally do not recognize antigens as peptides presented by MHC proteins. We will not discuss them further, so that, from here on, when we refer to T cells, we mean T cells with $\alpha\beta$ TCRs.

As with BCRs, TCRs are tightly associated in the plasma membrane with a number of invariant membrane-bound proteins that are involved in passing the signal from an antigen-activated receptor to the cell interior. We will discuss these proteins in more detail later, when we consider some of the molecular events involved in T and B cell activation. First, we consider the special ways in which T cells recognize foreign antigen on the surface of an APC or target cell.

Activated Dendritic Cells Activate Naïve T Cells

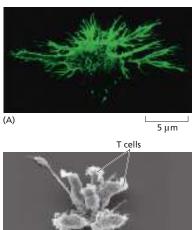

Generally, naïve T cells, including naïve helper and cytotoxic T cells, proliferate and differentiate into effector cells and memory cells only when they see their specific antigen on the surface of an activated dendritic cell in a peripheral lymphoid organ (Figure 24-33). The activated dendritic cell displays the antigen in a complex with MHC proteins on its surface, along with co-stimulatory proteins (see Figure 24-11). The memory T cells that develop, however, can be re-activated by the same antigen-MHC complex on the surface of other types of APCs (target cells), including macrophages and B cells—as well as by dendritic cells.

Immature dendritic cells are located in most tissues-underlying epithelial layers of the skin and gut, for example—where they are constantly sampling and processing proteins in their environment. They become activated to mature when their pattern recognition receptors (PRRs) encounter pathogen-associated molecular patterns (PAMPs) on an invading pathogen or its products. The pathogen or products are ingested, and the microbial proteins are cleaved into peptide fragments, which are loaded onto MHC proteins, as we discuss later. The activated dendritic cells then migrate via the lymph from the site of infection to local lymph nodes or gut-associated lymphoid organs, a process aided by the expression of the chemokine receptor CCR7. Here, they present the foreign antigens, displayed

heterodimer. (A) Schematic drawing of a TCR composed of an $\boldsymbol{\alpha}$ and a β polypeptide chain. Each chain has a large extracellular part that is folded into two Ig-like domains—one variable and one constant. A V_{α} and a V_{β} domain (shaded in blue) form the antigen-binding

Figure 24-32 A T cell receptor (TCR)

site. Unlike Igs, which have two binding sites for antigen, TCRs have only one. Although not shown, the $\alpha\beta$ -heterodimer is noncovalently associated with a large set of invariant membrane-bound proteins that help activate the T cell when the TCRs bind their specific antigen (see Figure 24-45B). A typical T cell has about 30,000 TCRs on its surface. (B) The three-dimensional structure of the extracellular part of a TCR. The antigen-binding site is formed by the hypervariable loops of both the V_{α} and V_{β} domains (black), located at the distal end of the domains, and it is similar in its overall dimensions and geometry to the antigen-binding site of an Ig molecule. (B, PDB code: 1TCR.)

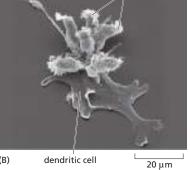

Figure 24-33 Dendritic cells.

Turley.)

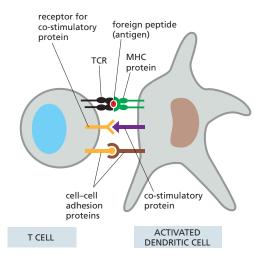

Figure 24–34 The three general types of proteins on the surface of an activated dendritic cell involved in activating a T cell. Although not shown, activated dendritic cells also secrete soluble cytokines that influence the T cell activation process. The invariant polypeptide chains that are always stably associated with the TCR are also not shown; they are discussed later and illustrated in Figure 24–45B and Movie 24.7.

as peptide–MHC complexes on the dendritic cell surface, for recognition by the relevant T cells (see Figure 24–11).

Activated dendritic cells display three types of protein molecules on their surface that have a role in activating a T cell to become an effector cell or memory cell (Figure 24–34): (1) MHC proteins, which present foreign peptides to the TCRs; (2) co-stimulatory proteins, which bind to complementary receptors on the T cell surface; and (3) cell-cell adhesion molecules, which enable a T cell to bind to the dendritic cell for long enough to become activated, typically several hours or more. In addition, activated dendritic cells secrete a variety of cytokines that influence the type of effector helper T cell that develops, and different types of dendritic cells promote different outcomes (discussed later).

T Cells Recognize Foreign Peptides Bound to MHC Proteins

As discussed earlier (see Figure 24–11), MHC proteins capture intracellular peptide fragments of foreign proteins and display them on a cell surface for presentation to T cells. There are two main classes of MHC proteins, which are structurally and functionally distinct. Class I MHC proteins mainly present foreign peptides to cytotoxic T cells, whereas class II MHC proteins mainly present foreign peptides to helper and regulatory T cells (Figure 24–35). Some class I-like MHC proteins present microbial lipid and glycolipid antigens to T cells, but these proteins are not encoded within the MHC region of the genome, and we will not consider them further.

Both class I and class II MHC proteins are heterodimers, in which two extracellular domains form a *peptide-binding groove*, which always has a variable small peptide noncovalently bound in it. In class I MHC proteins, the two domains that form the peptide-binding groove are provided by the transmembrane α chain, which is noncovalently associated with a small subunit called β_2 -microglobulin;

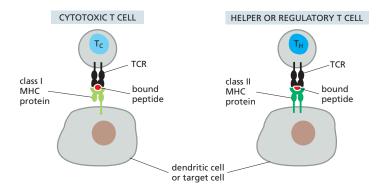

Figure 24–35 Recognition by T cells of peptides bound to MHC proteins. Cytotoxic T (T_C) cells recognize foreign peptides in association with class I MHC proteins, whereas helper T (T_H) cells recognize foreign peptides in association with class II MHC proteins; regulatory T cells also recognize self or foreign peptides in association with class II MHC proteins. In all cases, the T cell recognizes the peptide–MHC complexes on the surface of an APC —either a dendritic cell or a target cell. Different types of dendritic cells activate naïve cytotoxic and helper T cells (not shown).

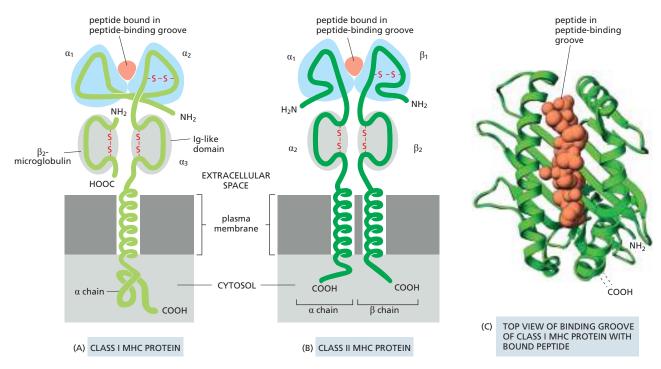

Figure 24–36 Class I and class II MHC proteins. (A) The transmembrane α chain of the class I molecule has three extracellular domains, α_1 , α_2 , and α_3 , each encoded by a separate exon. The α chain is noncovalently associated with a smaller, nontransmembrane polypeptide chain, β_2 -microglobulin, which is not encoded within the MHC region of the genome. The α_3 domain and β_2 -microglobulin are Ig-like. While β_2 -microglobulin is invariant, the α chain is extremely polymorphic, mainly in the α_1 and α_2 domains. (B) In class II MHC proteins, both the α chain and the β chain are transmembrane polypeptides encoded within the MHC and are polymorphic, mainly in the α_1 and β_1 domains; the α_2 and β_2 domains are Ig-like. Thus, there are striking similarities between class I and class II MHC proteins: in both, the two outermost domains (shaded in *blue*) are polymorphic and interact to form a groove that binds peptide fragments. The S–S disulfide bonds in A and B are shown in *red*. (C) Top view of the three-dimensional structure of the peptide-binding groove of a human class I MHC protein (*green*) with a bound peptide (*red*), as would be seen by a TCR on a cytotoxic T cell. Two α helices form the sides of the groove, and a β pleated sheet forms the groove's floor (Movie 24.8 and Movie 24.9). (C, PDB code: 1FZK.)

in class II MHC proteins, a different α chain and a large, noncovalently associated β chain each contribute an extracellular domain to form the peptide-binding groove (Figure 24–36). A TCR binds to both the peptide and the ridges of the binding groove. Humans have three major class I proteins, called *HLA-A*, *HLA-B*, and *HLA-C*, and three class II proteins, called *HLA-DP*, *HLA-DQ*, and *HLA-DR* (HLA stands for human leukocyte antigen, as these proteins were first demonstrated on human leukocytes). Figure 24–37 shows how the genes that encode these proteins are arranged in the MHC region of human chromosome 6.

T CELLS AND MHC PROTEINS

There are important differences between the class I and class II MHC proteins with regard to the cell types that express them and the origin of the peptides in their peptide-binding grooves. Almost all of our nucleated cells express class I proteins. Their peptide-binding groove displays one of a diverse collection of peptides (typically 8–10 amino acids in length). In a healthy cell, the peptides originate from the

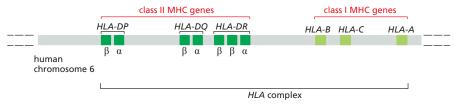

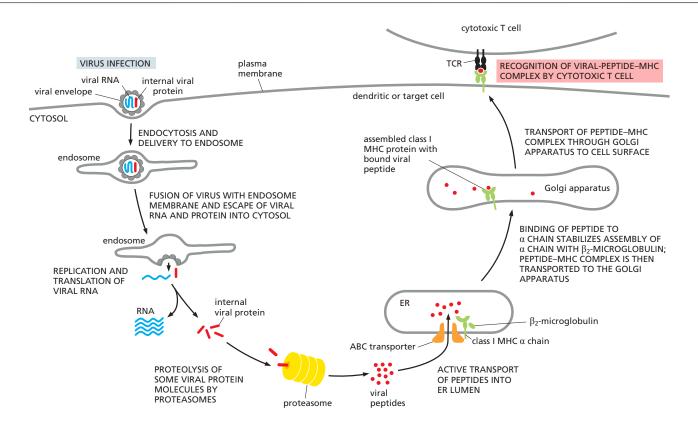

Figure 24-37 Human MHC genes. This simplified schematic drawing shows the location of the genes that encode the transmembrane subunits of class I (light green) and class II (dark green) MHC proteins. The genes shown encode the three main types of class I MHC proteins (HLA-A, HLA-B, and HLA-C) and three types of class II MHC proteins (HLA-DP, HLA-DQ, and HLA-DR). An individual can therefore make six types of class I MHC proteins (three encoded by maternal genes and three by paternal genes) and more than six types of class II MHC proteins. Because of the extreme polymorphism of the MHC genes, the chances are very low that the maternal and paternal alleles will be the same. The number of class II MHC proteins that an individual can make is greater than six because there are two DRB genes and because maternally encoded and paternally encoded polypeptide chains can sometimes pair. The entire region shown spans about 7 million base pairs and contains other genes that are not shown.

MBOC7_ptr_ch24_1353-1404.indd 1385 02/12/21 12:22 PM

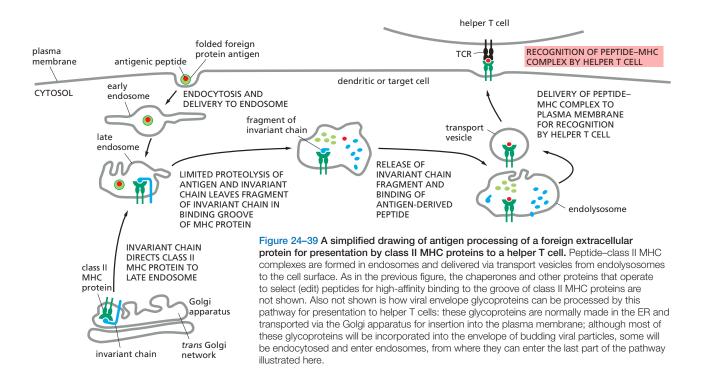

cell's own cytosolic and nuclear proteins that have undergone partial degradation in proteasomes in the processes of normal protein turnover and quality control mechanisms. Some of the peptide fragments produced in this way are actively transported into the lumen of the endoplasmic reticulum (ER) by a specialized transporter in the ER membrane; there, they are loaded onto newly synthesized class I MHC α chains. This process depends on a peptide-loading complex that assembles transiently in the ER membrane; the complex consists of the transporter, chaperone proteins, and other proteins that assist in peptide selection by the class I MHC α chain and its partner β_2 -microglobulin. The self-peptide-MHC complex produced is then transported through the Golgi apparatus to the cell surface. Such complexes are not dangerous, however, because the cytotoxic T cells that could recognize them have been eliminated or inactivated or suppressed by regulatory T cells in the process of self-tolerance (see Figure 24-21). By contrast, in a cell infected by a pathogen such as a virus, the pathogen proteins will be processed in the same way, and peptides derived from them will be displayed on the infected cell surface bound to class I MHC proteins; there, they are recognized by effector cytotoxic T cells expressing the appropriate TCRs, thereby targeting the infected cell for destruction (Figure 24-38).

In general, antigen-presenting cells (APCs) are the main cells that express class II MHC proteins. Dendritic cells are the major APCs, as they are specialized for this function, and only they can activate naïve T cells. Other immune cells that are targets of effector T cell regulation, including B cells and macrophages, are also APCs and express class II MHC proteins, as do thymus epithelial cells (discussed later). Other epithelial cells can also be induced to express class II MHC proteins and act as APCs, but only when they encounter infection or inflammation. All APCs load their newly synthesized class II MHC proteins with peptides derived mainly from extracellular proteins that are endocytosed and delivered to endosomes. The newly synthesized class II MHC proteins initially contain an *invariant chain*, which acts as both a guide and a guardian of the peptide-binding

Figure 24-38 A simplified drawing of antigen processing of an internal viral protein for presentation by class I MHC proteins to a cytotoxic T cell. An effector cvtotoxic T cell kills a virus-infected cell when it recognizes fragments of an internal viral protein bound to class I MHC proteins on the surface of the infected cell. Not all viruses enter the cell in the way that this enveloped RNA virus does, but fragments of internal viral proteins always follow the pathway shown. Only a small proportion of the viral proteins synthesized in the cytosol are degraded and transported to the cell surface, but this is sufficient to attract an attack by a cytotoxic T cell. Several chaperone and other proteins in the ER lumen combine with the ABC transporter and MHC protein to form a peptide-loading complex that aids peptide selection (editing) and the assembly of peptide-class I MHC protein complexes (not shown) Both the final assembly of a class I MHC protein and its transport in vesicles to the cell surface require the presence of either a self or foreign peptide in the peptide-binding groove of the MHC protein (Movie 24.10).

MBOC7_ptr_ch24_1353-1404.indd 1386 02/12/21 12:22 PM

groove, preventing the groove from prematurely binding a peptide until the class II MHC protein reaches the endocytic pathway. Here, invariant chain removal is initiated by proteolysis and completed by the action of a chaperone protein, allowing peptide fragments (typically 12–20 amino acids long) produced from endocytosed proteins to bind to the groove of the class II MHC proteins. These peptide–MHC complexes are then transported to the plasma membrane for display on the surface of the APC. In a healthy host cell, class II MHC protein grooves are loaded with self peptides derived from normal proteins and will be ignored by most T cells because of self-tolerance mechanisms (although they will be recognized by regulatory T cells as part of these self-tolerance mechanisms—see Figure 24–21). During an infection, however, pathogen proteins are also endocytosed and processed in the same way, enabling APCs to present pathogen peptides bound to class II MHC proteins to T cells expressing an appropriate TCR (Figure 24–39).

The distinction just discussed between the antigen-processing pathways for loading peptides onto class I and class II MHC proteins is not absolute. Dendritic cells, for example, need to be able to activate cytotoxic T cells to kill virus-infected cells even when the virus does not infect dendritic cells themselves. To do so, a specialized subset of dendritic cells uses a process called **cross-presentation**, which begins when these noninfected dendritic cells phagocytose virus-infected host cells or their fragments. In one pathway, at least, the ingested viral proteins are transported by a special mechanism from phagolysosomes into the cytosol, where they are degraded in proteasomes; the resulting protein fragments are then transported into the ER lumen and loaded onto assembling class I MHC proteins, as described earlier (see Figure 24–38). Cross-presentation by dendritic cells is not confined to endocytosed pathogens and their products: it also operates to activate cytotoxic T cells against tumor antigens of cancer cells and the foreign MHC proteins on the cells of foreign organ grafts.

During an infection, only a small fraction of the many thousands of MHC proteins on the surface of an APC or target cell will have pathogen peptides bound to them. This is sufficient, however: fewer than 50 copies of the same peptide–MHC complex on a dendritic cell, for example, can activate a helper T cell that has a

MBOC7_ptr_ch24_1353-1404.indd 1387 02/12/21 12:22 PM

TABLE 24–3 Properties of Human Class I and Class II MHC Proteins				
	Class I	Class II		
Genetic loci	HLA-A, HLA-B, HLA-C	HLA-DM, HLA-DO, HLA- DP, HLA-DQ, HLA-DR		
Chain structure	α chain + β_2 -microglobulin	α chain + β chain		
Cell distribution	Most nucleated cells	Dendritic cells, B cells, macrophages, thymus epithelial cells, some others		
Presents antigen to	Cytotoxic T cells	Helper T cells, regulatory T cells		
Source of peptide fragments	Mainly proteins made in cytoplasm	Mainly endocytosed plasma membrane and extracellular proteins		
Polymorphic domains	$\alpha_1 + \alpha_2$	$\alpha_1 + \beta_1$		
Recognition by co-receptor	CD8	CD4		

TCR that binds the complex with a high-enough affinity. **Table 24–3** compares the properties of class I and class II MHC proteins.

MHC Proteins Are the Most Polymorphic Human Proteins Known

Although any individual can make only a small number of different class I and class II MHC proteins, together these proteins must be able to present peptide fragments from almost any foreign protein to T cells. Thus, unlike the antigen-binding site of an Ig protein, the peptide-binding groove of each MHC protein must be able to bind a very large number of different peptides. The genes encoding class I and class II MHC proteins (see Figure 24–37) are the most *polymorphic* known in higher vertebrates: in the human population, for example, there are more than 2000 allelic variants of these genes. The corresponding variations in the MHC proteins are functionally important, as they are concentrated in the floor and walls of the peptide-binding grooves and allow MHC molecules in different individuals to bind different arrays of peptides.

It is thought that infectious diseases have been an important driving force for generating this remarkable MHC polymorphism. In the evolutionary war between pathogens and the adaptive immune system, pathogens will tend to change their proteins through mutation so that the peptides derived from them will not fit in the MHC peptide-binding grooves. When a pathogen succeeds, it can sweep through a population as an epidemic. In such circumstances, the few individuals who produce a new allelic form of MHC protein that can bind peptides derived from the altered pathogen will have a large selective advantage. This type of selection will tend to promote and maintain a large diversity of MHC proteins in the population. In West Africa, for example, individuals with a specific MHC allele (*HLA-B53*) have a reduced susceptibility to a severe form of malaria that is endemic there; although this allele is rare elsewhere, it is found in 25% of the West African population.

The extensive diversity of human MHC proteins is the main reason that individuals who receive a foreign organ transplant must be treated with strong immunosuppressive drugs to prevent the immunological rejection of the grafted organ. Of all the foreign proteins that the graft expresses, the MHC proteins are by far the most powerful stimulators of the recipient's T cells, which would rapidly destroy the graft if they were not prevented from doing so by such drugs. Foreign MHC proteins are powerful T cell stimulants because T cells respond to them in the same way they respond to self MHC proteins that have foreign peptides bound to them; for this reason, the proportion of a person's T cells that can specifically recognize any foreign MHC protein is relatively high.

MBOC7_ptr_ch24_1353-1404.indd 1388 02/12/21 12:22 PM

CD4 and CD8 Co-receptors on T Cells Bind to Invariant Parts of MHC Proteins

The affinity of TCRs for peptide–MHC complexes on an APC is usually too low by itself to mediate a functional interaction between the two cells. T cells normally require *accessory receptors* to help stabilize the interaction by increasing the overall strength of the cell–cell adhesion. Unlike TCRs or MHC proteins, the accessory receptors are invariant and do not bind to foreign peptides. Once bound to the surface of a dendritic cell, for example, a T cell increases the strength of the binding by activating an integrin adhesion protein, which then binds more strongly to an Ig-like protein on the surface of the dendritic cell. This increased adhesion enables the T cell to remain bound long enough to become activated.

When an accessory receptor has a direct role in activating the T cell by generating its own intracellular signals, it is called a **co-receptor**. The most important and best understood of the co-receptors on T cells are the CD4 and CD8 proteins, both of which are single-pass transmembrane proteins with extracellular Ig-like domains. Like TCRs, they recognize MHC proteins, but, unlike TCRs, they bind to invariant parts of the MHC protein, far away from the peptide-binding groove. **CD4** is expressed on both helper T cells and regulatory T cells and binds to class II MHC proteins, whereas **CD8** is expressed on cytotoxic T cells and binds to class I MHC proteins (**Figure 24–40**).

CD4 and CD8 contribute to T cell recognition by helping the T cell to focus on particular MHC proteins, and thereby on particular types of target cells. Thus, the recognition of class I MHC proteins by CD8 allows cytotoxic T cells to focus on any type of infected host cell, while the recognition of class II MHC proteins by CD4 allows helper and regulatory T cells to focus on the target immune cells that they help or suppress, respectively. The cytoplasmic tail of the CD4 and CD8 proteins is associated with a member of the Src family of cytoplasmic tyrosine kinases (discussed in Chapter 15) called *Lck*, which phosphorylates various intracellular signaling proteins on tyrosines and thereby participates in the activation of the T cell (discussed later).

The AIDS virus (HIV) uses CD4 molecules (as well as chemokine receptors) to gain entry to helper T cells (see Figure 23–18). Individuals with AIDS are susceptible to infection by microbes that are not normally dangerous because HIV depletes helper T cells. As a result, most individuals with AIDS die of infection within several years of the onset of symptoms, unless they are treated with a combination of anti-HIV drugs. HIV also uses CD4 and chemokine receptors to enter macrophages, which also have both of these types of receptors on their surface.

Developing Thymocytes Undergo Positive and Negative Selection

The development of $\alpha\beta$ T cells begins when bone marrow-derived lymphoid progenitor cells enter the outer part of the thymus, the *cortex*, from the bloodstream. There, the progenitor cells develop into thymus lymphocytes, **thymocytes**, which undergo stepwise development under the influence of a variety of signals from thymus epithelial cells, dendritic cells, macrophages, fibroblasts, and other stromal cells.

In an early step, the thymocytes are induced to express V(D)J recombinase, which enables them to begin to rearrange their TCR gene segments and make $\alpha\beta$ TCRs. If the cells fail to express such a cell-surface TCR, they will not receive the signals they need to survive and continue to develop, and they will die by apoptosis by default. Because peripheral $\alpha\beta$ T cells can only see pathogen-derived peptides in the context of self MHC proteins, developing $\alpha\beta$ thymocytes need to express TCRs that have some affinity for self MHC proteins to be potentially useful; those expressing TCRs unable to bind to any self-peptide-self-MHC complex would generally also fail to receive survival signals and therefore also die by apoptosis.

Soon after producing $\alpha\beta$ TCRs, the developing thymocytes express both CD4 and CD8 co-receptors. These so-called *double-positive thymocytes* interact with

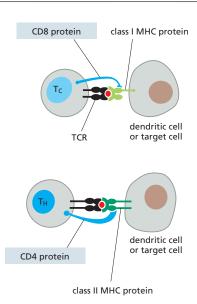

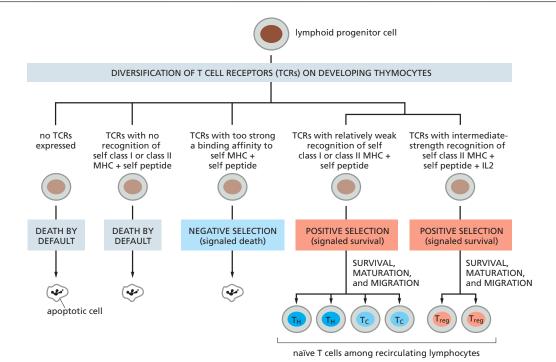

Figure 24-40 CD4 and CD8 co-receptors on the surface of T cells. Cytotoxic T (T_C) cells express CD8, which recognizes class I MHC proteins, whereas helper T (T_H) cells and regulatory T cells (not shown) express CD4, which recognizes class II MHC proteins. Note that the co-receptors bind to the same MHC protein that the TCR has engaged, so that they are brought together with TCRs during the antigen recognition process. Whereas the TCR binds to the variable (polymorphic) parts of the MHC protein that form the peptidebinding groove, the co-receptor binds to the invariant part, well away from the binding groove.

epithelial cells in the thymus cortex that express self peptides bound to class I and class II MHC proteins. In a process called **positive selection**, a thymocyte expressing a TCR that binds with an appropriate affinity to a self peptide bound to either a class I MHC protein (using CD8 as a co-receptor) or a class II MHC protein (using CD4 as a co-receptor) on cortical epithelial cells is signaled to survive and continue to mature. As part of this process, depending on the TCR's preference for class I or class II MHC proteins, the CD4 or CD8 co-receptor that will not be needed is silenced by DNA methylation of the respective gene. The resulting CD4 or CD8 *single-positive thymocytes* ultimately leave the inner part of the thymus (the *medulla*) to become *naïve T cells*: the CD4 cells become either helper T cells or regulatory T cells (discussed later), while the CD8 cells become cytotoxic T cells.

Before that, however, after the developing single-positive thymocytes move from the cortex into the medulla, they undergo two more selection processes (on the surface of medullary epithelial and dendritic cells) that have crucial roles in immunological self-tolerance. Thymocytes with TCRs that bind too strongly to self peptides bound to class I or class II MHC proteins could be dangerous if they were to continue to mature and leave the thymus, as they could then potentially attack similar self complexes on normal cells in peripheral tissues and thereby cause an autoimmune disease. Such strong binding (via TCRs and either CD4 or CD8 co-receptors) signals such thymocytes to undergo apoptosis in a process called negative selection, an example of clonal deletion acting in central immunological self-tolerance (see Figure 24-21). In a second form of positive selection, some CD4-positive thymocytes that bind strongly to self peptides bound to class II MHC proteins (but not strongly enough for negative selection to operate) in the presence of secreted IL2 develop into regulatory T cells (Treg cells), which mediate clonal suppression in peripheral lymphoid tissues, an important mechanism in peripheral self-tolerance (see Figure 24-21). The various positive and negative selection processes that operate during thymocyte development are summarized in Figure 24-41.

For negative selection in the thymus to be an effective mechanism of peripheral T cell self-tolerance, APCs in the thymus must display an array of self peptides bound to self MHC molecules that reflect the self peptides derived from self proteins in peripheral tissues, as well as in the thymus. The thymus, however, would

Figure 24-41 Negative and positive selection in the thymus. Developing thymocytes with no TCRs or with TCRs that have no recognition of MHC proteins with a peptide bound would be of no use and fail to receive survival signals and die by default ("from neglect") by apoptosis. In the process of negative selection, thymocytes with TCRs with such strong binding affinity to self-peptide-self-MHC complexes that the cells would be potentially dangerous are actively signaled to die by apoptosis. In the process of positive selection, thymocytes with TCRs with appropriate binding affinity for self-peptide-self-MHC complexes are signaled to survive, mature, and migrate to peripheral lymphoid organs, where they function as helper (T_H), cytotoxic (T_C), or regulatory T (T_{req}) cells, depending on the class of MHC they recognize and the binding affinity of their TCRs: T_C cells recognize peptides in association with class I MHC proteins, whereas T_H and T_{reg} cells recognize peptides in association with class II MHC proteins. As indicated, whereas thymocytes with TCRs that bind weakly to self peptides bound to self class II MHC proteins end up as T_H cells, those with TCRs that bind with intermediate strength to self peptides bound to self class II MHC proteins (in the presence of IL2) end up as Treg cells.

MBOC7_ptr_ch24_1353-1404.indd 1390 02/12/21 12:22 PM

not be expected to produce many of the proteins that are specifically expressed in other organs. As an example, it would not be expected to produce insulin, and yet it is crucial to delete thymocytes with TCRs that could recognize insulin-derived peptides bound to self MHC proteins on the surface of insulin-secreting β cells in the pancreas; a failure to do so would result in the T cell-dependent destruction of the β cells and, as a consequence, *type 1 (or juvenile) diabetes*.

The mechanism that enables the deletion of such cells in the thymus depends on a subpopulation of epithelial cells in the thymus medulla that expresses a promiscuous transcriptional regulator called AIRE (autoimmune regulator), which is specific to these epithelial cells. The AIRE protein acts as part of a multiprotein complex to induce the production of small amounts of mRNA from 75 to 90% of all genes, including those that encode tissue-restricted proteins such as insulin. When the peptides derived from the proteins encoded by these genes are bound to MHC proteins and displayed on the surface of these epithelial cells, this is sufficient to ensure the deletion of most of the potentially self-reactive thymocytes. Mutations that inactivate the AIRE gene cause a severe multi-organ autoimmune disease in both mice and humans, indicating the importance of AIRE in self-tolerance.

Having left the thymus, naïve helper and cytotoxic T cells continually receive survival signals as a result of weak binding to self-peptide-self-MHC-protein complexes. These naïve T cells, however, are normally only activated to proliferate and differentiate into effector and memory T cells in a peripheral lymphoid organ and only when their TCRs bind with high affinity to a pathogen-derived peptide in the binding groove of an MHC protein on the surface of an activated dendritic cell that expresses co-stimulatory signals. We now consider the functions of the different subclasses of effector T cells, beginning with cytotoxic T cells.

Cytotoxic T Cells Induce Infected Target Cells to Undergo Apoptosis

Cytotoxic T cells (T_C cells), like the NK cells discussed earlier, protect us against intracellular pathogens (including viruses, bacteria, and parasites) that multiply in the cytoplasm of a host cell. Both types of cytotoxic cells kill infected host cells before the pathogen can escape to infect neighboring host cells. Before a naïve T_C cell can kill, however, it has to become an effector cell by activation on an APC, usually an activated dendritic cell that has pathogen-derived peptides bound to class I MHC proteins on its surface. The effector T_C cell can then recognize any target cell harboring the same pathogen and expressing some of the same peptide-MHC complexes on its surface: its TCRs cluster, along with CD8 co-receptors, adhesion molecules, and intracellular signaling proteins (discussed later), at the interface between the two cells, forming an immunological synapse. In this process, the effector T_C cell reorganizes its cytoskeleton to focus its killing apparatus on the target cell, secreting its toxic proteins into a confined space (Figure 24-42); in this way, it avoids killing neighboring cells. A similar synapse forms when an effector helper T cell interacts with its target cell, except that the co-receptor is CD4 (Movie 24.11).

An effector T_C cell (or an NK cell) can employ one of two strategies to kill the target, both of which operate by inducing the target cell to activate caspases and kill itself by undergoing apoptosis. One mechanism uses a protein called *Fas ligand* on the killer-cell surface, which binds to a transmembrane receptor protein called *Fas* on the target cell; this mechanism is discussed in Chapter 18 (see Figure 18–6). The other mechanism is the main one used by both NK cells and T_C cells to kill an infected target cell. The killer cell stores various toxic proteins within secretory vesicles in its cytoplasm that it releases into the synaptic space by exocytosis. The toxic proteins include *perforin* and proteases called *granzymes*. The perforin is homologous to complement component C9 and polymerizes in the target-cell plasma membrane (see Figure 24–8), forming a transmembrane pore that locally disrupts the membrane and allows the granzymes to enter the target cell. Once in the cytosol, one of the granzymes,

MBOC7_ptr_ch24_1353-1404.indd 1391 02/12/21 12:22 PM

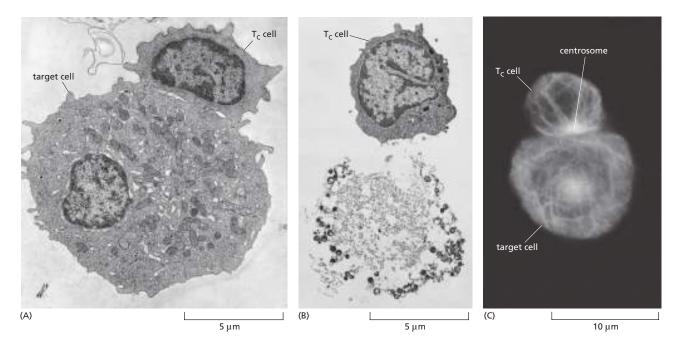

Figure 24–42 Effector cytotoxic T cells killing target cells in culture. (A) Electron micrograph showing an effector cytotoxic T cell (T_C cell) binding to a target cell in culture. The T_C cells were obtained from mice immunized with the target cells, which are foreign tumor cells. (B) Electron micrograph showing a T_C cell and a tumor cell that the T_C cell has killed. In an animal, as opposed to in a culture dish, the killed target cell would be phagocytosed by a neighboring cell (often a macrophage) long before it disintegrated in the way that it has here. (C) Micrograph of a T_C cell and a tumor cell after immunofluorescence staining with anti-tubulin antibodies. Note that the centrosome in the T_C cell is located at the point of cell–cell contact with the target cell —called an immunological synapse. The secretory granules (not visible) in the T_C cell are initially transported along microtubules to the centrosome, which then moves to the synapse, delivering the granules to where they can release their contents directly onto the target-cell surface. (A and B, from D. Zagury et al., *Eur. J. Immunol.* 5:818–822, 1975. With permission from John Wiley & Sons; C, © 1982 B. Geiger et al. Originally published in *J. Cell Biol.* https://doi.org/10.1083/jcb.95.1.137. With permission from Rockefeller University Press.)

granzyme B, cleaves and activates executioner caspases, thereby inducing apoptosis (Figure 24-43).

Effector Helper T Cells Help Activate Other Cells of the Innate and Adaptive Immune Systems

In contrast to T_C cells, **helper T cells (T_H cells)** are crucial for defense against both extracellular and intracellular pathogens, and they express CD4 rather than CD8 co-receptors and recognize foreign peptides bound to class II rather than class I MHC proteins. Once naïve T_H cells are induced on activated dendritic cells to become effector cells, they can help activate other immune cells: they help activate B cells to become antibody-secreting cells and later to undergo Ig class switching and somatic hypermutation; they help activate macrophages to destroy any intracellular pathogens multiplying within the macrophage's phagosomes; and they further stimulate the activated dendritic cells that activated either naïve

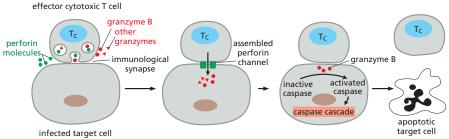

Figure 24-43 The main way that an effector T_C cell (or NK cell) kills an infected target cell. This simplified drawing shows how the killer cell releases perforin and granzymes onto the surface of an infected target cell by localized exocytosis at an immunological synapse. The high concentration of Ca2+ in the extracellular fluid causes the perforin to assemble into transmembrane channels that disrupt the target-cell plasma membrane, allowing the granzymes to enter the target-cell cytosol. One of the granzymes, granzyme B, cleaves and thereby activates executioner caspases (caspase-3 and caspase-7) to initiate a caspase cascade, leading to apoptosis (see Figure 18-6). A single cytotoxic cell can kill multiple target cells in sequence. It remains a mystery why the released perforins do not disrupt the plasma membrane of the killer cell itself (Movie 24.12 and Movie 24.13).

MBOC7_ptr_ch24_1353-1404.indd 1392 02/12/21 12:22 PM

 T_C cells or naïve T_H cells—to maintain or increase the dendritic cells' activated state. In each case, the effector T_H cell recognizes the same complex of foreign peptide and class II MHC protein on the target-cell surface that it initially recognized on the activated dendritic cell. As discussed later, the T_H cell stimulates the target cell both by secreting a variety of cytokines (mainly interleukins) and by displaying co-stimulatory proteins on the T_H cell surface. As we discuss now, different subtypes of T_H effector cells have different functions.

Naïve Helper T Cells Can Differentiate into Different Types of Effector T Cells

In response to infection, a naïve T_H cell can differentiate into several distinct types of effector T cells, depending on the nature of the pathogen and on the cytokines the T_H cell encounters while being activated, which mainly depends on the activating dendritic cell. These different effector T cell types include four subtypes of helper T cells— T_{FH} , $T_H I$, $T_H 2$, and $T_H I 7$ cells—and regulatory T cells (T_{reg} cells). Initially, the naïve T_H cells differentiate into two subpopulations of helper T cells: follicular helper T cells (T_{FH} cells), which support B cell antibody production in lymphoid follicles (see Figure 24–20) in peripheral lymphoid organs, and non- T_{FH} helper T cells that will develop into $T_H I$, $T_H I$, or $T_H I I$ effector $T_H I$ cells; most of the latter three cell types migrate from the peripheral lymphoid organ where they differentiated to the site of infection, where they help innate immune cells fight the pathogen.

Figure 24–44 summarizes both the cytokines that help induce these different effector T cells and some of the cytokines the effector cells then secrete, as well as the main transcription regulators that control the development of the effector cells. Naïve T_H cells activated in the presence of *interleukin-6 (IL6)* develop into effector T_{FH} cells, which are located in lymphoid follicles, where they secrete a variety of cytokines, including IL21, to help specific B cells to proliferate and differentiate into antibody-secreting effector cells and undergo somatic hypermutation and Ig class switching within germinal centers (see Figure 24–20). Naïve T_H cells activated by dendritic cells secreting *IL12* develop into effector T_{H1} cells, which

Figure 24-44 Differentiation of naïve helper T cells into different types of effector helper cells or regulatory T cells in a peripheral lymphoid organ. The nature of the pathogen and the cytokines produced by the activating dendritic cell (and by other innate immune cells in the environment) mainly determine which type of effector T cell develops, as indicated. Some of the main cytokines produced by each type of effector cell are also shown, and the master transcription regulator for each subset is indicated in the nucleus. Some of the differentiated effector cells are "plastic," in that they are able to change the cytokines they produce in response to changes in their environment (not shown).

MBOC7_ptr_ch24_1353-1404.indd 1393 02/12/21 12:22 PM

produce <code>interferon-y</code> (<code>IFNy</code>) to help activate macrophages to destroy pathogens that either invaded the macrophage or were ingested by it; the <code>IFNy</code> can also help activate naïve cytotoxic T cells in a peripheral lymphoid organ to become effector T_C cells. Naïve T_H cells activated in the presence of <code>IL4</code> develop into effector T_H2 cells, which secrete <code>IL4</code>, <code>IL5</code>, and <code>IL13</code> to help fight extracellular pathogens, including parasites; they stimulate B cells to switch from making <code>IgM</code> and <code>IgD</code> to making <code>IgE</code> antibodies, which can bind to mast cells and basophils, as discussed earlier. Naïve T_H cells activated in the presence of <code>IL6</code>, <code>IL23</code>, and <code>TGF\$</code> develop into effector <code>T_H17</code> cells; these cells secrete <code>IL17</code> and <code>IL22</code> to promote production and recruitment of neutrophils and to stimulate barrier epithelial cells to secrete cytokines and antimicrobial peptides.

In some cases, naïve T_H cells that encounter their antigen in a peripheral lymphoid organ in the presence of TGF\$\beta\$ and in the absence of IL6 develop into regulatory T cells (Treg), which suppress rather than help immune cells. They are called induced Treg cells to distinguish them from natural Treg cells, which develop in the thymus by positive selection during thymocyte development (see Figure 24-41). Both types of T_{reg} cells suppress the activation or function of various other kinds of innate and adaptive immune cells, by means of both secreted suppressive cytokines such as IL10 and TGF β and inhibitory proteins on the T_{reg} cell surface. Induced Treg cells are mainly concerned with suppressing immune responses to foreign antigens (preventing responses to harmless ingested or inhaled antigens and commensal microbes, as well as limiting responses against pathogens to avoid excessive reactions that cause unwanted tissue injury); natural T_{reg} cells are concerned with preventing immune responses to self molecules (see Figure 24-21). Both induced and natural Treg cells express the transcription regulator FoxP3, which serves as both a marker of these cells and a master controller of their development: if the gene encoding this protein is inactivated in mice or humans, the individuals fail to produce any Treg cells and develop a fatal autoimmune disease involving multiple organs—findings that establish the crucial importance of T_{reg} cells in self-tolerance.

Both T and B Cells Require Multiple Extracellular Signals for Activation

Foreign antigen binding to BCRs or TCRs initiates the process whereby the B or T cells are stimulated to proliferate and differentiate into effector and memory cells. As mentioned earlier, these antigen receptors do not act on their own: they are stably associated with invariant transmembrane polypeptide chains that are required to relay the signal into the cell. In B cells, these are called $Ig\alpha$ and $Ig\beta$ (Figure 24–45A), while in T cells they exist in a complex called CD3, composed of four types of polypeptide chains (Figure 24–45B). In both cases, the associated

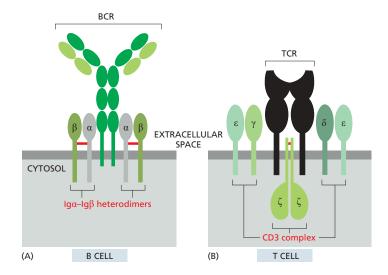

Figure 24–45 The invariant chains associated with BCRs and TCRs. (A) Each BCR is associated with two invariant heterodimers, each composed of an $\lg \alpha$ and an $\lg \beta$ polypeptide chain linked by a disulfide bond (red). (B) Each TCR is associated with an invariant CD3 complex composed of two disulfidebonded ζ chains, two ϵ chains, and one δ and one γ chain; these chains form homodimers or heterodimers, as shown.

MBOC7_ptr_ch24_1353-1404.indd 1394 02/12/21 12:22 PM

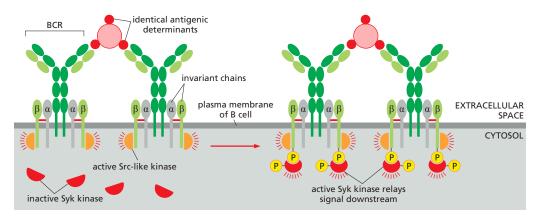

Figure 24–46 Early signaling events in a B cell activated by the binding of specific foreign antigen to its BCRs. If the antigen is on the surface of a pathogen or is a soluble macromolecule with two or more identical antigenic determinants (as shown), it cross-links adjacent BCRs, causing them and their associated invariant chains to cluster, as shown. A Src-like cytoplasmic tyrosine kinase (which can be either Fyn or Lyn) is associated with the cytosolic tail of $lg\beta$; it joins the cluster and phosphorylates both the $lg\alpha$ and $lg\beta$ invariant chains (for simplicity, only the phosphorylation on $lg\beta$ is shown). An important transmembrane protein tyrosine phosphatase called CD45 is also required to remove inactivating phosphates from these Src-like kinases for the signaling process to occur (not shown). The resulting phosphotyrosines on $lg\alpha$ and $lg\beta$ serve as docking sites for another Src-like tyrosine kinase called Syk, which becomes phosphorylated and thereby activated to relay the signal onward.

The pathway from TCRs is similar (including a requirement for CD45), except that the first Src-like kinase is *Lck* (instead of Fyn or Lyn), and it is associated with a CD4 or CD8 co-receptor and phosphorylates tyrosines on all the CD3 polypeptide chains shown in Figure 24–45B; the second Src-like kinase is *ZAP70*, which is homologous to the Syk kinase in B cells (Movie 24.14).

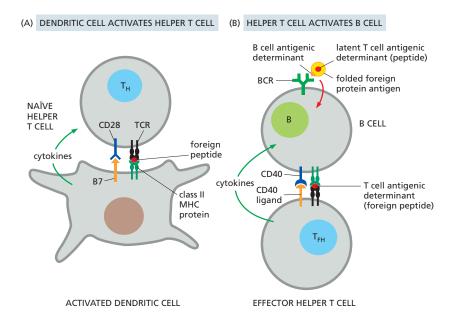

proteins help convert extracellular antigen binding to the BCR or TCR into intracellular signals, and they do so in similar ways.

Antigen binding to BCRs or TCRs clusters these receptors and their associated invariant chains (and CD4 or CD8 co-receptors in the case of TCRs). This clustering activates a Src family cytoplasmic tyrosine kinase (discussed in Chapter 15) to phosphorylate tyrosines on the cytoplasmic tails of some of the invariant chains. The phosphotyrosines then serve as docking sites for a second cytoplasmic tyrosine kinase, which becomes phosphorylated and activated by the first kinase; the second kinase then relays the signal downstream by phosphorylating other intracellular signaling proteins on tyrosines. Some of these early events in the signaling pathway activated by BCRs are shown in Figure 24–46.

Signaling through BCRs or TCRs and their associated proteins alone is not sufficient to activate a lymphocyte to proliferate and differentiate. Extracellular co-stimulatory signals produced by another cell are also required, and they are provided by both membrane-bound proteins (see Figure 24-34) and secreted cytokines. Indeed, signaling through the BCR or TCR with insufficient co-stimulation can either eliminate the lymphocyte (clonal deletion) or inactivate it, with both of these mechanisms contributing to peripheral self-tolerance (see Figure 24-21). For a naïve T cell, an activated dendritic cell provides the co-stimulatory signals; these include the transmembrane B7 proteins, which are recognized by the co-receptor protein CD28 on the surface of the T cell (Figure 24-47A). For a B cell, an effector T_{FH} cell provides the co-stimulatory signals; these include the transmembrane CD40 ligand, which binds to CD40 receptors on the B cell (Figure 24-47B). The CD40 ligand on effector T_H cells acts in two other situations: (1) it acts back on CD40 receptors on the dendritic cell surface to increase and sustain the activation of the dendritic cell, creating a positive feedback loop; and (2) it acts as a costimulatory signal on the surface of an effector T_H1 cell, allowing the T cell to help activate an infected macrophage to destroy the pathogens it harbors.

In addition to receptors for co-stimulatory proteins, both B and T cells have inhibitory proteins on their surface that negatively regulate the cell's activity, preventing excessive or inappropriate responses. Two such proteins, *CTLA4* and *PD1*, expressed by T cells have attracted great attention because of their roles in suppressing the ability of T cells to inhibit cancer progression. They inhibit T cell activity in different ways: CTLA4 inhibits T cell activation by competing with the

MBOC7_ptr_ch24_1353-1404.indd 1395 02/12/21 12:22 PM

transmembrane co-receptor protein CD28 (see Figure 24–47A), whereas PD1 is expressed on activated T cells, and its prolonged binding to its cell-surface ligand (PDL1 or PDL2) on various cell types, including cancer cells, inhibits the activity of the T cells. Monoclonal antibodies against either CTLA4 or PD1 (or PDL1), or especially against both of these inhibitory pathways, can relieve the inhibition and allow T_C cells to destroy the tumor cells in many patients with metastatic cancer (see Figure 20–46).

Many Cell-Surface Proteins Belong to the Ig Superfamily

Most of the proteins that mediate antigen recognition and cell-cell recognition in the adaptive immune system contain one or more Ig or Ig-like domains, suggesting that the proteins have a common evolutionary history. Included in this very large **Ig superfamily** are antibodies, TCRs, MHC proteins, the CD4, CD8, and CD28 co-receptors, the B7 co-stimulatory proteins, and most of the invariant polypeptide chains associated with TCRs and BCRs, as well as the various Fc receptors on lymphocytes and other leukocytes. Many of these proteins are dimers or higher oligomers, in which Ig or Ig-like domains of one chain interact with those in another (**Figure 24–48**).

In both vertebrates and invertebrates, many proteins in the Ig superfamily are also found outside immune systems, where they often function in cell-cell recognition and adhesion processes, both during development and in adult tissues. It seems likely that the entire gene superfamily evolved from a primordial gene coding for a single Ig-like domain, similar to that encoding β_2 -microglobulin (see Figure 24–36). In present-day family members, a separate exon usually encodes the amino acids in each Ig-like domain, consistent with the likelihood that new family members arose during evolution by exon and gene duplications.

Vaccination Against Pathogens Has Been Immunology's Greatest Contribution to Human Health

As all organisms do, we continually battle with our pathogens. Despite the sophistication of our immune defenses described in this chapter, this battle has been remarkably evenly matched. As discussed in Chapter 23, all pathogens have developed multiple ways of overcoming their host's defenses, at least for long enough to replicate and establish an infection. Most pathogens have the important advantage of multiplying and evolving much more rapidly than humans; in particular, viruses, as a collection, have evolved mechanisms for blocking essentially every

Figure 24-47 Comparison of the costimulatory proteins required to activate a helper T cell and a B cell in response to the same foreign protein. (A) A naïve helper T cell (T_H) is activated by a peptide fragment of a foreign protein bound to a class II MHC protein on the surface of an activated dendritic cell. The co-stimulatory protein on the dendritic cell (a B7 protein either CD80 or CD86) binds to the CD28 co-receptor on the T_H cell, providing a necessary co-stimulatory signal to the T_H cell; in addition, cytokines secreted by the dendritic cell (and by other nearby innate immune cells) influence what subtype of effector helper cell the T_H cell becomes (see Figure 24-44). (B) Once activated to become an effector cell, the TH cell-most commonly a follicular TH cell (TFH; see Figure 24-44)—can help activate B cells that have the same peptide-MHC protein complexes on their surface as the dendritic cell that activated the naïve T_H cell. These B cells have BCRs that bind an antigenic determinant on the surface of a folded foreign protein, and the B cells endocytose the protein (red arrow): the protein is then cleaved into peptides, some of which are carried to the B cell surface by class II MHC proteins. There, some of the peptide-MHC complexes are recognized by the TCRs on the T_{FH} cell (see Figure 24-39). Note that the BCRs and TCRs recognize different antigenic determinants of the protein. As indicated, the costimulatory protein used by the effector T_{FH} cell is CD40 ligand, which binds to the CD40 co-receptor on the B cell; the T_{FH} cell also secretes cytokines (green arrow) including IL21 (see Figure 24-44) to help stimulate the B cell to undergo somatic hypermutation and class switching (not shown). The CD4 co-receptor on TH cells and the invariant chains associated with the TCRs and BCRs are omitted in both A and B for simplicity

MBOC7_ptr_ch24_1353-1404.indd 1396 02/12/21 12:22 PM

1397

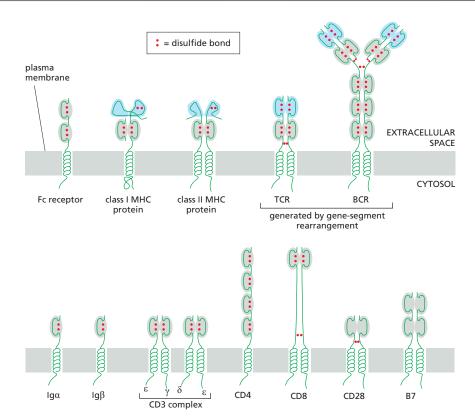

Figure 24-48 Some of the cell-surface proteins discussed in this chapter that belong to the Ig superfamily. The Ig and Ig-like domains are shaded in gray, except for the antigen-binding Ig and Ig-like domains of BCRs and TCRs, respectively, which are shaded in blue. Note that the antigen-binding domains of class I and class II MHC proteins (also shaded in blue) are not Ig-like. The Ig superfamily also includes many cell-surface proteins involved in cell-cell interactions outside the immune system, such as the neural cell adhesion molecules (NCAMs; see Figure 19-29) and the receptors for various protein growth factors discussed in Chapter 15 (not shown). There are more than 750 members of the Ig superfamily in humans, making it the most populous family of proteins encoded in the human genome.

step of our innate and adaptive immune responses. In response, humans have developed public health measures and powerful antipathogen drugs and vaccines that reinforce our natural immunological defenses.

The modern era of **vaccination** began in 1796, when Edward Jenner reported that material from skin lesions in cattle suffering from cowpox protects humans against smallpox, which at that time was a devastating epidemic disease. Although the cowpox virus is closely related to the smallpox virus, it does not cause disease in humans. Smallpox was officially eradicated worldwide by 1980 through widespread and coordinated vaccination with intact *vaccinia* virus (a relative of the cowpox virus), after the disease had killed roughly 500 million people in the preceding 100 years. Today, vaccination (from the Latin word *vaccus*, meaning "cow") is widely used to control the spread of many different pathogens, saving millions of human lives a year worldwide. In the best cases, a vaccine induces strong, long-lasting, adaptive immunological memory, mimicking and often bettering the protection induced by the natural infection, but without causing disease; that is, it is strongly immunogenic but not pathogenic.

There are currently three classes of vaccines approved for use against different pathogens in humans (Table 24–4). In the first class are *whole microbe vaccines*. These are generally strongly immunogenic but require specific manipulations to avoid pathogenicity. A common method is *attenuation*, in which the pathogen is passaged repeatedly through either a foreign host or cultured foreign cells until it accumulates mutations that render it no longer pathogenic in humans. To eliminate the risk of a genetic reversion to a pathogenic form, some vaccines of this class consist of either *extracts* of the pathogen or whole pathogens that have been *inactivated* by heating, chemical treatment, or, now commonly, by genetic manipulation.

The second class, *subunit vaccines*, are even safer, consisting of one or more individual components of the pathogen—either purified from the pathogen or, more commonly, produced by recombinant DNA technology. Most subunit vaccines are composed of viral proteins: common examples consist of viral coat proteins self-assembled *in vitro* to form *virus-like particles*. Other subunit vaccines are composed of bacterial macromolecules: examples are inactivated forms

MBOC7_ptr_ch24_1353-1404.indd 1397 02/12/21 12:22 PM

Class of vaccine	Diseases (pathogens)*			
Whole microbe (or microbial extract)				
Attenuated bacteria	Tuberculosis (BCG, attenuated bovine <i>Mycobacterium</i> tuberculosis), typhoid fever (<i>Salmonella enterica</i> serovar Typhi, oral vaccine)			
Killed bacteria	Pertussis (whooping cough; Bordetella pertussis), cholera (Vibrio cholerae)			
Bacterial extract	Cholera (Vibrio cholerae)			
Attenuated virus	Measles, mumps, rubella (German measles), varicella (chickenpox, shingles), influenza, rotavirus, polio (oral vaccine), hepatitis A and B			
Inactivated virus	Rabies, influenza, polio, hepatitis A and B			
Sub	punit			
Bacterial capsular polysaccharide	Meningitis (Neisseria meningitidis), typhoid fever (Salmonella enterica serovar Typhi), bacterial pneumonia (Streptococcus pneumoniae)			
Bacterial polysaccharide-protein conjugate	Meningitis (<i>Haemophilus influenzae</i>), bacterial pneumonia (<i>Streptococcus pneumoniae</i>)			
Bacterial protein toxids	Tetanus (Clostridium tetani), diphtheria (Corynebacterium diphtheriae), pertussis (toxoid + other bacterial proteins)			
Viral protein (usually recombinant)	Hepatitis A and B, human influenza viruses			
Virus-like particles composed of viral coat proteins	Cervical cancer (human papillomavirus types 16 and 18)			
Nuclei	c acid**			
Recombinant RNA virus vector, based on vesicular stomatitis virus, engineered to express an Ebola virus surface protein***	Ebola hemorrhagic fever (Ebola virus)			
Recombinant DNA virus vector, based on adenovirus, engineered to express a form of SARS-CoV-2 spike protein (see Figure 24–50)****	COVID-19 (SARS-CoV-2 coronavirus)			
Lipid nanoparticles containing modified mRNA that encodes a form of SARS-CoV-2 spike protein (see Figure 24–50)****	COVID-19 (SARS-CoV-2 coronavirus)			

of secreted protein toxins (toxoids), which in their active forms cause diseases such as tetanus and diphtheria, and the capsular polysaccharides that surround various bacteria (see Table 24-4).

To be maximally effective, a vaccine needs to stimulate both B cell and T cell immune responses. Subunit vaccines composed solely of bacterial capsular polysaccharides, for example, are relatively ineffective because they only activate B cells. Because helper T cells are required to induce B cell memory, antibody affinity maturation, and Ig class switching, such polysaccharide vaccines only induce short-lived, low-affinity, IgM anti-polysaccharide antibodies, providing weak and brief protection. Chemically coupling (conjugating) the polysaccharide to a protein such as tetanus or diphtheria toxoid to produce a conjugate vaccine solves this problem: the protein component provides the foreign peptides that

MBOC7_ptr_ch24_1353-1404.indd 1398 02/12/21 12:22 PM

^{**}Some (such as the Ebola vaccine) can replicate in recipient cells, others (including those shown in Figure 24-50) cannot.

^{***}This was the first nucleic acid vaccine approved (in 2019) for human use.

^{****}These vaccines were given Emergency Use Authorization at the end of 2020 or in 2021 and were approved in 2021.

T CELLS AND MHC PROTEINS 1399

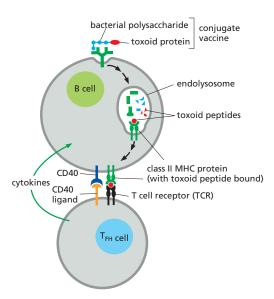

Figure 24-49 How conjugate vaccines against bacterial polysaccharide antigens activate both B cells and helper T cells. In this case, the polysaccharide is chemically coupled to a protein toxoid. The B cells recognize the polysaccharide part of the conjugate, endocytose the conjugate, and cleave the protein part into peptide fragments in endolysosomes. The peptide fragments are then transported by class II MHC proteins to the B cell surface, where the peptide-MHC complexes are recognized by helper T cells (see Figure 24-39). The helper T cells (T_{FH} cells) help activate the B cells to produce both high-affinity IgG anti-polysaccharide antibodies (see Figure 24-47B) and memory B cells (not shown).

activate the helper T cells required for optimal stimulation of the appropriate polysaccharide-specific B cells, as illustrated in Figure 24–49.

As discussed earlier in the chapter, for a vaccine to activate adaptive immune responses, it first must activate dendritic cells. A vaccine composed of a whole microbe or a microbial extract fulfills this requirement because it contains pathogen-associated molecular patterns (PAMPs) that activate pattern recognition receptors (PRRs) on innate immune cells, especially dendritic cells. Subunit vaccines that lack PAMPs require the addition of an *adjuvant*, a substance that enhances the immunogenicity of antigens, usually by activating PRRs.

The third and most recent type of vaccines contains genetically engineered DNA or RNA molecules that encode pathogen proteins or parts of such proteins. The development of these *nucleic acid vaccines* has required the knowledge and tools produced by decades of fundamental research to make the vaccines tolerable, safe, and effective. The first such vaccine approved for human use (in 2019) was a recombinant RNA virus vector vaccine encoding an Ebola virus surface protein (see Table 24–4). But the use of nucleic acid vaccines only took off in 2021, in response to the COVID-19 pandemic, which has infected hundreds of millions of people and caused millions of deaths. Because only a pathogen's genome sequence is needed to develop a nucleic acid vaccine against the pathogen, it was possible to produce the first safe and effective DNA- and RNA-based vaccines for large-scale human use within a year from the publication (in January 2020) of the RNA genome sequence of the causative SARS-CoV-2 virus.

Figure 24–50 illustrates how two different kinds of nucleic acid vaccines against COVID-19 work: both encode forms of the protein "spike" found on the surface of the SARS-CoV-2 virus (see Figure 1–49). A number of whole microbe and subunit vaccines are also in wide use or in development around the world to fight the COVID-19 pandemic. But, given the recent success of nucleic acid vaccines, it seems likely that they will revolutionize how most new vaccines are produced in the future.

A successful vaccination program against a pathogen usually requires that most of the population becomes immune to it, either naturally by infection or by vaccination. Such *herd immunity* slows the spread of an infection by decreasing the number of susceptible individuals in the population. To produce herd immunity, a vaccine needs to be well tolerated, safe and effective, and widely perceived to be so. The importance of both herd immunity and the public acceptance of a vaccine was inadvertently demonstrated by the response to a false and fraudulent report of a link between a measles vaccine and autism. After publication of the report in 1998, the uptake of the vaccine in Britain decreased substantially, leading to an increase in both the size and frequency of measles outbreaks (Figure 24–51).

MBOC7_ptr_ch24_1353-1404.indd 1399 02/12/21 12:22 PM

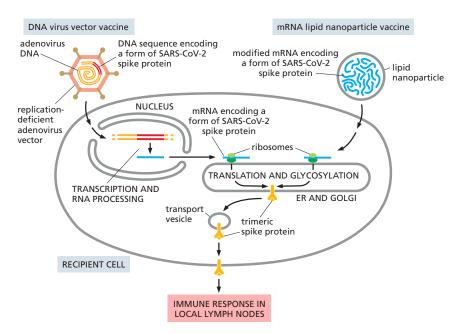

Figure 24–50 How two kinds of widely used nucleic acid COVID-19 vaccines work. In both, the nucleic acids encode forms of the spike (S) protein, which normally protrudes from the surface of the SARS-CoV-2 coronavirus (see Figure 1–49 and Figure 9–50); these spikes on the virus bind to receptors on various human cells and help the virus enter the cells. The DNA virus vector vaccine shown on the left is representative of two COVID-19 vaccines that received early authorization for emergency use in humans—known as the Oxford–AstraZeneca vaccine and the Janssen–Johnson & Johnson vaccine—both of which are based on adenovirus vectors (chimpanzee and human, respectively). These vectors, which have been genetically engineered to prevent their replication in human cells, transfer their DNA into the nucleus of these cells, where it produces mRNAs. As indicated, the vector-encoded mRNAs move to the cytoplasm, where they are translated on endoplasmic reticulum (ER)-bound ribosomes to produce the spike proteins. After glycosylation in the ER and Golgi apparatus, the spike proteins are transported to the cell surface as trimeric spikes.

The mRNA lipid nanoparticle vaccine shown on the right is representative of the first COVID-19 vaccines of this kind authorized for emergency use in humans—known as the Pfizer—BioNTech and the Moderna vaccines. The mRNA is synthesized *in vitro* with nucleoside modifications (uridines replaced by methylpseudouridines) to prevent the mRNA from binding to PRRs and triggering a destructive inflammatory response, which would otherwise decrease the vaccine's tolerability and the mRNA's translation. In addition, the mRNA is designed with a nucleotide sequence that maximizes its translation efficiency. Finally, the mRNA molecules are encapsulated in tiny, complex lipid nanoparticles: this coating protects the mRNAs, enhances the vaccine's uptake into host-cell endosomes, and mediates the release of the mRNA from the endosomes into the cytosol.

In all cases the vaccine is injected into an arm muscle, from where it is carried via lymphatic vessels to local lymph nodes. Both in the muscle and in lymph nodes, antigen-presenting cells (most important, dendritic cells) take up the vaccine and are activated in the process. In these cells, the mRNAs are translated into spike protein, which is then glycosylated and transported to the cell surface as indicated. In the lymph nodes, the activated dendritic cells present peptide fragments of the spike protein, bound to MHC proteins on the dendritic-cell surface, to spike-specific helper and cytotoxic T cells, which are thereby activated to proliferate and differentiate into effector cells. The effective helper T cells then help stimulate spike-specific B cells to proliferate and differentiate into effector cells that secrete neutralizing anti-spike antibodies, while the cytotoxic T cells kill any host cells that subsequently become infected with the SARS-CoV-2 virus. At the same time, the activated dendritic cells stimulate the production of spike-specific memory B and T cells, which a second immunization can further increase in number and effectiveness. Later, a natural encounter with the SARS-CoV-2 virus will call these memory cells into action to protect vaccinated individuals against COVID-19 disease.

It remains to be seen how long the protection lasts and how effective it will be against new mutant SARS-CoV-2 virus variants, as they arise and are selected to resist our collective adaptive immune responses to either immunization or natural infection. Fortunately, the nucleic acid vaccines, especially mRNA vaccines, can be resynthesized rapidly to increase their effectiveness against any such genetic variants.

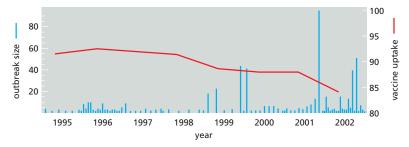

Summary

There are three main functionally distinct classes of T cells. Cytotoxic T cells (T_C cells) directly kill infected host cells by the targeted secretion of perforins and granzymes onto the surface of the infected cells, inducing them to kill themselves by undergoing apoptosis. Helper T cells (T_H cells) help B cells to make antibody responses, macrophages to destroy the microorganisms they harbor, and dendritic cells to activate T_C cells. By contrast, regulatory T cells (T_{reg} cells) produce suppressive proteins (such as the cytokines IL10 and $TGF\beta$) to inhibit other immune cells.

All T cells express cell-surface antigen receptors (TCRs), which are encoded by genes that are assembled from multiple gene segments during T cell development in the thymus. $\alpha\beta$ TCRs recognize peptide fragments of foreign proteins that are displayed in association with MHC proteins on the surface of antigen-presenting cells (APCs), including T cell targets. Naïve T cells are activated in peripheral

MBOC7_ptr_ch24_1353-1404.indd 1400 02/12/21 12:22 PM

T CELLS AND MHC PROTEINS 1401

lymphoid organs by activated dendritic cells, which secrete cytokines and express peptide–MHC complexes, co-stimulatory proteins, and various cell-cell adhesion molecules on their surface.

Class I MHC proteins present foreign peptides to T_C cells, whereas class II MHC proteins present foreign peptides to T_H cells and self and foreign peptides to T_{reg} cells. Whereas class I MHC proteins are expressed on almost all nucleated vertebrate cells, class II MHC proteins are normally restricted to APCs, including dendritic cells, macrophages, and B lymphocytes. Both classes of MHC proteins have a single peptide-binding groove, which binds a large set of small peptide fragments produced intracellularly by normal protein-degradation processes: class I MHC proteins mainly bind fragments produced in the cytosol, whereas class II MHC proteins mainly bind fragments produced in endocytic compartments. The peptide-MHC complexes are transported to the cell surface, where complexes that contain a peptide derived from a foreign protein are recognized by TCRs, which interact with both the peptide and the walls of the peptide-binding groove. T cells also express CD4 or CD8 co-receptors, which recognize invariant regions of MHC proteins: T_H cells and T_{reg} cells express CD4, which recognizes class II MHC proteins; T_C cells express CD8, which recognizes class I MHC proteins.

A combination of positive and negative selection processes operate during thy-mocyte development to help ensure that only T cells with potentially useful TCRs survive, mature, and emigrate from the thymus, while all other thymocytes die by apoptosis. After leaving the thymus, the na \tilde{t}_C cells continually receive survival signals when their tCRs recognize self-peptide-self-MHC complexes, but they can only be activated to become effector cells when their tCRs encounter foreign peptides in the grooves of MHC proteins on an activated dendritic cell. The cells that leave the thymus as natural tCRs recognize self-peptide in the thymus as natural tCRs recognize cells help maintain self-tolerance by suppressing self-reactive tC cells that escape negative selection in the thymus.

The production of an effector T cell from a naïve T cell requires multiple signals from an activated dendritic cell. MHC-peptide complexes on the dendritic cell surface provide one signal, by binding to both TCRs and to either a CD4 co-receptor on a T_H or T_{reg} cell or to a CD8 co-receptor on a T_C cell; co-stimulatory proteins on the dendritic cell surface and secreted cytokines provide the other signals. When naïve T_H cells are initially activated on a dendritic cell in a peripheral lymphoid organ, they can differentiate into various types of effector T cells, depending on the invading pathogen and the cytokines in their environment. They can become effector T_{FH} cells, which remain in the lymphoid organ to support B cell antibody production in lymph follicles, or they can develop into effector T_H1, T_H2, or T_H17 cells, which mainly migrate to sites of infection, where they help other immune cells fight the pathogen; alternatively, they can develop into induced T_{reg} cells, which suppress other immune cells. The various effector T_H cells recognize the same complex of foreign peptide and class II MHC protein on the surface of the target cell they are helping as they initially recognized on the dendritic cell that activated them; they activate their target cells by a combination of membrane-bound co-stimulatory proteins and secreted cytokines. T_{reg} cells use cell-surface and secreted inhibitory proteins to suppress their target cells.

Both T cells and B cells require multiple signals for activation. Antigen binding to the TCRs or BCRs provides one signal, while co-stimulatory proteins binding to co-receptors and cytokines binding to their complementary cell-surface receptors provide the others. Effector T_H cells provide the co-stimulatory signals and secreted cytokines for B cells, whereas APCs provide them for T cells.

Figure 24-51 The importance of herd immunity and public acceptance of a vaccine. After the publication in 1998 of a false link between measles vaccination and autism, fewer children in Britain were vaccinated against the measles virus (red line), and outbreaks of measles (blue bars) increased in both frequency and size. About 95% of a population needs to be immune to measles to achieve herd immunity (the comparable value for COVID-19 is estimated to be between 65 and 90%, depending on the virus variant). The vaccine uptake shown is the percentage of children completing a primary course of the measles, mumps, and rubella (MMR) vaccine at their second birthday. (Data courtesy of V.A.A. Jansen and M.E. Ramsey. Adapted from V.A.A. Jansen et al., Science 301:804, 2003. With permission from AAAS.)

MBOC7_ptr_ch24_1353-1404.indd 1401 02/12/21 12:22 PM

PROBLEMS

Which statements are true? Explain why or why not.

- **24–1** T cells whose receptors strongly bind a self-peptide-self-MHC complex are killed off in peripheral lymphoid organs when they encounter the self peptide on an antigen-presenting dendritic cell.
- **24–2** To guarantee that the antigen-presenting cells in the thymus will display a complete repertoire of self peptides to allow elimination of self-reactive T cells, the thymus recruits dendritic cells from all over the body.
- **24–3** The antibody diversity created by the combinatorial joining of V, D, and J segments by V(D)J recombination pales in comparison to the enormous diversity created by the random gain and loss of nucleotides at V, D, and J joining sites.

Discuss the following problems.

- 24–4 Why do living trees not rot? Redwood trees, for example, can live for centuries, but once they die they decay fairly quickly. What might this suggest?
- 24–5 It would be disastrous if a complement lytic attack were not confined to the surface of the pathogen that is the target of the attack. Yet, the proteolytic cascade involved in the attack liberates biologically active molecules at several steps: one that diffuses away and one that remains bound to the target surface. How does the complement attack remain localized to the pathogen when active products leave the pathogen surface?
- **24–6** On the basis of its sequence similarity to Apobec 1, which deaminates C to U in RNA, activation-induced deaminase (AID) was originally proposed to work on RNA. But definitive experiments in *Escherichia coli* demonstrated that AID deaminates C to U in DNA. The authors of the paper expressed AID in bacteria and followed mutations in a selectable gene. They found that AID expression increased mutations about fivefold above the background level in the absence of AID expression. More important, they found that 80% of the induced mutations were $G \rightarrow A$ or $C \rightarrow T$. Does this fit with your expectation if AID-induced mutations arose by deamination of C to U in the DNA?

[Hint: Imagine what would happen if the G:U mismatch created by AID was replicated several times; how would the sequences of the final mutations relate to the original G-C base pair?]

24–7 For many years it was a complete mystery how cytotoxic T cells could recognize and respond to a viral protein in a virus-infected cell when the protein seemed to be present only in the nucleus of the cell. The answer was revealed in a classic paper that took advantage of a clone of cytotoxic T cells whose T cell receptor (TCR) was directed against an antigen associated with the nuclear protein of the 1968 strain of influenza virus. The authors of the paper

found that when they incubated noninfected living cells in high concentrations of certain peptides derived from the viral nuclear protein, the cells became sensitive to lysis by subsequent incubation with the cytotoxic T cells. Using various peptides from the 1968 strain and the 1934 strain (with which the cytotoxic T cells did not react), the authors defined the particular peptide responsible for the killing response of the T cell (Figure Q24–1).

- **A.** Which part of the viral protein gives rise to the peptide that is recognized by the clone of cytotoxic T cells? Why do not all of the viral peptides sensitize the target cells for lysis by the cytotoxic T cells?
- **B.** It is known that the MHC proteins come to the cell surface with peptides already bound. How then do you imagine that these experiments worked when the peptides were added to the outside of the living target cells?

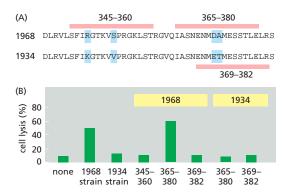

Figure Q24–1 Viral nuclear protein recognition by cytotoxic T cells (Problem 24–7). (A) Sequences of a segment of the nuclear protein from the 1968 and 1934 strains of influenza virus. Peptides used in the experiments in B are highlighted by pink bars. The amino acid differences between the viral proteins are highlighted in blue. (B) Cytotoxic T cell–mediated lysis of target cells. The target cells were untreated (none), transfected with nuclear protein genes (1968 or 1934 strain), or preincubated with high concentrations of nuclear protein peptides from the 1968 or 1934 strain, as indicated by the yellow highlights.

24–8 Working out the roles of MHC proteins in T cell antigen recognition was complicated. One of the key observations came from studying how different kinds of class I MHC proteins influence the way cytotoxic T cells killed cells infected with lymphocytic choriomeningitis virus (LCMV). Cytotoxic T cells derived from mice expressing "k-type" class I MHC proteins lysed LCMV-infected cells expressing the same k-type MHC protein, but they did not lyse LCMV-infected cells from mice expressing "d-type" class I MHC proteins (Figure Q24–2). Similarly, cytotoxic T cells from d-type mice infected with LCMV lysed infected d-type cells, but not infected k-type cells. LCMV can kill both k-type and d-type mice.

A. If homozygous d-type mice were bred to homozygous k-type mice to generate d-type/k-type heterozygous progeny, would you expect that cytotoxic T cells derived

PROBLEMS 1403

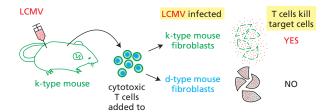

Figure Q24–2 Pattern of killing of LCMV-infected fibroblasts by cytotoxic T cells from an LCMV-infected k-type mouse (Problem 24–8).

from these LCMV-infected heterozygotes would be able to lyse LCMV-infected d-type cells? How about LCMV-infected k-type cells? Explain your answers.

B. Oddly enough, LCMV infection does not kill mice that lack a thymus (and therefore lack T cells)—such as "nude" mice, so called because they also lack hair. If a thymus is transplanted back into a nude mouse, the mouse will then die when infected with LCMV. Suppose that a developing d-type/k-type heterozygous nude mouse was given a thymus from a d-type donor and was later infected with LCMV. Would you expect its cytotoxic T cells to be able to lyse LCMV-infected d-type cells? How about infected k-type cells? Explain your answers.

24–9 Before exposure to a foreign antigen, T cells with receptors specific for the antigen are a tiny fraction of the T cells—of the order 1 in 10^5 or 1 in 10^6 T cells. After exposure to the antigen, only a small number of dendritic cells typically display the antigen on their surface. How long does it take for such antigen-presenting dendritic cells to interact with the antigen-specific T cells, which is the key first step in T cell activation and clonal expansion? To begin to address this question, scientists

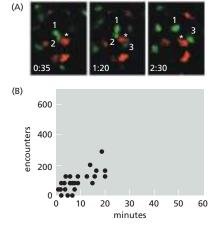

Figure Q24–3 Scanning of the T cell repertoire by dendritic cells in the absence of antigen (Problem 24–9). (A) Contacts between different T cells and one dendritic cell. T cells are *green* and dendritic cells are *red*. The dendritic cell labeled with an asterisk contacts a total of three T cells (numbered) over time in this sequence of images. Times are shown as hours:minutes. (B) Plot of T cell contacts for individual dendritic cells over time. (A, from P. Bousso and E. Robey, *Nat. Immunol.* 4:579–585, published 2003 by Nature Publishing Group. Reproduced with permission of SNCSC.)

studied T-cell-dendritic-cell interactions in the absence of specific antigen. They isolated T cells and dendritic cells from unimmunized mice, labeled the T cells *green* and the dendritic cells *red*, and injected them into an unimmunized mouse. After 20 hours, they isolated a local lymph node and scored the contacts between the two cell types visually using two-photon fluorescence microscopy (**Figure Q24–3A**). The frequency of contacts between the two types of cells is given in **Figure Q24–3B**. Assuming that 100 dendritic cells present a specific antigen in an immunized mouse, how long would it take them to scan 10^5 T cells to find one or more antigen-specific T cells? How long to scan 10^6 T cells?

24–10 At first glance, it would seem a dangerous strategy for the thymus to actively promote the survival, maturation, and emigration of developing T cells that bind weakly to self peptides bound to self MHC proteins. Would it not be safer to get rid of these T cells, along with those that bind strongly to such self-peptide-self-MHC complexes, as this would seem a more secure way to avoid autoimmune reactions?

24-11 CD4 proteins on helper and regulatory T cells serve as co-receptors that bind to invariant parts of class II MHC proteins. CD4 is thought to increase the adhesion between T cells and antigen-presenting cells (APCs) that are initially connected only weakly by the TCR bound to its specific peptide-MHC complex. To test this possibility, you label cell-surface MHC proteins with a fluorescently labeled peptide so that you can detect individual peptide-MHC complexes at the interface between the APCs and the T cells in a culture dish. To detect T cell responses the sign of a productive contact-you load them with a Ca²⁺ indicator dye to detect the increase in cytosolic Ca²⁺ that occurs when lymphocytes are activated. You now count the peptide-MHC complexes at a large number of interfaces (immunological synapses) and measure the Ca²⁺ signal in the adherent T cells (Figure Q24-4, red dots). When you repeat the experiment in the presence of blocking antibodies against CD4, you get a different result (blue dots). Do these results support or refute the notion that CD4 augments T-cell-APC binding? Explain your answer.

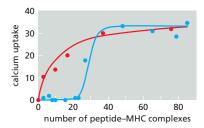

Figure Q24–4 Role of CD4 in the T cell response (Problem 24–11). The uptake of Ca²⁺ in cells with different numbers of fluorescently labeled peptide–MHC complexes at the interface between the T cells and the antigen-presenting cells. The results in the absence of CD4-blocking antibodies are shown by the *red curve*; results in the presence of CD4 antibodies are shown by the *blue curve*.

Glossary

ABC transporters A large class of membrane transport proteins that use the energy of ATP hydrolysis to transfer peptides or small molecules across membranes. (Chapter 11) (Figure 11–16)

acetyl CoA Small water-soluble activated carrier molecule. Consists of an acetyl group linked to coenzyme A (CoA) by an easily hydrolyzable, energy-rich thioester bond. (Chapter 2) (Figure 2–38)

acetylcholine receptor (AChR) Membrane protein that responds to binding of acetylcholine (ACh). The nicotinic AChR is a transmitter-gated ion channel that opens in response to ACh. The muscarinic AChR is not an ion channel, but a G-protein-coupled cell-surface receptor. (Chapter 11)

acid A proton donor. Substance that releases protons (H^+) when dissolved in water, forming hydronium ions (H_3O^+) and lowering the pH. (Chapter 2) (Panel 2–2, pp. 96–97)

acid hydrolases Hydrolytic enzymes—including proteases, nucleases, glycosidases, lipases, phospholipases, phosphatases, and sulfatases—that work best at acidic pH; these enzymes are found within the lysosome. (Chapter 13)

action potential Rapid, transient, self-propagating electrical excitation in the plasma membrane of a cell such as a neuron or muscle cell. Action potentials, or nerve impulses, make possible long-distance signaling in the nervous system. (Chapter 11) (Figure 11–33)

activated carrier Small diffusible molecule that stores easily exchangeable energy in the form of one or more energy-rich covalent bonds. Examples are ATP, acetyl CoA, FADH₂, NADH, and NADPH. (Chapter 2) (Figure 2–31)

activation energy The extra energy that must be acquired by atoms or molecules in addition to their ground-state energy in order to reach the transition state required for them to undergo a particular chemical reaction. (Figure 2–21)

activation-induced deaminase (AID) The enzyme catalyzing the processes of somatic hypermutation and immunoglobulin class switching in activated B cells. (Chapter 24)

active site Region of an enzyme surface to which a substrate molecule binds in order to undergo a catalyzed reaction. (Chapter 3)

active transport Movement of a molecule across a membrane or other barrier driven by energy other than that stored in the electrochemical or concentration gradient of the transported molecule itself. (Chapter 11)

adaptation (1) Adaptation (desensitization): adjustment of sensitivity following repeated stimulation. The mechanism that allows a cell to react to small changes in stimuli even against a high background level of stimulation. (2) Evolutionary adaptation: an evolved trait. (Chapters 11, 15)

adaptive immune system System of lymphocytes providing highly specific and long-lasting defense against pathogens in vertebrates. It consists of two major classes of lymphocytes: B lymphocytes (B cells), which secrete antibodies that bind specifically to the pathogen or its products, and T lymphocytes (T cells), which can either directly kill cells infected with the pathogen or produce secreted or cell-surface signal proteins that stimulate other host cells to help eliminate the pathogen. (Chapter 24) (Figure 24–2)

adaptor protein, **adaptor** General term for a protein that functions solely to link two or more different proteins together in an intracellular signaling pathway or protein complex. (Chapters 13, 15) (Figure 15–11)

adenylyl cyclase (**adenylate cyclase**) Membrane-bound enzyme that catalyzes the formation of cyclic AMP from ATP. An important component of some intracellular signaling pathways. (Chapter 15)

adherens junction Cell junction in which the cytoplasmic face of the plasma membrane is attached to actin filaments. Examples include adhesion belts linking adjacent epithelial cells and focal contacts on the lower surface of cultured fibroblasts. (Chapter 19)

adhesins Specific proteins or protein complexes of pathogenic bacteria that recognize and bind cell-surface molecules on the host cells to enable tight adhesion and colonization of tissues. (Chapter 23)

adhesion belt Adherens junctions in epithelia that form a continuous belt (*zonula adherens*) just beneath the apical face of the epithelium, encircling each of the interacting cells in the sheet. (Chapter 19)

ADP (adenosine 5'-diphosphate) Nucleotide derivative (a nucleoside diphosphate) produced by hydrolysis of the terminal phosphate of ATP. Regenerates ATP when phosphorylated by an energy-generating process such as oxidative phosphorylation. (Chapter 2) (Figure 2–33)

adult stem cells Undifferentiated cells found throughout the body that undergo cell divisions to maintain homeostasis of adult tissues and replenish damaged tissues; also known as somatic stem cells. (Chapter 22)

aerobic respiration Process by which a cell obtains energy from sugars or other organic molecules by allowing their carbon and hydrogen atoms to combine with the oxygen in air to produce CO_2 and H_2O , respectively. (Chapters 2 and 14)

affinity constant (K_a) The equilibrium constant for a simple binding interaction, when expressed as [AB]/[A][B]. Also known as the *association constant*. (Chapter 3)

affinity maturation Progressive increase in the affinity of antibodies for the immunizing antigen with the passage of time after immunization. (Chapter 24)

G:2

AIRE (autoimmune regulator) A protein expressed by a subpopulation of epithelial cells in the thymus that stimulates the production of small amounts of self proteins characteristic of other organs, exposing developing thymocytes to these proteins for the purpose of self-tolerance. (Chapter 24)

Akt Serine/threonine protein kinase that acts in the PI-3-kinase–Akt intracellular signaling pathway; involved especially in signaling cells to grow and survive. Also called protein kinase B (PKB). (Chapter 15)

allele One of several alternative forms of a gene. In a diploid cell, each gene will typically have two alleles, occupying the same corresponding position (locus) on homologous chromosomes. (Chapters 5, 8)

allosteric protein A protein that can adopt at least two distinct conformations, and for which the binding of a ligand at one site causes a conformational change that alters the activity of the protein at a second site; this allows one type of molecule in a cell to alter the fate of a molecule of another type, a feature widely exploited in enzyme regulation. (Chapter 3)

allostery (adjective **allosteric**) Change in a protein's conformation brought about by the binding of a regulatory ligand (at a site other than the protein's catalytic site) or by covalent modification. The change in conformation alters the activity of the protein; it can also form the basis of directed movement. (Chapter 3) (Figures 3–71 and 16–53)

alpha helix (α **helix**) Common folding pattern in proteins, in which a linear sequence of amino acids folds into a right-handed helix stabilized by internal hydrogen-bonding between backbone atoms. (Chapter 3) (Figure 3–6)

alternative RNA splicing Production of different RNAs from the same gene by splicing the transcript in different ways. (Chapter 7) (Figure 7–59)

amino acid Organic molecule containing both an amino group and a carboxyl group. Those that serve as building blocks of proteins are alpha amino acids, having both the amino and carboxyl groups linked to the same carbon atom. (Chapter 1) (Figure 3–1 and Panel 3–1, pp. 118–119)

aminoacyl-tRNA synthetase Enzyme that attaches the correct amino acid to a tRNA molecule to form an aminoacyl-tRNA. (Chapter 6) (Figure 6–58)

amoeboid cell migration A rapid mode of cell locomotion typical of amoebae and white blood cells that is characterized by protrusion of actin-rich pseudopodia at the leading edge, formation of weak attachments to the substratum, and actomyosin-based contraction at the rear of the cell. (Chapter 16)

AMPA receptor Glutamate-gated ion channel in the mammalian central nervous system that carries most of the depolarizing current responsible for excitatory postsynaptic potentials. (Chapter 11)

amphiphilic Having both hydrophobic and hydrophilic regions, as in a phospholipid or a detergent molecule. (Chapter 10)

amyloid fibrils Self-propagating, stable β -sheet aggregates built from hundreds of identical polypeptide chains that become layered one over the other to create a continuous stack of β sheets. The unbranched fibrous structure can contribute to human diseases when not controlled. (Chapter 3)

anaphase (1) Stage of mitosis during which sister chromatids separate and move away from each other. (2) In meiosis, anaphase I and II are the stages during which chromosome homolog pairs separate (I), and then sister chromatids separate (II). (Panel 17–1, pp. 1048–1049)

anaphase A The stage of mitosis during which chromosome segregation occurs as chromosomes move toward the two spindle poles. (Chapter 17)

anaphase B The stage of mitosis during which chromosome segregation occurs as spindle poles separate and move apart. (Chapter 17)

anaphase-promoting complex, or cyclosome (APC/C)Ubiquitin ligase that catalyzes the ubiquitylation and destruction of securin and M- and S-cyclins, initiating the separation of sister chromatids in the metaphase-to-anaphase transition during mitosis. (Chapter 17)

anchorage dependence Dependence of cell growth, proliferation, and survival on attachment to a substratum. (Chapter 19)

anchoring junction Cell junction that attaches cells to neighboring cells or to the extracellular matrix. (Chapter 19) (Table 19–1, p. 1107)

angiogenesis Growth of new blood vessels by sprouting from existing ones. (Chapter 20)

antenna complex Part of a photosystem that captures light energy and channels it into the photochemical reaction center. It consists of protein complexes that bind large numbers of chlorophyll molecules and other pigments. (Chapter 14)

Antennapedia complex One of two gene clusters in *Drosophila* that contain *Hox* genes; genes in the *Antennapedia* complex control the differences among the thoracic and head segments of the body. (Chapter 21)

anti-apoptotic Bcl2 family proteins Proteins (for example, Bcl2, BclxL) on the cytosolic surface of the outer mitochondrial membrane that bind and inhibit pro-apoptotic Bcl2 family proteins and thereby help prevent inappropriate activation of the intrinsic pathway of apoptosis. (Chapter 18)

anti-IAP proteins Produced in response to various apoptotic stimuli and, by binding to IAPs (inhibitory antiapoptotic proteins), prevent their binding to a caspase—thereby blocking the inhibition of apoptosis provided by IAPs. (Chapter 18)

antibiotic Substance such as penicillin or streptomycin that is toxic to microorganisms. Often a natural product of a particular microorganism or plant. (Chapter 23)

antibody (or **immunoglobulin**) Protein secreted by activated B cells in response to a pathogen or foreign molecule. Binds tightly to the pathogen or foreign molecule, inactivating it or marking it for destruction by phagocytosis or complement-induced lysis. (Chapters 3, 24) (Figure 24–23)

antibody response Adaptive immune response in which B cells are activated to secrete antibodies that circulate in the bloodstream or enter other body fluids, where they can bind specifically to the foreign antigen that stimulated their production. (Chapter 24)

anticodon Sequence of three nucleotides in a transfer RNA (tRNA) molecule that is complementary to a three-nucleotide codon in a messenger RNA (mRNA) molecule. (Chapter 6)

antigen Any molecule that can bind specifically to an antibody or B cell receptor, or any protein fragment bound to an MHC protein that can bind specifically to a T cell receptor. (Chapters 3, 24)

antigen-presenting cell (APC) Cell that displays foreign antigen complexed with an MHC protein on its surface for presentation to T lymphocytes. (Chapter 24)

antigenic determinant Specific region of an antigen that binds to an antibody or a complementary receptor on the surface of a B cell (BCR) or T cell (TCR). (Chapter 24)

antigenic variation Ability to change the antigens displayed on the cell surface; a property of some pathogenic microorganisms that enables them to evade attack by the adaptive immune system. (Chapter 23)

antiparallel Describes the relative orientation of the two strands in a DNA double helix or two paired regions of a polypeptide chain; the chemical polarity of one strand is opposite to that of the other. (Chapter 4)

antiporter Carrier protein that transports two different ions or small molecules across a membrane in opposite directions, either simultaneously or in sequence. (Chapter 11) (Figure 11–8)

Apaf1 Adaptor protein of the intrinsic apoptotic pathway; on binding cytochrome *c*, oligomerizes to form an apoptosome. (Chapter 18)

apical Referring to the tip of a cell, a structure, or an organ. The apical surface of an epithelial cell is the exposed free surface, opposite to the basal surface. The basal surface rests on the basal lamina that separates the epithelium from other tissue. (Chapter 19)

apoptosis Form of programmed cell death, in which a "suicide" program is activated within an animal cell, leading to rapid cell death mediated by intracellular proteolytic enzymes called caspases. (Chapter 18)

apoptosome Heptamer of Apaf1 proteins that forms on activation of the intrinsic apoptotic pathway; it recruits and activates initiator caspases that subsequently activate downstream executioner caspases to induce apoptosis. (Chapter 18)

aquaporin (water channel) Channel protein embedded in the plasma membrane that greatly increases the cell's permeability to water, allowing transport of water, but not ions, at a high rate across the membrane. (Chapter 11)

archaea (archaebacteria) Single-celled organisms without a nucleus, superficially similar to bacteria. At a molecular level, more closely related to eukaryotes in genetic machinery than are bacteria. Archaea and bacteria together make up the prokaryotes. (Figure 1–9)

ARF proteins Monomeric GTPase in the Ras superfamily responsible for regulating both COPI coat assembly and clathrin coat assembly. (Chapter 13) (Table 15–5, p. 915)

Arp2/3 complex Complex containing two actin-related proteins that binds to an actin filament and then nucleates actin filament growth from the minus end. (Chapter 16)

arrestin Member of a family of proteins that contributes to GPCR desensitization by preventing the activated receptor from interacting with G proteins; also serves as an adaptor to couple the receptor to clathrin-dependent endocytosis. (Chapter 15) (Figure 15–43)

association constant (K_a) The equilibrium constant for a simple binding interaction, when expressed as [AB]/[A][B]. Also known as the *affinity constant*. (Chapter 3)

astral microtubule In the mitotic spindle, any of the microtubules radiating from the aster that are not attached to a kinetochore of a chromosome. (Chapter 17)

asymmetric cell division Cell division in which some important molecule or molecules are distributed unequally

between the two daughter cells, causing these cells to become different from each other. (Figures 21–35 and 22–16)

ATM (ataxia telangiectasia mutated protein) Protein kinase activated by double-strand DNA breaks. If breaks are not repaired, ATM initiates a signal cascade that culminates in cell-cycle arrest. Related to ATR. (Chapter 17)

ATP (adenosine 5'-triphosphate) Nucleoside triphosphate composed of adenine, ribose, and three phosphate groups. The principal carrier of chemical energy in cells. The terminal phosphate groups are highly reactive in the sense that their hydrolysis, or transfer to another molecule, takes place with the release of a large amount of free energy. (Chapter 2) (Figure 2–33)

ATP synthase (F₁F_o **ATP synthase**) Abundant transmembrane enzyme complex in the inner membrane of mitochondria and the thylakoid membrane of chloroplasts. Driven by an electrochemical proton gradient, it catalyzes the formation of ATP from ADP and phosphate during oxidative phosphorylation and photosynthesis. Also present in the plasma membrane of bacteria. (Chapter 14)

ATR (ataxia telangiectasia and Rad3 related protein)
Protein kinase activated by DNA damage. If damage remains unrepaired, ATR helps initiate a signal cascade that culminates in cell-cycle arrest. Related to ATM. (Chapter 17)

autoimmune disease Pathological state in which the body mounts a disabling adaptive immune response against one or more of its own molecules. (Chapter 24)

autophagosome Organelle surrounded by a double membrane that contains engulfed cytoplasmic cargo in the initial stages of autophagy. (Chapter 13)

autophagy Digestion of cytoplasm and worn-out organelles by the cell's own lysosomes. (Chapter 13)

auxin Plant hormone, indole-3-acetic acid, with numerous roles in plant growth and development. (Chapter 15)

axon Long nerve-cell projection that can rapidly conduct nerve impulses over long distances so as to deliver signals to other cells. (Chapter 11)

axoneme Bundle of microtubules and associated proteins that forms the core of a cilium or a flagellum in eukaryotic cells and is responsible for their movements. (Chapter 16)

B cell receptor (BCR) The transmembrane immunoglobulin protein on the surface of a B cell that serves as its receptor for antigen. (Chapter 24)

bacterial artificial chromosome (BAC) Cloning vector that can accommodate large pieces of DNA, typically up to 1 million base pairs. (Chapter 8)

bacteriorhodopsin Pigmented protein found in the plasma membrane of a salt-loving archaeon, *Halobacterium salinarum* (*Halobacterium halobium*). Pumps protons out of the cell in response to light. (Chapter 10)

bacterium (plural **bacteria**) (**eubacterium**) Member of the domain bacteria, one of the three main branches of the tree of life (archaea, bacteria, and eukaryotes). Bacteria and archaea both lack a distinct nuclear compartment and together comprise the prokaryotes. (Chapter 23) (Figure 1–9)

Bak A main effector Bcl2 family protein of the intrinsic pathway of apoptosis in mammalian cells that is bound to the mitochondrial outer membrane even in the absence of an apoptotic signal; activation is usually by activated pro-apoptotic BH3-only proteins. (Chapter 18)

basal Situated near the base. Opposite the apical surface. (Chapter 19)

basal lamina (plural basal laminae) Thin mat of extracellular matrix that separates epithelial sheets, and many other types of cells such as muscle or fat cells, from connective tissue. Sometimes called basement membrane. (Chapter 19) (Figure 19-51)

base (1) A substance that can reduce the number of protons in solution, either by accepting H⁺ ions directly or by releasing OH⁻ ions, which then combine with H⁺ to form H₂O. (Chapter 2) (2) The purines and pyrimidines in DNA and RNA are organic nitrogenous bases and are commonly referred to simply as bases. (Panel 2-2, pp. 96-97)

base excision repair DNA repair pathway in which single faulty bases are removed from the DNA helix and replaced. Compare nucleotide excision repair. (Chapter 5) (Figure 5-41)

base pair Two nucleotides in an RNA or DNA molecule that are held together by hydrogen bonds; for example, G paired with C, and A paired with T or U. (Chapter 4)

basement membrane Thin mat of extracellular matrix that separates epithelial sheets, and many other types of cells such as muscle or fat cells, from connective tissue. Also called basal lamina. (Chapter 19) (Figure 19-51)

Bax A main effector Bcl2 family protein of the intrinsic pathway of apoptosis in mammalian cells; located mainly in the cytosol, it translocates to the mitochondria only after activation, usually by activated pro-apoptotic BH3-only proteins. (Chapter 18)

Bcl2 Anti-apoptotic Bcl2 family protein of the outer mitochondrial membrane that binds and inhibits pro-apoptotic Bcl2 family proteins and prevents inappropriate activation of the intrinsic pathway of apoptosis. (Chapter 18)

Bcl2 family Family of intracellular proteins that either promote or inhibit apoptosis by regulating the release of cytochrome c and other mitochondrial proteins from the intermembrane space into the cytosol. (Chapter 18)

BclxL Anti-apoptotic Bcl2 family protein of the outer mitochondrial membrane that binds and inhibits pro-apoptotic Bcl2 family proteins and prevents inappropriate activation of the intrinsic pathway of apoptosis. (Chapter 18)

benign Of tumors: self-limiting in growth, and noninvasive. (Chapter 20)

beta sheet (β sheet) Common structural motif in proteins in which different sections of the polypeptide chain run alongside each other, joined together by hydrogen-bonding between atoms of the polypeptide backbone. Also known as a $\boldsymbol{\beta}$ pleated sheet. (Chapter 3) (Figure 3-6)

beta-catenin (β-catenin) Multifunctional cytoplasmic protein involved in cadherin-mediated cell-cell adhesion, linking cadherins to the actin cytoskeleton. Can also act independently as a transcription regulatory protein. Has an important role in animal development as part of a Wnt signaling pathway. (Chapter 15)

BH3-only proteins The largest subclass of Bcl2 family proteins. Produced or activated in response to an apoptotic stimulus, these proteins promote apoptosis mainly by inhibiting anti-apoptotic proteins in the Bcl2 family. (Chapter 18)

bi-orientation In mitosis, the attachment of sister chromatids to opposite poles of the mitotic spindle, so that they move to opposite ends of the cell when they separate in anaphase. (Chapter 17)

binding site Region on the surface of one molecule (usually a protein or nucleic acid) that can interact with another molecule through noncovalent bonding. (Chapter 3)

biomolecular condensate An aggregate inside cells, formed by a process analogous to liquid-liquid phase separation and based on fluctuating weak interactions between scaffold proteins; concentrates selected protein and RNA molecules in a membraneless compartment. (Chapters 1, 3, 12) (Figures 3-77 and 12-5)

BiP Endoplasmic reticulum (ER)-resident chaperone protein. Member in the family of hsp70-type chaperones. (Chapter 12)

Bithorax complex One of two gene clusters in Drosophila that contain Hox genes; genes in the Bithorax complex control the differences among the abdominal and thoracic segments of the body. (Chapter 21)

bivalent A four-chromatid structure formed during meiosis, consisting of a duplicated chromosome tightly paired with its homologous duplicated chromosome. (Chapter 17)

blastomere One of the many similar cells formed by the early cleavages of a fertilized egg. (Chapter 21)

blastula Early stage of an animal embryo, usually consisting of a hollow ball of epithelial cells surrounding a fluid-filled cavity, before gastrulation begins. (Chapter 21)

blebbing Membrane protrusion formed when the plasma membrane detaches locally from the underlying actin cortex, allowing cytoplasmic flow and hydrostatic pressure within the cell to push the membrane outward. (Chapter 16)

bone Dense and rigid connective tissue comprising a mixture of tough fibers (type I collagen fibrils), which resist pulling forces, plus solid particles (calcium phosphate as hydroxylapatite crystals), which resist compression. (Chapter 21)

brassinosteroids Class of steroid signal molecules in plants that regulate the growth and differentiation of plants throughout their life cycle via binding to a cell-surface receptor kinase to initiate a signaling cascade. (Chapter 15)

bright-field microscope Normal light microscope in which the image is obtained by simple transmission of light through the object being viewed. (Chapter 9)

Brownian motion The random movement of particles or molecules suspended in a liquid or gas, caused by molecular collisions. (Chapter 1)

buffer Solution of weak acid or weak base that resists the pH change that would otherwise occur when small quantities of acid or base are added. (Chapter 2)

C3 The pivotal complement protein that is activated by the early components of all three complement pathways (the classical pathway, the lectin pathway, and the alternative pathway). (Figure 24-7)

Ca²⁺ pump (calcium pump, Ca²⁺ ATPase) Transport protein in the membrane of sarcoplasmic reticulum of muscle cells (and elsewhere). Pumps Ca²⁺ out of the cytoplasm into the sarcoplasmic reticulum using the energy of ATP hydrolysis. (Chapter 11)

Ca2+-activated K+ channel Opens in response to the raised concentration of Ca²⁺ in nerve cells that occurs in response to an action potential. Increased K⁺ permeability makes the membrane harder to depolarize, increasing the delay between action potentials and decreasing the response of the cell to constant, prolonged stimulation (adaptation). (Chapter 11)

Ca²⁺/calmodulin-dependent kinase (**CaM-kinase**) Serine/threonine protein kinase that is activated by Ca²⁺/calmodulin. Indirectly mediates the effects of an increase in cytosolic Ca²⁺ by phosphorylating specific target proteins. (Chapter 15) (Figure 15–34)

cadherin Member of the large cadherin superfamily of transmembrane adhesion proteins. Mediates homophilic Ca^{2+} -dependent cell–cell adhesion in animal tissues. (Chapter 19) (Figure 19–3 and Table 19–1, p. 1107)

cadherin superfamily Family of classical and nonclassical cadherin proteins with more than 180 members in humans. (Chapter 19)

calmodulin Ubiquitous intracellular Ca^{2+} -binding protein that undergoes a large conformation change when it binds Ca^{2+} , allowing it to regulate the activity of many target proteins. In its activated (Ca^{2+} -bound) form, it is called Ca^{2+} /calmodulin. (Chapter 15) (Figure 15–34)

calnexin Carbohydrate-binding chaperone protein in the endoplasmic reticulum (ER) membrane; binds to oligosaccharides on incompletely folded proteins and retains them in the ER. (Chapter 12)

calreticulin Carbohydrate-binding chaperone protein in the endoplasmic reticulum (ER) lumen; binds to oligosaccharides on incompletely folded proteins and retains them in the ER. (Chapter 12)

CaM-kinase II Multifunctional Ca²⁺/calmodulin-dependent protein kinase that phosphorylates itself and various target proteins when activated. Found in most animal cells but is especially abundant at synapses in the brain; it is involved in some forms of synaptic plasticity in vertebrates. (Chapter 15) (Figure 15–35)

cancer stem cells Rare cancer cells capable of dividing indefinitely. (Chapter 20)

cancer-critical genes Genes whose alteration contributes to the causation or evolution of cancer by driving tumorigenesis. (Chapter 20)

capsid Protein coat of a virus, formed by the self-assembly of one or more types of protein subunit into a geometrically regular structure. (Chapter 23) (Figure 3–27)

carbohydrate layer The carbohydrate-rich zone on the eukaryotic cell surface attributable to glycoproteins, glycolipids, and proteoglycans of the plasma membrane. (Chapter 10)

carbon-fixation reaction Process by which inorganic carbon (as atmospheric CO₂) is incorporated into organic molecules. The second stage of photosynthesis. (Chapter 14) (Figure 14–40)

carcinogenesis The generation of cancer. (Chapter 20)

carcinoma Cancer of epithelial cells. The most common form of human cancer. (Chapter 20)

cargo The membrane components and soluble molecules carried by transport vesicles. (Chapter 13)

cartilage Form of connective tissue composed of cells (chondrocytes) embedded in a matrix rich in type II collagen and chondroitin sulfate proteoglycan. (Chapters 19, 21)

caspase Intracellular protease that is involved in mediating the intracellular events of apoptosis. (Figures 18–3 and 18–4)

catalyst Substance that can lower the activation energy of a reaction (thus increasing its rate), without itself being consumed by the reaction. (Chapters 1, 2, 3)

caveola (plural **caveolae**) Invaginations at the cell surface that bud off internally to form pinocytic vesicles. Thought to form from lipid rafts, regions of membrane rich in certain lipids. (Chapter 13)

caveolins Family of unusual integral membrane proteins that are the major structural proteins in caveolae. (Chapter 13)

CD4 Co-receptor protein on helper T cells and regulatory T cells that binds to a nonvariable part of class II MHC proteins (on antigen-presenting cells) outside the peptide-binding groove. (Chapter 24) (Figure 24–40)

CD8 Co-receptor protein on cytotoxic T cells that binds to a nonvariable part of class I MHC proteins (on antigen-presenting cells and infected target cells) outside the peptide-binding groove. (Chapter 24) (Figure 24–40)

Cdc20 Activating subunit of the anaphase-promoting complex/cyclosome (APC/C). (Chapter 17)

Cdc25 Protein phosphatase that dephosphorylates Cdks and increases their activity. (Chapter 17)

Cdc42 Member of the Rho family of monomeric GTPases that regulate the actin and microtubule cytoskeletons, cell-cycle progression, gene transcription, and membrane transport. (Chapter 15)

Cdc6 Protein essential in the preparation of DNA for replication. With Cdt1 it binds to an origin recognition complex on chromosomal DNA and helps load the Mcm proteins onto the DNA. (Figure 5–31)

Cdh1 Activating subunit of the anaphase-promoting complex/cyclosome (APC/C). (Chapter 17)

Cdk inhibitor protein (CKI) Protein that binds to and inhibits cyclin–Cdk complexes, primarily involved in the control of G_1 and S phases. (Chapter 17)

Cdt1 Protein essential in the preparation of DNA for replication. With Cdc6 it binds to origin recognition complexes on chromosomes and helps load the Mcm proteins on to the DNA. (Chapter 17) (Figure 5–31)

cDNA clone Clone containing double-stranded cDNA molecules derived from the protein-coding mRNA molecules present in a cell. (Chapter 8)

cDNA library Collection of cloned DNA molecules representing complementary DNA copies of the mRNA produced by a cell. (Chapter 8)

cell cortex Specialized layer of cytoplasm on the inner face of the plasma membrane. In animal cells it is an actin-rich layer responsible for movements of the cell surface. (Chapter 16)

cell cycle (**cell-division cycle**) Reproductive cycle of a cell: the orderly sequence of events by which a cell duplicates its chromosomes and other cell contents, and then divides into two. (Chapters 4, 17) (Figure 17–4)

cell-cycle control system Network of regulatory proteins that governs progression of a eukaryotic cell through the cell cycle. (Chapter 17)

cell determination Process whereby a cell progressively loses the potential to form other cell types, as development proceeds. (Chapter 21)

cell doctrine The nineteenth-century proposal that all living organisms are composed of one or more cells and that all cells arise from the division of other living cells. (Chapter 9)

cell memory Retention by cells and their descendants of persistently altered patterns of gene expression, without any

G.0

change in DNA sequence. See also epigenetic inheritance. (Chapters 7, 21)

cell plate Flattened membrane-bounded structure that forms by fusing vesicles in the cytoplasm of a dividing plant cell and is the precursor of the new cell wall. (Chapter 17)

cellulose Long, unbranched chains of glucose; major constituent of plant cell walls. (Chapter 19)

cellulose microfibril Highly ordered crystalline aggregate formed from bundles of about 18 cellulose chains, arranged with the same polarity and stuck together in overlapping parallel arrays by hydrogen bonds between adjacent cellulose molecules. (Chapter 19)

central (**primary**) **lymphoid organ** Organ in which T or B lymphocytes are produced from precursor cells. In adult mammals, these are the thymus and bone marrow, respectively. (Chapter 24) (Figure 24–12)

centriole Short cylindrical array of microtubules, closely similar in structure to a basal body. A pair of centrioles is usually found at the center of a centrosome in animal cells. (Chapter 16) (Figure 16–42)

centromere Constricted region of a mitotic chromosome that holds sister chromatids together. This is also the site on the DNA where the kinetochore forms so as to capture microtubules from the mitotic spindle. (Chapter 4) (Figure 4–43)

centrosome Centrally located organelle of animal cells that is the primary microtubule-organizing center (MTOC) and acts as the spindle pole during mitosis. In most animal cells it contains a pair of centrioles. (Chapter 17) (Figures 16–41 and 17–27)

cerebral cortex Outermost layer of the hemispheres of the brain; the most complex structure in the human body. (Figure 21–41)

CG island Region of DNA in vertebrate genomes with a greater than average density of CG sequences; the C nucleotides in these regions generally remain unmethylated. (Chapter 7)

channel (membrane channel) Transmembrane protein complex that allows inorganic ions or other small molecules to diffuse passively across the lipid bilayer. (Chapter 11) (Figure 11–3)

channelrhodopsin Photosensitive protein forming a cation channel across the membrane that opens in response to light. (Chapter 11)

charge separation In photosynthesis, the light-induced transfer of a high-energy electron from chlorophyll to an acceptor molecule resulting in the formation of a positive charge on the chlorophyll and a negative charge on a mobile electron carrier. (Figure 14-45)

chemical carcinogens Disparate chemicals that are carcinogenic—due to the ability to cause mutations—when fed to experimental animals or painted repeatedly on their skin. (Chapter 20)

chemical group Certain common combinations of atoms—such as methyl ($-CH_3$), hydroxyl (-OH), carboxyl (-COOH), carbonyl (-C=O), phosphate ($-PO_3^{2-}$), sulfhydryl (-SH), and amino ($-NH_2$) groups—that have distinct chemical and physical properties and influence the behavior of the molecule in which the group occurs. (Chapter 2)

chemiosmotic coupling (chemiosmosis) Mechanism in which an electrochemical proton gradient across a membrane (composed of a pH gradient plus a membrane potential) is used

to drive an energy-requiring process, such as ATP production or the rotation of bacterial flagella. (Chapter 14)

chemotaxis Movement of a cell toward or away from some diffusible chemical. (Chapter 16)

chiasma (plural **chiasmata**) X-shaped connection visible between paired homologous chromosomes during meiosis. Represents a site of chromosomal crossing-over, a form of genetic recombination. (Chapter 17)

chlorophyll Light-absorbing green pigment that plays a central part in photosynthesis in bacteria, plants, and algae. (Chapter 14)

chloroplast Membrane-bounded organelle in green algae and plants that contains chlorophyll and carries out photosynthesis. (Chapters 12, 14)

cholera toxin Secreted toxic protein of *Vibrio cholerae* responsible for causing the watery diarrhea associated with cholera. Comprises an A subunit with enzymatic activity and a B subunit that binds to host-cell receptors to direct subunit A to the host-cell cytosol. (Chapter 23)

cholesterol An abundant lipid molecule with a characteristic four-ring steroid structure. An important component of the plasma membranes of animal cells. (Chapter 10) (Figure 10–4)

chromatin Complex of DNA, histones, and non-histone proteins found in the nucleus of a eukaryotic cell. The material of which chromosomes are made. (Chapter 4)

chromatin immunoprecipitation Technique by which chromosomal DNA bound by a particular protein can be isolated and identified by precipitating it by means of an antibody against the protein. (Chapter 8) (Figures 8–67 and 8–68)

chromosome Structure composed of a very long DNA molecule and associated proteins that carries part (or all) of the hereditary information of an organism. Especially evident in plant and animal cells undergoing mitosis or meiosis, during which each chromosome becomes condensed into a compact rodlike structure visible in the light microscope. (Chapter 4)

cilium (plural **cilia**) Hairlike extension of a eukaryotic cell containing a core bundle of microtubules. Many cells contain a single nonmotile cilium, while others contain large numbers that perform repeated beating movements. *Compare* **flagellum**. (Chapter 16)

circadian clock Internal cyclical process that produces a particular change in a cell or organism with a period of around 24 hours; for example, the sleep–wakefulness cycle in humans. (Chapter 15)

cis face Face on the same or near side. (Chapter 13)

cis Golgi network (CGN) Network of fused vesicular tubular clusters that is closely associated with the cis face of the Golgi apparatus and is the compartment at which proteins and lipids enter the Golgi from the ER. (Chapter 13)

cis-regulatory sequences DNA sequences to which transcription regulators bind to control the rate of gene transcription. In nearly all cases, these sequences must be on the same chromosome (that is, *in cis*) to the genes they control. (Chapter 7) (Figure 7–18)

cisternal maturation mechanism One hypothesis for how the Golgi apparatus achieves and maintains its polarized structure and how molecules move from one cisterna to another. This model views the cisternae as dynamic structures that mature from early to late by acquiring and then losing

specific Golgi-resident proteins as they move through the Golgi stack with cargo. (Chapter 13)

citric acid cycle [tricarboxylic acid (TCA) cycle; Krebs cycle] Central metabolic pathway found in aerobic organisms. Oxidizes acetyl groups derived from food molecules, generating the activated carriers NADH and FADH₂, some GTP, and waste CO₂. In eukaryotic cells, it occurs in the mitochondria. (Chapter 2) (Panel 2–9, pp. 110–111)

clamp loader Protein complex that utilizes ATP hydrolysis to load the sliding clamp onto a primer-template junction in the process of DNA replication. (Chapter 5)

class I MHC protein One of two classes of major histocompatibility complex (MHC) protein. Found on the surface of almost all vertebrate cell types, where it can present foreign peptides derived from a pathogen such as a virus to cytotoxic T cells. (Chapter 24) (Figures 24–35 and 24–36A)

class II MHC protein One of two classes of major histocompatibility complex (MHC) protein. Found on the surface of various antigen-presenting cells, where it presents peptides to helper and regulatory T cells. (Chapter 24) (Figures 24–35 and 24–36B)

class switch recombination An irreversible change at the DNA level when a B cell switches from making IgM and IgD to making one of the secondary classes of immunoglobulin. (Chapter 24)

class switching Change from making one class of immunoglobulin (for example, IgM) to making another class (for example, IgG) that many B cells undergo during the course of an adaptive immune response. Involves DNA rearrangements called class switch recombination. (Chapter 24) (Figure 24–30)

classical cadherins Family of cadherin proteins, including E-cadherin, N-cadherin, and P-cadherin, that are closely related in sequence throughout their extracellular and intracellular domains. (Chapter 19)

clathrin Protein that assembles into a polyhedral cage on the cytosolic side of a membrane so as to form a clathrin-coated pit, which buds off by endocytosis to form an intracellular clathrin-coated vesicle. (Chapter 13) (Figure 13–6)

clathrin-coated pits Specialized regions typically occupying about 2% of the total plasma membrane area at which the endocytic pathway often begins. (Chapter 13)

clathrin-coated vesicles Coated vesicles inside the cell that transport material from the plasma membrane and between endosomal and Golgi compartments. (Chapter 13)

cleave, cleavage (1) Physical splitting of a cell into two. (2) Specialized type of cell division seen in many early embryos whereby a large cell becomes subdivided into many smaller cells without growth. (Chapter 21)

clonal selection The process whereby, from a population of T and B lymphocytes with a vast repertoire of randomly generated antigen-specific receptors, a given foreign antigen activates (selects) only those lymphocyte clones that display a receptor that fits the antigen. Explains how the adaptive immune system can respond to millions of different antigens in a highly specific way. (Chapter 24) (Figure 24–15)

co-receptor In immunology: an accessory receptor on B cells or T cells that does not bind antigen but binds to a co-stimulatory signal and helps activate the lymphocyte, by helping to activate an intracellular signaling pathway. (Chapter 24)

co-stimulatory signal In immunology: a secreted or membrane-bound signal protein that helps activate an antigen-responding B cell or T cell. (Chapter 24)

co-translational Occurring as translation proceeds. Examples include the import of a protein into the endoplasmic reticulum before the polypeptide chain is completely synthesized (co-translational translocation; Figure 12–24), and the folding of a nascent protein into its secondary and tertiary structure as it emerges from a ribosome (Figure 6–83C). (Chapter 12)

coat-recruitment GTPases Members of a family of monomeric GTPases that have important roles in vesicle transport, being responsible for coat assembly at the membrane. (Chapter 13)

coated vesicle Small membrane-enclosed organelle with a cage of proteins (the coat) on its cytosolic surface. Formed by the pinching off of a coated region of membrane (coated pit). Some coats are made of clathrin, others are made from other proteins. (Chapter 13)

codon Sequence of three nucleotides in a DNA or mRNA molecule that represents the instruction for incorporation of a specific amino acid into a growing polypeptide chain. (Chapter 6)

coenzyme Small molecule tightly associated with an enzyme that participates in the reaction that the enzyme catalyzes, often by forming a covalent bond to the substrate. Examples include biotin, NAD⁺, and coenzyme A. (Chapter 3)

cohesin, cohesin complex Complex of proteins that uses ATP hydrolysis energy to organize an interphase chromosome into a series of looped domains; during mitosis, cohesins also hold sister chromatids together along their length before their separation. (Chapters 4, 17) (Figures 4–57 and 17–23)

coiled-coil Especially stable rodlike protein structure formed by two or more α helices coiled around each other. (Chapter 3) (Figure 3–8)

collagen Fibrous protein rich in glycine and proline that is a major component of the extracellular matrix in animals, conferring tensile strength. Exists in many forms: type I, the most common, is found in skin, tendon, and bone; type II is found in cartilage; type IV is present in basal laminae. (Chapter 19) (Figures 3–24 and 19–38)

collagen fibril A higher-order collagen polymer of fibrillar collagens that assemble into thin structures (10–300 nm in diameter) many hundreds of micrometers long in mature tissues. (Chapter 19)

colony-stimulating factor (CSF) General name for numerous signal molecules that control differentiation of blood cells. (Chapter 15)

colorectal cancer Cancer arising from the epithelium lining the colon (the large intestine) and rectum (the terminal segment of the gut). (Chapter 20)

column chromatography Technique for separation of a mixture of substances in solution by passage through a column containing a porous solid matrix. Substances are retarded to different extents by their interaction with the matrix and can be collected separately from the column. Depending on the matrix, separation can be according to charge, hydrophobicity, size, or the ability to bind to other molecules. (Chapter 8)

commensalism Ecologic relationship between microbes and their host in which the microbe benefits but offers no benefit and causes no harm. (Chapter 23)

committed progenitor Cell derived from a stem cell that divides for a limited number of times before terminally differentiating; also known as a transit amplifying cell.

complement system System of blood proteins that can be activated by antibody–antigen complexes or pathogens to help eliminate the pathogens by directly causing their lysis, by promoting their phagocytosis, or by activating an inflammatory response. (Chapter 24) (Figure 24–7)

complementary (1) Of nucleic acid sequences: capable of forming a perfect base-paired duplex with each other (Figure 4–5). (2) Of other interacting molecules, such as an enzyme and its substrate: having biochemical or structural features that marry up, so that noncovalent bonding is facilitated. (Chapter 4) (Figure 2–4)

complementation test Test to determine whether two mutations that produce similar phenotypes are in the same or different genes. (Chapter 8) (Panel 8–1, pp. 520–521)

complex oligosaccharides Broad class of *N*-linked oligosaccharides, attached to mammalian glycoproteins in the endoplasmic reticulum and modified in the Golgi apparatus, containing *N*-acetylglucosamine, galactose, sialic acid, and fucose residues. (Chapter 13)

condensin, condensin complex Complex of proteins involved in chromosome condensation prior to mitosis. Target for M-Cdk. (Chapters 4, 17) (Figure 17–25)

conditional mutation Mutation that changes a protein or RNA molecule so that its function is altered only under some conditions, such as at an unusually high or unusually low temperature. (Chapter 8)

cone photoreceptor (cone) Photoreceptor cell in the vertebrate retina that is responsible for color vision in bright light. (Chapter 15)

confocal microscope Type of light microscope that produces a clear image of a given plane within a solid object. It uses a laser beam as a pinpoint source of illumination and scans across the plane to produce a two-dimensional "optical section." (Chapter 9) (Figure 9–24)

conformation The folded, three-dimensional structure of a polypeptide chain. (Chapter 3)

connective tissue Any supporting tissue that lies between other tissues and consists of cells embedded in a relatively large amount of extracellular matrix. Includes bone, cartilage, and loose connective tissue. (Chapter 19)

connexin Protein component of gap junctions, a four-pass transmembrane protein. Six connexins assemble in the plasma membrane to form a connexon, or "hemichannel." (Chapter 19) (Figure 19–25)

connexon Water-filled pore in the plasma membrane formed by a ring of six connexin protein subunits. Half of a gap junction: connexons from two adjoining cells join to form a continuous channel through which ions and small molecules can pass. (Chapter 19) (Figure 19–25)

consensus nucleotide sequence A summary or "average" of a large number of individual nucleotide sequences derived by comparing many sequences with the same basic function and tallying up the most common nucleotides found at each position. (Chapter 6) (Figure 6–12)

conservative site-specific recombination A type of DNA recombination that takes place between short, specific sequences of DNA and occurs without the gain or loss of

nucleotides. Unlike homologous recombination, it does not require an extensive region of homology between the two recombining DNA molecules. (Chapter 5)

constant region In immunology: region of an immunoglobulin or T cell receptor chain that has a constant amino acid sequence. (Chapter 24)

constitutive secretory pathway Pathway present in all cells by which molecules such as plasma membrane proteins are continually delivered to the plasma membrane from the Golgi apparatus in vesicles that fuse with the plasma membrane. The default route to the plasma membrane if no other sorting signals are present. (Chapter 13) (Figure 13–38)

contact-dependent secretion system Specialized bacterial systems that secrete effector proteins directly into host cell targets. (Chapter 23) (Figure 23–7)

contact-dependent signaling Form of intercellular signaling in which signal molecules remain bound to the surface of the signaling cell and influence only cells that contact it. (Chapter 15)

contractile ring Ring containing actin and myosin that forms under the surface of animal cells undergoing cell division. It contracts to pinch the two daughter cells apart. (Chapter 17) (Figure 17–43)

convergent extension Rearrangement of cells within a tissue that causes it to extend in one dimension and shrink in another. (Chapter 21) (Figure 21–48)

COPI-coated vesicles Coated vesicles that transport material in the secretory pathway, budding from Golgi compartments. (Chapter 13)

COPII-coated vesicles Coated vesicles that transport material early in the secretory pathway, budding from the endoplasmic reticulum. (Chapter 13)

copy number variations (CNVs) A difference between two individuals in the same population in the number of copies of a particular block of DNA sequence. This variation arises from occasional duplications and deletions of these sequences.

cortex The cytoskeletal network in the cortical region of the cytosol just beneath the plasma membrane. (Chapter 10)

coupled reaction Linked pair of chemical reactions in which the free energy released by one reaction serves to drive the other. (Chapter 2) (Figure 2–29)

covalent bond Stable chemical link between two atoms produced by sharing one or more pairs of electrons. (Chapter 2) (Panel 2–1, pp. 94–95)

CRE-binding (CREB) protein Transcription regulator that recognizes the cyclic AMP response element (CRE) in the regulatory region of genes activated by cAMP. On activation by PKA, phosphorylated CREB recruits a transcriptional coactivator (CREB-binding protein; CBP) to stimulate transcription of target genes. (Chapter 15) (Figure 15–28)

CRISPR A defense mechanism in bacteria using small noncoding RNA molecules (crRNAs) to seek out and destroy invading viral genomes through complementary base-pairing and targeted nuclease digestion. (Chapter 7)

crista (plural **cristae**) A specialized invagination of the inner mitochondrial membrane. (Chapter 14)

cross-linking glycan One of a heterogeneous group of branched polysaccharides that help to cross-link cellulose

microfibrils into a complex network. Has a long linear backbone of one sugar type (glucose, xylose, or mannose) with short side chains of other sugars. (Chapter 19)

cross-presentation A process in which extracellular proteins taken up by specialized dendritic cells can give rise to peptides that can be presented by their class I MHC proteins to cytotoxic T cells. (Chapter 24)

crRNAs Small noncoding RNAs (~30 nucleotides) that are the effectors of CRISPR-mediated immunity in bacteria. (Chapter 7)

cryo-electron microscopy Technique for examining a thin film of an aqueous suspension of biological material that has been frozen rapidly enough to create vitreous ice. The specimen is then kept frozen and transferred to the electron microscope. Image contrast is low, but this type of microscopy permits the determination of atomic-level structures because the image is generated solely by the macromolecular structures present. (Chapters 9, 12)

cryptochrome Plant flavoprotein sensitive to blue light. Structurally related to blue-light-sensitive enzymes called photolyases (involved in the repair of ultraviolet-induced DNA damage). Also found in animals, where they have an important role in circadian clocks. (Chapter 15)

cyclic AMP (**cAMP**) Nucleotide that is generated from ATP by adenylyl cyclase in response to various extracellular signals. It acts as a small intracellular signaling molecule, mainly by activating cAMP-dependent protein kinase (PKA). It is hydrolyzed to AMP by a phosphodiesterase. (Chapter 15) (Figure 15–25)

cyclic-AMP-dependent protein kinase (protein kinase A; PKA) Enzyme that phosphorylates target proteins in response to a rise in intracellular cyclic AMP. (Chapter 15) (Figure 15–27)

cyclic AMP phosphodiesterase Specific enzyme that rapidly and continually destroys cyclic AMP, forming 5'-AMP. (Chapter 15) (Figure 15–26)

cyclic GMP (**cGMP**) Nucleotide that is generated from GTP by guanylyl cyclase in response to various extracellular signals. (Chapter 15)

cyclic GMP phosphodiesterase Specific enzyme that rapidly hydrolyzes and degrades cyclic GMP. (Chapter 15)

cyclin Protein that periodically rises and falls in concentration in step with the eukaryotic cell cycle. Cyclins activate crucial protein kinases (called cyclin-dependent protein kinases, or Cdks) and thereby help control progression from one stage of the cell cycle to the next. (Chapter 17)

cyclin-Cdk complex Protein complex formed periodically during the eukaryotic cell cycle as the level of a particular cyclin increases. A cyclin-dependent kinase (Cdk) thereby becomes activated. (Chapter 17) (Figures 17–9 and 17–10, and Table 17–1, p. 1034)

cyclin-dependent kinase (Cdk) Protein kinase that has to be complexed with a cyclin protein in order to act. Different cyclin-Cdk complexes trigger different steps in the cell-division cycle by phosphorylating specific target proteins. (Chapter 17) (Figure 17–9)

cyclosome See **anaphase-promoting complex**. (Chapter 17)

cytochrome Family of colored heme-containing proteins that transfer electrons during respiration and photosynthesis. (Chapter 14)

cytochrome *c* Soluble component of the mitochondrial electron-transport chain. As a second type of function, its release into the cytosol from the mitochondrial intermembrane space initiates apoptosis. (Chapters 14, 18)

cytochrome *c* **oxidase complex** Third of the three electron-driven proton pumps in the respiratory chain. It accepts electrons from cytochrome *c* and generates water using molecular oxygen as an electron acceptor. (Chapter 14) (Figure 14–18)

cytochrome *c* **reductase** Second of the three electron-driven proton pumps in the respiratory chain. Accepts electrons from ubiquinone and passes them to cytochrome *c*. (Chapter 14) (Figure 14–18)

cytokine Extracellular signal protein or peptide that acts as a local mediator in cell-cell communication. (Chapter 24)

cytokine receptor Cell-surface receptor that binds a specific cytokine or hormone and acts through the JAK-STAT signaling pathway. (Chapter 15) (Figure 15–57)

cytokinesis Division of the cytoplasm of a plant or animal cell into two, as distinct from the associated division of its nucleus (which is mitosis). Part of M phase. (Chapter 17) (Panel 17–1, pp. 1048–1049)

cytoplasm Contents of a cell that are contained within its plasma membrane but, in the case of eukaryotic cells, outside the nucleus. (Chapter 12)

cytoplasmic tyrosine kinase Enzyme activated by certain cell-surface receptors (tyrosine-kinase-associated receptors) that transmits the receptor signal onward by phosphorylating target cytoplasmic proteins on tyrosine side chains. (Chapter 15)

cytoskeleton System of protein filaments in the cytoplasm of a eukaryotic cell that gives the cell shape and the capacity for directed movement. Its most abundant components are actin filaments, microtubules, and intermediate filaments. (Chapter 16)

cytosol Contents of the main compartment of the cytoplasm, defined as excluding membrane-bounded organelles such as endoplasmic reticulum and mitochondria. (Chapter 12)

cytotoxic T cell (Tc cell) Type of T cell responsible for killing host cells infected with a virus or another type of intracellular pathogen. (Chapter 24) (Figure 24-42)

D gene segment A short DNA sequence that encodes a part of the variable region of an immunoglobulin heavy chain or the β chain of a T cell receptor (TCR). (Chapter 24)

dark-field microscopy Type of light microscopy in which oblique rays of light focused on the specimen do not enter the objective lens, but light that is scattered by components in the living cell can be collected to produce a bright image on a dark background. (Chapter 9) (Figure 9–6)

death-inducing signaling complex (**DISC**) Complex in which initiator caspases interact and are activated after extracellular ligands bind to cell-surface death receptors in the extrinsic pathway of apoptosis. (Chapter 18)

death receptor Transmembrane receptor protein that can signal the cell to undergo apoptosis when it binds its extracellular ligand. (Chapter 18) (Figure 18–6)

default pathway The transport pathway of proteins directly to the cell surface via the nonselective constitutive secretory pathway, entry into which does not require a particular signal. (Chapter 13)

G:10 Glossary

defensin Positively charged, amphipathic, antimicrobial peptide—secreted by epithelial cells—that binds to and disrupts the membranes of many pathogens. (Chapter 24)

delayed K⁺ **channel** Neuronal voltage-gated K⁺ channel that opens after membrane depolarization during the falling phase of an action potential, being delayed because of its slower activation kinetics than that of Na⁺ channels. Its opening causes a K⁺ efflux that drives the membrane potential back toward its original negative value, enabling it to transmit a second impulse. (Chapter 11)

Delta Single-pass transmembrane signal protein displayed on the surface of cells that binds to the Notch receptor protein on a neighboring cell, activating a contact-dependent signaling mechanism. (Chapter 15)

dendrite Extension of a nerve cell, often elaborately branched, that receives stimuli from other nerve cells. (Chapter 11)

dendritic cell The most potent type of antigen-presenting cell, which takes up antigen and processes it for presentation to T cells. It is required for activating naïve T cells. (Chapter 24) (Figure 24–11)

deoxyribonucleic acid (DNA) Polynucleotide formed from covalently linked deoxyribonucleotide units. The store of hereditary information within a cell and the carrier of this information from generation to generation. (Figure 4–3 and Panel 2–6, pp. 104–105)

depolarization Deviation in the electrical potential across the plasma membrane toward a positive value. A depolarized cell has a potential that is positive outside and negative inside. (Chapter 11)

desensitization See adaptation. (Chapter 15)

desmosome Anchoring cell-cell junction, usually formed between two epithelial cells. Characterized by dense plaques of protein into which intermediate filaments in the two adjoining cells insert. (Chapter 19) (Figure 19–2)

detergent Small amphiphilic molecule, more soluble in water than in lipids, that disrupts hydrophobic associations and destroys the lipid bilayer thereby solubilizing membrane proteins. (Chapter 10)

diacylglycerol (DAG) Lipid produced by the cleavage of inositol phospholipids in response to extracellular signals. Composed of two fatty acid chains linked to glycerol, it serves as a small signaling molecule to help activate protein kinase C (PKC). (Chapter 15) (Figure 15–29)

dideoxy sequencing The standard enzymatic method of DNA sequencing. (Chapter 8)

differential-interference-contrast microscope Type of light microscope that exploits the interference effects that occur when light passes through parts of a cell of different refractive indices. Used to view unstained living cells. (Chapter 9)

differentiation Process by which a cell undergoes a change to an overtly specialized cell type. (Chapter 21)

diffusion The net drift of molecules through space due to random thermal movements. (Chapter 2)

Dishevelled Scaffold protein recruited to the Frizzled family of cell-surface receptors upon their activation by Wnt binding that helps relay the signal to other signaling molecules. (Chapter 15)

dissociation constant The reciprocal of the association constant, with units of moles/liter. (Chapter 3)

DNA cloning (1) The act of making many identical copies (typically billions) of a DNA molecule—the amplification of a particular DNA sequence. (2) Also, the isolation of a particular stretch of DNA (often a particular gene) from the rest of the cell's genome. (Chapter 8)

DNA helicase Enzyme that harnesses ATP hydrolysis energy to open a region of the DNA helix into its single strands as an aid to DNA replication or DNA repair. (Chapter 5)

DNA library Collection of cloned DNA molecules, representing either an entire genome (genomic library) or complementary DNA copies of the mRNA produced by a cell (cDNA library). (Chapter 8)

DNA ligase Enzyme that joins the ends of two strands of DNA together with a covalent bond to produce one continuous DNA strand. (Chapter 5)

DNA methylation Addition of methyl groups to DNA. Extensive methylation of the cytosine base in CG sequences is used in plants and animals to help keep genes in an inactive state. (Chapter 7)

DNA-only transposon Transposable element that exists as DNA throughout its life cycle. Many of these elements move by cut-and-paste transposition. See also **transposon**. (Chapter 5)

DNA polymerase Enzyme that synthesizes DNA by joining nucleotides together using a DNA template as a guide; its substrates are the four nucleoside triphosphates: A, G, C, and T. (Chapter 5)

DNA primase Enzyme that synthesizes a short strand of RNA on a DNA template, producing an RNA primer for DNA synthesis. (Chapter 5) (Figure 5–10)

DNA repair A set of different enzymatic processes for repairing the many accidental lesions that occur continually in DNA. (Chapter 5)

DNA replication Process by which a copy of a DNA molecule is made. (Chapter 1)

DNA supercoiling A conformation with loops or coils that DNA adopts in response to superhelical tension; conversely, creating various loops or coils in the helix can create such tension. (Chapter 6)

DNA topoisomerase (topoisomerase) Enzyme that binds to DNA and reversibly breaks a phosphodiester bond in one or both strands. Topoisomerase I creates transient singlestrand breaks, allowing the double helix to swivel and relieving superhelical tension. Topoisomerase II creates transient doublestrand breaks, allowing one double helix to pass through another and thus resolving knots and tangles. (Chapter 5) (Figures 5–22 and 5–23)

DNA transcription See transcription. (Chapter 6)

DNA tumor virus General term for a variety of different DNA viruses that can cause tumors. (Chapter 20)

dolichol Isoprenoid lipid molecule that anchors the precursor oligosaccharide in the endoplasmic reticulum membrane during protein glycosylation. (Chapter 12)

domain (**protein domain**) Portion of a protein that has a tertiary structure of its own. Larger proteins are generally composed of several domains, each connected to the next by short flexible regions of polypeptide chain. Homologous domains are recognized in many different proteins. (Chapter 3)

 $\label{eq:Dorsal} \textbf{Dorsal} \quad \text{Transcription regulator of the NF}_{\kappa} \textbf{B} \text{ family regulating gene expression and involved in establishing the dorsoventral axis in an embryo. (Chapter 21)}$

double helix The three-dimensional structure of DNA, in which two antiparallel DNA chains, held together by hydrogenbonding between the bases, are wound into a helix. (Chapter 4) (Figure 4–5)

drivers Mutations that are causal factors in the development of cancer. (Chapter 20)

dynamic instability Sudden conversion from growth to shrinkage, and vice versa, in a protein filament such as a microtubule or actin filament. (Chapter 16) (Panel 16–2, pp. 960–961, and Figure 16–40)

dynamin Cytosolic GTPase that binds to the neck of a clathrin-coated vesicle in the process of budding from the membrane and which is involved in completing vesicle formation. (Chapter 13)

dynein Large motor protein that undergoes ATP-dependent movement along microtubules. (Chapter 16)

E2F protein Transcription regulatory protein that switches on many genes that encode proteins required for entry into the S phase of the cell cycle. (Chapter 17)

early endosome Common receiving compartment with which most endocytic vesicles fuse and where internalized cargo is sorted either for return to the plasma membrane or for degradation by inclusion in a late endosome. (Chapter 13)

ectoderm Embryonic epithelial tissue that is the precursor of the epidermis and nervous system. (Chapter 21)

edema factor One of the two A subunits of anthrax toxin; an adenylyl cyclase that catalyzes production of cAMP, leading to ion imbalance and consequent edema in the skin or lung. (Chapter 23)

effector cell Cell that carries out the final response or function in a particular process. The main effector cells of the immune system, for example, are activated lymphocytes and phagocytes that help eliminate pathogens. (Chapter 24)

egg-polarity genes Genes in the *Drosophila* egg that define the anteroposterior and dorsoventral axes of the future embryo through the creation of landmarks (mRNA or protein) in the egg that provide signals organizing the developmental process. (Chapter 21)

elastic fiber Extensible fiber formed by the protein elastin in many animal connective tissues, such as in skin, blood vessels, and lungs, which gives them their stretchability and resilience. (Chapter 19)

elastin Extracellular protein that forms extensible fibers (elastic fibers) in connective tissues. (Chapters 3, 19)

electrochemical gradient Combined influence of a difference in the concentration of an ion on two sides of a membrane and the electrical charge difference across the membrane (membrane potential). Ions or charged molecules can move passively only down their own electrochemical gradient. (Chapter 11)

electrochemical proton gradient The driving force for the production of ATP by ATP synthase. See also **electrochemical gradient**. (Chapter 14)

electron microscope Microscope that uses a beam of electrons to create the image. (Chapter 9)

electron microscope (EM) tomography Technique for viewing three-dimensional specimens in the electron microscope in which multiple views are taken from different directions by tilting the specimen holder. The views are

combined computationally to give a three-dimensional image. (Chapter 9)

electron-transport chain Series of reactions in which electron carrier molecules pass electrons "down the chain" from higher to successively lower energy levels. The energy released during such electron movement can be used to power various processes. Electron-transport chains present in the inner mitochondrial membrane (called the respiratory chain) and in the thylakoid membrane of chloroplasts generate an electrochemical proton gradient across the membrane that is used to drive ATP synthesis. See especially Figures 14–18 and 14–52. (Chapters 2, 14)

electrostatic attraction A noncovalent, ionic attraction between two molecules carrying groups of opposite charge. (Chapter 2) (Panel 2–3, pp. 98–99)

embryonic stem cells (ES cells) Cells derived from the inner cell mass of the early mammalian embryo. Capable of giving rise to all the cells in the body. Can be grown in culture, genetically modified, and inserted into a blastocyst to develop a transgenic animal. (Chapter 22)

endocrine cell Specialized animal cell that secretes a hormone into the blood. Usually part of a gland, such as the thyroid or pituitary gland. (Chapter 15)

endocycle Variation of the cell cycle in which multiple rounds of DNA replication occur without intervening M phases. (Chapter 17)

endocytic vesicle Vesicle formed as material ingested by the cell during endocytosis is enclosed by a small portion of the plasma membrane, which first invaginates and then pinches off to form the vesicle. (Chapter 13)

endocytosis Uptake of material into a cell by an invagination of the plasma membrane and its internalization in a membrane-enclosed vesicle. See also **pinocytosis** and **phagocytosis**. (Chapter 13)

endoderm Embryonic tissue that is the precursor of the gut and associated organs. (Chapter 21)

endoplasmic reticulum (ER) Extensive, net-like membranebounded compartment in the cytoplasm of eukaryotic cells, where lipids are synthesized and membrane-bound proteins and secretory proteins are made. (Chapter 12) (Figure 12–15)

endosome maturation Process by which early endosomes mature to late endosomes and endolysosomes; in the conversion process, the endosome membrane protein composition changes, the endosome moves away from the cell periphery and close to the nucleus, and the endosome ceases to recycle material to the plasma membrane and irreversibly commits its remaining contents to degradation. (Chapter 13)

endothelial cell Flattened cell type that forms a sheet (the endothelium) lining all blood and lymphatic vessels. (Chapter 21)

engulfment Process by which a portion of the cytoplasm becomes enclosed by a double membrane, such as during autophagy. (Chapter 12)

entropy (S) Thermodynamic quantity that measures the degree of disorder or randomness in a system; the higher the entropy, the greater the disorder. (Chapter 2) (Panel 2–7, pp. 106–107)

enveloped virus Virus with a capsid surrounded by a lipid bilayer membrane (the envelope), which is often derived from the host-cell plasma membrane when the virus buds from the cell. (Chapter 23) (Figure 23–12)

enzyme Protein that catalyzes a specific chemical reaction. (Chapters 2, 3)

enzyme-coupled receptor A major type of cell-surface receptor that has a cytoplasmic domain that either has enzymatic activity or is associated with an intracellular enzyme. In either case, the enzymatic activity is stimulated by an extracellular ligand binding to the receptor. (Chapter 15) (Figure 15–6)

ephrin One of a family of membrane-bound protein ligands for the Eph receptor tyrosine kinases (RTKs) that, among many other functions, stimulate repulsion or attraction responses that guide the migration of cells and nerve cell axons during animal development. (Chapter 15)

epidermis Epithelial layer covering the outer surface of the body. Has different structures in different animal groups. The outer layer of plant tissue is also called the epidermis. (Chapter 22)

epigenetic inheritance Inheritance of phenotypic changes in a cell or organism that do not result from changes in the nucleotide sequence of DNA. Can be due to positive feedback loops of transcription regulators or to heritable modifications in chromatin such as DNA methylation or histone modifications. (Chapters 4, 7) (Figure 7–56)

epistasis analysis Analysis to discover the order in which genes act, by investigating if a mutation in one gene can mask the effect of a mutation in another gene when both mutations are present in the same organism or cell. (Chapter 8)

epithelial tissue A tissue, such as the lining of the gut or the epidermal covering of the skin, in which cells are closely bound together into sheets called epithelia. (Chapter 19)

epithelium (plural **epithelia**) Sheet of cells covering the outer surface of a structure or lining a cavity. (Chapter 19)

equilibrium State in a chemical reaction where there is no net change in free energy to drive the reaction in either direction. The ratio of product to substrate reaches a constant value at chemical equilibrium. (Chapters 2, 3) (Figure 2–30)

equilibrium constant (K) The ratio of forward and reverse rate constants for a reaction. Equal to the association or affinity constant (K_a) for a simple binding reaction (A + B \rightarrow AB). See also **affinity constant**, **association constant**, **dissociation constant**. (Chapters 2, 3) (See p. 146.)

ER lumen The space enclosed by the membrane of the endoplasmic reticulum (ER). (Chapter 12)

ER resident protein Protein that remains in the lumen of the endoplasmic reticulum (ER) or its membranes and carries out its function there, as opposed to the many proteins that are present in the ER only in transit. (Chapter 12)

ER retention signal Short amino acid sequence on a protein that prevents it from moving out of the endoplasmic reticulum (ER). Found on those proteins that are resident in the ER and function there. (Chapter 12)

ER signal sequence N-terminal signal sequence that directs proteins to enter the endoplasmic reticulum (ER). Cleaved off by signal peptidase after entry. (Chapter 12)

erythrocyte Small hemoglobin-containing blood cell of vertebrates that transports oxygen to, and carbon dioxide from, tissues. Also called a red blood cell. (Chapter 22)

erythropoietin A hormone produced by the kidney that stimulates the production of red blood cells in bone marrow. (Chapter 15)

ESCRT protein complexes Four protein complexes (ESCRT-0, ESCRT-I, ESCRT-II, and ESCRT-III) that act sequentially to shepherd mono-ubiquitylated membrane proteins on endosomal membranes into intralumenal vesicles. The ESCRT-III complex catalyzes the pinching-off reaction. (Chapter 13)

ethylene Small gas molecule that is a plant growth regulator influencing plant development in various ways including promoting fruit ripening, leaf abscission, and plant senescence and functioning as a stress signal in response to wounding, infection, and flooding. (Chapter 15)

euchromatin Region of an interphase chromosome that stains diffusely; "normal" chromatin, as opposed to the more condensed heterochromatin. (Chapter 4)

eukaryote Organism composed of one or more cells that have a distinct nucleus. Member of one of the three main divisions of the living world, the other two being bacteria and archaea. (Chapter 1) (Figures 1–9 and 1–21)

eukaryotic initiation factor (**eIF**) Protein that helps load initiator tRNA on to the ribosome, thus initiating translation. (Chapter 6)

excitatory neurotransmitter Neurotransmitter that opens cation channels in the postsynaptic membrane, causing an influx of Na⁺, and in many cases Ca²⁺, that depolarizes the postsynaptic membrane toward the threshold potential for firing an action potential. (Chapter 11)

executioner caspases Apoptotic caspases that catalyze the widespread cleavage events during apoptosis that kill the cell. (Chapter 18)

exocytosis Excretion of material from the cell by vesicle fusion with the plasma membrane; can occur constitutively or be regulated. (Chapter 13)

exon Segment of a eukaryotic gene that consists of a sequence of nucleotides that will be represented in mRNA or in a final transfer, ribosomal, or other mature RNA molecule. In protein-coding genes, exons encode the amino acids in the protein. An exon is usually adjacent to a noncoding DNA segment called an intron. (Chapters 4, 6) (Figure 4–15)

expansion microscopy (ExM) A microscopy technique in which superresolution is achieved by physically enlarging the specimen. Biological material is labeled with fluorescent probes before being embedded in a polymer gel. The sample is then gently swollen before examination in a light microscope. (Chapter 9)

extracellular pathogens Pathogens that disturb host cells and can cause serious disease without replicating in host cells. (Chapter 23)

extracellular signal molecule Any secreted or cell-surface chemical signal that binds to receptors and regulates the activity of the cell expressing the receptor. (Chapter 15)

extrinsic pathway Pathway of apoptosis triggered by extracellular signal proteins binding to cell-surface death receptors. (Chapter 18)

facultative pathogens Bacteria that replicate in an environmental reservoir such as water or soil and only cause disease if they happen to encounter a susceptible host. (Chapter 23)

FAD/FADH₂ (flavin adenine dinucleotide/reduced flavin adenine dinucleotide) Electron carrier pair that

functions in the citric acid cycle and fatty acid oxidation. One molecule of FAD gains two electrons plus two protons in becoming the activated carrier FADH₂. (Chapter 2) (Figure 2–39)

Fas (Fas protein, Fas death receptor) Transmembrane death receptor that initiates apoptosis when it binds its extracellular ligand (Fas ligand). (Chapter 18) (Figure 18–6)

Fas ligand Ligand that activates the cell-surface death receptor, Fas, triggering the extrinsic pathway of apoptosis. (Chapter 18)

fat Energy-storage lipid in cells. Composed of triglycerides—fatty acids esterified with glycerol. (Chapter 2)

fate map Representation showing which cell types will later derive from which regions of a developing tissue; for example, from the blastula. (Chapter 21) (Figure 21–27)

Fc receptor One of a family of cell-surface receptors that bind the tail region (Fc region) of an antibody molecule. Different Fc receptors are specific for different classes of antibodies, such as IgG, IgA, or IgE. (Chapter 24)

feedback inhibition The process in which a product of a reaction feeds back to inhibit a previous reaction in the same pathway. (Chapter 3) (Figures 3–52 and 3–53)

fermentation Anaerobic energy-yielding metabolic pathway involving the oxidation of organic molecules. Anaerobic glycolysis refers to the process whereby pyruvate is converted into lactate or ethanol, with the conversion of NADH to NAD⁺. (Chapter 2) (Figure 2–50)

fibril-associated collagen A collagen (including types IX and XII) that has a flexible triple-stranded helical structure and binds to the surface of collagen fibrils. Mediates the interactions of these collagen fibrils with one another and with other matrix macromolecules to help determine their organization in the matrix. (Chapter 19)

fibrillar collagen Class of fibril-forming collagens (including type I collagen, the most common type and the principal collagen of skin and bone) that have long rope-like structures with few or no interruptions and which assemble into collagen fibrils. (Chapter 19)

fibroblast Common cell type found in connective tissue. Secretes an extracellular matrix rich in collagen and other extracellular matrix macromolecules. Migrates and proliferates readily in wounded tissue and in tissue culture. (Chapter 19)

fibronectin Extracellular matrix protein involved in adhesion of cells to the matrix and guidance of migrating cells during embryogenesis. Integrins on the cell surface are receptors for fibronectin. (Chapter 19)

filopodium (plural **filopodia**) (**microspike**) Thin, spike-like protrusion with an actin filament core, generated on the leading edge of a crawling animal cell. (Chapter 16) (Figure 16–17)

flagellum (plural **flagella**) Long, whiplike protrusion whose undulations drive a cell through a fluid medium. Eukaryotic flagella are longer versions of cilia. Bacterial flagella are smaller and completely different in construction and mechanism of action. *Compare* **cilium**. (Chapter 16)

fluorescence microscope Microscope designed to view material stained with fluorescent dyes or proteins. Similar to a light microscope but the illuminating light is passed through one set of filters before the specimen, to select those wavelengths that excite the dye, and through another set of filters before the

light reaches the eye, to select only those wavelengths emitted when the dye fluoresces. (Chapter 9) (Figure 9–10)

fluorescence recovery after photobleaching (FRAP)Technique for monitoring the kinetic parameters of a protein by analyzing how fluorescent protein molecules move into an area

of the cell bleached by a beam of laser light. (Chapter 9) (Figure 9–20)

fluorescence resonance energy transfer (FRET)

Technique for monitoring the closeness of two fluorescently labeled molecules (and thus their interaction) in cells. Also known as Förster resonance energy transfer. (Chapter 9) (Figure 9–19)

focal adhesion kinase (FAK) Cytoplasmic tyrosine kinase present at cell–matrix junctions (focal adhesions) in association with the cytoplasmic tails of integrins. (Chapter 15)

follicular helper T cell (**T**_{FH} **cell**) Type of T cell located in lymphoid follicles that secretes various cytokines to stimulate B cells to undergo antibody class switching and somatic hypermutation. (Chapter 24)

formin Dimeric protein that nucleates the growth of straight, unbranched actin filaments that can be cross-linked by other proteins to form parallel bundles. (Chapter 16)

Förster resonance energy transfer See fluorescence resonance energy transfer (FRET). (Chapter 9)

FRAP See fluorescence recovery after photobleaching. (Chapter 9)

free energy (G) (Gibbs free energy) The energy that can be extracted from a system to drive reactions. Takes into account changes in both energy and entropy. (Chapter 2) (Panel 2–7, pp. 106–107)

free-energy change (ΔG) Change in the free energy during a reaction: the free energy of the product molecules minus the free energy of the starting molecules. A large negative value of ΔG indicates that the reaction has a strong tendency to occur. (Chapter 2) (Panel 2–7, pp. 106–107)

free ribosome Ribosome that is free in the cytosol, unattached to any membrane. (Chapter 12)

FRET See fluorescence resonance energy transfer. (Chapter 9)

Frizzled Family of cell-surface receptors that are seven-pass transmembrane proteins that resemble GPCRs in structure but do not generally work through the activation of G proteins. Activated by Wnt binding to recruit the scaffold protein Dishevelled, which helps relay the signal to other signaling molecules. (Chapter 15)

fungus (plural **fungi**) Kingdom of eukaryotic organisms that includes the yeasts, molds, and mushrooms. Many plant diseases and a relatively small number of animal diseases are caused by fungi. (Chapter 23)

fusion protein Engineered protein that combines two or more normally separate polypeptides. Produced from a recombinant gene. (Chapter 8)

 $\Delta \mathbf{G}$ Change in the free energy during a reaction: the free energy of the product molecules minus the free energy of the starting molecules. A large negative value of ΔG indicates that the reaction has a strong tendency to occur. (Chapter 2) (Panel 2–7, pp. 106–107)

 ${f G_0}$ State of withdrawal from the eukaryotic cell-division cycle by entry into a quiescent digression from the ${f G_1}$ phase. A

G:14 Glossary

common, sometimes permanent, state for differentiated cells. (Chapter 17)

G₁ phase Gap 1 phase of the eukaryotic cell-division cycle, between the end of mitosis and the start of DNA synthesis. (Chapter 17) (Figure 17–4)

 G_1 -Cdk Cyclin–Cdk complex formed in vertebrate cells by a G_1 -cyclin and the corresponding cyclin-dependent kinase (Cdk). (Chapter 17) (Table 17–1, p. 1034)

G₁-cyclin Cyclin present in the G_1 phase of the eukaryotic cell cycle. Forms complexes with Cdks that help govern the activity of the G_1/S -cyclins, which control progression to S phase. (Chapter 17)

 G_1/S -Cdk Cyclin–Cdk complex formed in vertebrate cells by a G_1/S -cyclin and the corresponding cyclin-dependent kinase (Cdk). (Chapter 17) (Figure 17–10 and Table 17–1, p. 1034)

 G_1/S -cyclin Cyclin that activates Cdks in late G_1 of the eukaryotic cell cycle and thereby helps trigger progression through Start, resulting in a commitment to cell-cycle entry. Its level falls at the start of S phase. (Chapter 17) (Figure 17–10)

 ${f G_2}$ phase Gap 2 phase of the eukaryotic cell-division cycle, between the end of DNA synthesis and the beginning of mitosis. (Chapter 17) (Figure 17–4)

G2/M transition Point in the eukaryotic cell cycle at which the cell checks for completion of DNA replication before triggering the early mitotic events that lead to chromosome alignment on the spindle. (Chapter 17) (Figure 17–8)

ganglioside Any glycolipid having one or more sialic acid residues in its structure. Found in the plasma membrane of eukaryotic cells and especially abundant in nerve cells. (Chapter 10) (Figure 10–16)

gap gene In *Drosophila* development, a gene that is expressed in specific broad regions along the anteroposterior axis of the early embryo, and which helps designate the main divisions of the insect body. (Chapter 21) (Figure 21–18)

gap junction Communicating channel-forming cell-cell junction present in most animal tissues that allows ions and small molecules to pass from the cytoplasm of one cell to the cytoplasm of the next. (Chapter 19)

gastrulation Important stage in animal embryogenesis during which the embryo is transformed from a ball of cells to a structure with a gut (a gastrula). (Chapter 21)

gated transport Movement of proteins between the cytosol and the nucleus through the nuclear pore complexes in the nuclear envelope; these complexes function as selective gates. (Chapter 12)

geminin Protein that prevents the formation of the protein—DNA complexes required to initiate DNA replication forks during S phase and mitosis, thus ensuring that the chromosomes are replicated only once in each cell cycle. (Chapter 17)

gene Region of DNA that is transcribed as a single unit and carries information for a discrete hereditary characteristic, usually corresponding to (1) a single protein (or set of related proteins generated by variant post-transcriptional processing) or (2) a single RNA (or set of closely related RNAs). (Chapters 1, 7)

gene control region The set of linked DNA sequences regulating expression of a particular gene. Includes promoter and *cis*-regulatory sequences required to initiate transcription of the gene and control the rate of transcription. (Chapter 7) (Figure 7–20)

gene conversion Process by which DNA sequence information can be transferred from one DNA helix (which remains unchanged) to another DNA helix whose sequence is altered. It often accompanies general recombination events. (Chapter 5) (Figure 5–57)

gene family The set of genes in an organism related in DNA sequence because of their derivation from the same ancestor. (Chapter 1)

general transcription factor Any of the proteins whose assembly at all promoters of a given type is required for the binding and activation of RNA polymerase and the initiation of transcription. (Chapter 6) (Table 6–3, p. 333)

genetic code The set of rules specifying the correspondence between nucleotide triplets (codons) in DNA or RNA and amino acids in proteins. (Chapter 6) (Figure 6–52)

genetic instability Abnormally increased spontaneous mutation rate, such as occurs in cancer cells. (Chapter 20)

genetic screen Procedure for discovery of genes affecting a specific phenotype by surveying large numbers of mutagenized individuals. (Chapter 8)

genetics The study of the genes of an organism on the basis of heredity and variation. (Chapter 8)

genome The totality of genetic information belonging to a cell or an organism; in particular, the DNA that carries this information. (Chapters 1, 4)

genome annotation Process attempting to mark out all the genes (protein-coding and noncoding) in a genome and ascribing functions to each. (Chapter 8)

genomic imprinting Phenomenon in which a gene is either expressed or not expressed in the offspring depending on which parent it is inherited from. (Chapter 7) (Figure 7–52)

genomic library Collection of cloned DNA molecules representing an entire genome. (Chapter 8)

genotype Genetic constitution of an individual cell or organism. The particular combination of alleles found in a specific individual. (Chapter 8) (Panel 8–1, pp. 520–521)

germ cell A cell in the germ line of an organism, which includes the haploid gametes and their specified diploid precursor cells. Germ cells contribute to the formation of a new generation of organisms and are distinct from somatic cells, which form the body and leave no descendants. (Chapter 5)

germ layer One of the three primary tissue layers (endoderm, mesoderm, and ectoderm) of an animal embryo. (Chapter 21) (Figure 21–3)

glial cell Supporting non-neural cell of the nervous system. Includes oligodendrocytes and astrocytes in the vertebrate central nervous system and Schwann cells in the peripheral nervous system. (Chapter 11)

glycerophospholipid Phospholipid derived from glycerol, abundant in biomembranes. (Chapter 10) (Figures 10–2 and 10–3)

glycogen Polysaccharide composed exclusively of glucose units. Used to store energy in animal cells. Large granules of glycogen are especially abundant in liver and muscle cells. (Chapter 2) (Figure 2–52 and Panel 2–4, pp. 100–101)

glycolipid Lipid molecule with a sugar residue or oligosaccharide attached. (Chapter 10) (Panel 2–5, pp. 102–103)

glycolysis Ubiquitous metabolic pathway in the cytosol in which sugars are incompletely degraded with production of ATP. Literally, "sugar splitting." (Chapter 2) (Figure 2–46 and Panel 2–8, pp. 108–109)

glycoprotein Any protein with one or more sugars or oligosaccharide chains covalently linked to amino acid side chains. Most secreted proteins and most proteins exposed on the outer surface of the plasma membrane are glycoproteins. (Chapter 12)

glycosaminoglycan (GAG) Long, linear, highly charged polysaccharide composed of a repeating pair of sugars, one of which is always an amino sugar. Mainly found covalently linked to a protein core in extracellular matrix proteoglycans. Examples include chondroitin sulfate, hyaluronan, and heparin. (Chapter 19) (Figure 19–32)

glycosylphosphatidylinositol anchor (GPI anchor) Lipid linkage by which some membrane proteins are bound to the membrane. The protein is joined, via an oligosaccharide linker, to a phosphatidylinositol anchor during its travel through the endoplasmic reticulum. (Chapters 10, 12) (Figure 12–30)

Golgi apparatus (Golgi complex) Complex organelle in eukaryotic cells, centered on a stack of flattened, membrane-enclosed spaces, in which proteins and lipids transferred from the endoplasmic reticulum are modified and sorted. It is also the site of synthesis of many cell-wall polysaccharides in plants and extracellular matrix glycosaminoglycans in animal cells. (Chapter 13) (Figure 13–27)

GPCR kinase (GRK) Member of a family of enzymes that phosphorylates multiple serines and threonines on a GPCR to produce receptor desensitization. (Chapter 15) (Figure 15–43)

G protein (heterotrimeric GTP-binding protein) A heterotrimeric GTP-binding protein with intrinsic GTPase activity that couples GPCRs to enzymes or ion channels in the plasma membrane. (Chapter 15) (Table 15–3, p. 907)

G-protein-coupled receptor (GPCR) A seven-pass cell-surface receptor that, when activated by its extracellular ligand, activates a G protein, which in turn activates either an enzyme or ion channel in the plasma membrane. (Chapter 15) (Figures 15–6 and 15–22)

Gram negative Description for bacteria that do not stain with Gram stain as a result of having a thin peptidoglycan cell wall outside their inner (plasma) membrane that is covered by a second lipid-containing outer membrane. (Chapter 23) (Figure 23–3)

Gram positive Description for bacteria that stain positive with Gram stain because of a thick layer of peptidoglycan cell wall outside their inner (plasma) membrane. (Chapter 23)

Gram staining A technique for classifying bacteria that is based on differences in the structure of the bacterial cell wall and outer surface. (Chapter 23)

granulocyte Category of white blood cell distinguished by conspicuous cytoplasmic granules. Includes neutrophils, basophils, and eosinophils. Arises from a granulocyte/macrophage (GM) progenitor cell. (Chapter 22) (Figure 22–11)

granulocyte/macrophage (GM) progenitor cell Committed progenitor cell in the bone marrow that gives rise to neutrophils and macrophages. (Figure 22–12)

green fluorescent protein (GFP) Fluorescent protein isolated from a jellyfish. Widely used as a marker in cell biology. (Chapters 8, 9) (Figure 9–16)

growth cone Migrating motile tip of a growing nerve cell axon or dendrite. (Chapter 16)

growth factor Extracellular signal protein that can stimulate a cell to grow. Growth factors often have other functions as well, including stimulating cells to survive or proliferate. Examples include epidermal growth factor (EGF) and platelet-derived growth factor (PDGF). (Chapter 17)

growth hormone (GH) Mammalian hormone secreted by the pituitary gland into the bloodstream that stimulates growth throughout the body. (Chapter 15)

GTP (guanosine 5'-triphosphate) Nucleoside triphosphate produced by the phosphorylation of GDP (guanosine diphosphate). Like ATP, it releases a large amount of free energy on hydrolysis of its terminal phosphate group. Has a special role in microtubule assembly, protein synthesis, and cell signaling. (Figure 2–59)

GTP-binding protein Also called GTPase; an enzyme that converts GTP to GDP. (Chapters 3, 15)

GTPase An enzyme that converts GTP to GDP. GTPases fall into two large families. Large *G proteins* (heterotrimeric *G proteins*) are composed of three different subunits and mainly couple GPCRs to enzymes or ion channels in the plasma membrane. Small monomeric *GTP-binding proteins* (also called *monomeric GTPases*) consist of a single subunit and help relay signals from many types of cell-surface receptors and have roles in intracellular signaling pathways, regulating intracellular vesicle trafficking, and signaling to the cytoskeleton. Both heterotrimeric G proteins and monomeric GTPases cycle between an active GTP-bound form and an inactive GDP-bound form and frequently act as molecular switches in intracellular signaling pathways. (Chapter 3) (Figure 3–63)

GTPase-activating protein (GAP) Protein that binds to a GTPase and inhibits it by stimulating its GTPase activity, causing the enzyme to hydrolyze its bound GTP to GDP. (Chapter 15) (Figure 15–8)

guanine nucleotide exchange factor (GEF) Protein that binds to a GTPase and activates it by stimulating it to release its tightly bound GDP, thereby allowing it to bind GTP in its place. (Chapter 15) (Figure 15–8)

haplotype block Combination of alleles and DNA markers that has been inherited in a large, linked block on one chromosome of a homologous pair—undisturbed by genetic recombination—across many generations. (Chapter 8)

Hedgehog protein Secreted extracellular signal molecule that has many different roles controlling cell differentiation and gene expression in animal embryos and adult tissues. Excessive Hedgehog signaling can lead to cancer. (Chapter 15)

helper T cell (**T_H cell**) Type of T cell that helps activate B cells to make antibodies, cytotoxic T cells to become effector cells, and macrophages to kill ingested pathogens. They can also help activate dendritic cells. (Chapter 24)

hematopoietic stem cells Stem cells located in the bone marrow that give rise to almost all blood-cell types. (Chapter 22)

hepatocyte The main liver cell type that carries out a variety of functions including blood protein synthesis, carbohydrate and lipid metabolism, and detoxification of harmful substances. (Chapter 22)

heterochromatin Chromatin that is highly condensed even in interphase; generally transcriptionally inactive. (*Compare* with **euchromatin**.) (Chapter 4)

heterochronic Describes genes involved in developmental timing; mutation results in cells of a specific fate behaving as cells at a different stage of development. (Chapter 21)

heterotrimeric GTP-binding protein See G protein. (Chapter 15)

high-mannose oligosaccharides Broad class of *N*-linked oligosaccharides, attached to mammalian glycoproteins in the endoplasmic reticulum, containing two *N*-acetylglucosamine residues and many mannose residues. (Chapter 13)

high-performance liquid chromatography (HPLC) Type of chromatography that uses columns packed with tiny beads of matrix; the solution to be separated is pushed through under high pressure. (Chapter 8)

histone One of a group of small abundant proteins, rich in arginine and lysine, that combine to form the nucleosome cores around which DNA is wrapped in eukaryotic chromosomes. (Chapter 4) (Figure 4–24)

histone chaperone (chromatin assembly factor) Protein that binds free histones, releasing them as they are incorporated into newly replicated chromatin. (Chapter 5) (Figure 4–27)

histone H1 "Linker" (as opposed to "core") histone protein that binds to DNA where it exits from a nucleosome and helps to compact nucleosomes. (Chapter 4) (Figure 4–30)

Holliday junction (cross-strand exchange) X-shaped structure formed in DNA molecules undergoing recombination, in which the two DNA molecules are held together by exchanging one of their two strands; also called a cross-strand exchange. (Chapter 5) (Figure 5–54)

homeotic selector gene In *Drosophila* development, a gene that defines and preserves the differences between body segments. (Chapter 21)

homolog One of two or more genes that are similar in sequence as a result of derivation from the same ancestral gene. The term covers both orthologs and paralogs. (Chapter 1) (Figure 1–20) See **homologous chromosomes**.

homologous chromosomes (homologs) The maternal and paternal copies of a particular chromosome in a diploid cell. (Chapter 4)

homologous recombination (general recombination)
Genetic exchange between a pair of identical or very similar
DNA sequences, often those located on two copies of the same
chromosome. Provides an error-free mechanism for repairing DNA
double-strand breaks. (Chapter 5) (Figures 5–47, 5–49, and 5–53)

homophilic Binding between molecules of the same kind, especially those involved in cell–cell adhesion. (Chapter 19) (Figure 19–5)

horizontal gene transfer Gene transfer between bacteria or archaea via natural transformation by released naked DNA, transduction by bacteriophages, or sexual exchange by conjugation. (Chapter 23)

hormone Signal molecule secreted by an endocrine cell into the bloodstream, which can then carry the signal to distant target cells. (Chapters 15, 21)

Hox complex A gene complex consisting of a series of *Hox* genes. (Chapter 21)

Hox genes Genes coding for transcription regulators, each gene containing a homeodomain, and specifying body-region differences. *Hox* mutations typically cause homeotic transformations. (Chapter 21)

Hox proteins Transcription regulatory proteins encoded by *Hox* genes; possess a highly conserved, 60-amino-acid-long DNA-binding homeodomain. (Chapter 21)

HPV Human papillomavirus; infects the cervical epithelium and is important as a cause of carcinoma of the uterine cervix. (Chapter 20)

hyaluronan (**hyaluronic acid**) Type of nonsulfated glycosaminoglycan with a regular repeating sequence of up to 25,000 identical disaccharide units and not linked to a core protein. Found in the fluid lubricating joints and in many other tissues. (Chapter 19) (Figures 19–33 and 19–34)

hybridization In molecular biology, the process whereby two complementary nucleic acid strands form a base-paired duplex DNA–DNA, DNA–RNA, or RNA–RNA molecule. Forms the basis of a powerful technique for detecting specific nucleotide sequences. (Chapter 8) (Figure 8–31)

hybridoma Hybrid cell line generated by fusion of a tumor cell and another cell type. Monoclonal antibodies are produced by hybridoma lines obtained by fusing antibody-secreting B cells with cells of a B-lymphocyte tumor. (Chapter 8) (Figure 8–3)

hydrogen bond Noncovalent bond in which an electropositive hydrogen atom is partially shared by two electronegative atoms. (Chapter 2) (Panel 2–3, pp. 98–99)

hydronium ion (H₃O⁺) Water molecule associated with an additional proton. The form generally taken by protons in aqueous solution. (Chapter 2)

hydrophilic Dissolving readily in water. Literally, "water loving." (Chapters 2, 10)

hydrophobic (lipophilic) Not dissolving readily in water. Literally, "water-fearing." (Chapters 2, 10)

hydrophobic force Force exerted by the hydrogen-bonded network of water molecules that brings two nonpolar surfaces together by excluding water between them. (Panel 2–3, pp. 98–99)

hyperpolarization Deviation in the electrical potential across the plasma membrane towards a more negative value. (Chapter 11)

hypervariable region In immunology: any of the three small parts of the variable region of an immunoglobulin or T cell receptor chain that show the highest variability from molecule to molecule and contribute to the antigen-binding site. (Chapter 24) (Figure 24–26)

IκB Inhibitory proteins that bind tightly to NFκB dimers and hold them in an inactive state within the cytoplasm of unstimulated cells. (Chapter 15)

Ig gene segments In immunology: short DNA sequences that are joined together during B cell and T cell development to produce the coding sequences for immunoglobulins and T cell receptors, respectively. (Chapter 24) (Figure 24–28)

Ig superfamily Large and diverse family of proteins that contain immunoglobulin or immunoglobulin-like domains. Most are involved in cell–cell interactions or antigen recognition. (Chapter 24) (Figure 24–48)

IgA Immunoglobulin A; the principal class of antibody in secretions, including saliva, tears, milk, and respiratory and intestinal secretions. (Chapter 24)

IgD Immunoglobulin D; produced by immature naïve B cells after leaving the bone marrow. Transmembrane IgD and IgM proteins, with the same antigen-binding site, form the B cell receptors (BCRs) on these cells. (Chapter 24)

IgE Immunoglobulin E; binds with high affinity via its tail region to a class of Fc receptors on the surface of mast cells (tissues) or basophils (blood), where it acts as an antigen receptor; antigen binding stimulates the secretion of cytokines and biologically active amines, which help attract white blood cells, antibodies, and complement proteins to the site of activation. (Chapter 24)

IgG Immunoglobulin G; the major antibody class in the blood, produced in especially large quantities during secondary antibody responses. The tail region of some IgG subclasses can bind to specific Fc receptors on macrophages and neutrophils. Antigen–IgG complexes can activate complement. (Chapter 24)

IgM Immunoglobulin M; the first class of immunoglobulin that a developing B cell in the bone marrow makes, forming B-cell receptors on its surface. IgM antibodies are the major class of antibody secreted into the blood in the early stages of a primary antibody response on first exposure to an antigen, where their pentameric structure (with 10 antigenbinding sites) allows strong binding to pathogens. When bound to antigen, it is highly efficient at activation of complement. (Chapter 24)

image processing Computer-based techniques in microscopy that process digital images in order to extract latent information. Enables compensation for some optical faults in microscopes, enhanced contrast to improve detection of small differences in light intensity, and subtraction of background irregularities in the optical system. (Chapter 9)

imaginal disc Group of cells that are set aside, apparently undifferentiated, in the *Drosophila* embryo and which will develop into an adult structure (for example, eye, leg, wing). Overt differentiation occurs at metamorphosis. (Chapter 21) (Figure 21–65)

immunization Method of inducing adaptive immune responses to pathogens or foreign molecules, usually involving the co-injection of an adjuvant, a molecule (often of microbial origin) that helps activate innate immune responses required for the adaptive responses. (Chapter 24)

immunoblotting See western blotting. (Chapter 8) immunoglobulin (Ig) See antibody. (Chapters 3, 24)

immunoglobulin (**Ig**) **domain** Characteristic protein domain of about 110 amino acids that is found in immunoglobulin light and heavy chains. Similar domains, known as immunoglobulin-like (Ig-like) domains, are present in many other proteins, which, together with Igs, constitute the Ig superfamily. (Chapter 24) (Figure 24–27)

immunoglobulin (Ig) superfamily Large and diverse family of proteins that contain immunoglobulin domains or immunoglobulin-like domains. Most are involved in cell–cell interactions or antigen recognition. (Chapter 19) (Figure 24–48)

immunogold electron microscopy Method to localize specific macromolecules using a primary antibody that binds to the molecule of interest and is then detected with a secondary antibody to which a colloidal gold particle has been attached. The gold particle is electron-dense and can be seen as a black dot in the electron microscope. (Figure 9–43)

immunological memory Long-lived property of the adaptive immune system that follows a primary immune response to many antigens, such that a subsequent encounter with the same antigen will provoke a more rapid and stronger secondary immune response. (Chapter 24) (Figure 24–16)

immunological self-tolerance The lack of response of the adaptive immune system to an antigen. Tolerance to self molecules is crucial to avoid autoimmune diseases. (Chapter 24) (Figure 24–21)

immunological synapse The highly organized interface that develops between a T cell and an antigen-presenting cell (APC) or target cell it is in contact with, formed by T-cell receptors binding to antigen–MHC complexes on the APC and cell adhesion proteins binding to their counterparts on the APCs. (Chapter 24)

induced fit A principle for increasing the specificity of substrate recognition by proteins and RNAs. In protein synthesis, the ribosome folds around a codon–anticodon interaction, and only when the match is correct does the subsequent reaction proceed efficiently. (Chapter 6)

induced pluripotent stem cells (iPS cells) Cells that are induced by artificial expression of specific transcription regulators to look and behave like the pluripotent embryonic stem cells that are derived from embryos. (Chapters 7, 22)

induced regulatory T cell (induced T_{reg} cell) A regulatory T cell (T_{reg} cell) that develops from naïve helper T cells when they are activated in the presence of TGF β in the absence of IL6. (Chapter 24)

inflammasome Intracellular protein complex formed after activation of cytoplasmic NOD-like receptors with adaptor proteins. It contains a caspase enzyme that cleaves proinflammatory cytokines from their precursor proteins. (Chapter 24)

inflammatory response Local response of a tissue to injury or infection—characterized clinically by redness, swelling, heat, and pain. Caused by invasion of white blood cells, which are attracted by and secrete various cytokines. (Chapter 24)

inhibitors of apoptosis (IAPs) Intracellular protein inhibitors of apoptosis. (Chapter 18)

inhibitory G protein (**G**_i) Heterotrimeric G protein that can regulate ion channels and inhibit the enzyme adenylyl cyclase in the plasma membrane. See also **G protein**. (Chapter 15) (Table 15–3, p. 907)

inhibitory neurotransmitter Neurotransmitter that opens transmitter-gated Cl^- or K^+ channels in the postsynaptic membrane of a nerve or muscle cell and thus tends to inhibit the generation of an action potential. (Chapter 11)

initial segment Specialized membrane region at the base of a nerve axon (adjacent to the cell body) that is rich in voltage-gated Na⁺ channels plus other classes of ion channels that all contribute to the encoding of membrane depolarization into action potential frequency. (Chapter 11)

initiator caspases Apoptotic caspases that begin the apoptotic process, activating the executioner caspases. (Chapter 18)

initiator tRNA Special tRNA that initiates translation. It always carries the amino acid methionine, forming the complex Met–tRNAi. (Chapter 6) (Figure 6–74)

innate immune response An early immune response in all organisms to a pathogen, which includes the production of antimicrobial molecules and the activation of phagocytic cells. Such a response is not specific for the pathogen, in contrast to an adaptive immune response. (Chapter 24)

innate immune system A variety of defense mechanisms that help prevent and fight infection. Unlike adaptive immune

G:18 Glossary

mechanisms, innate immune mechanisms act from the start of an infection, do not adapt to a specific pathogen, and do not generate immunological memory. (Chapter 24)

inner mitochondrial membrane Mitochondrial membrane that encloses the matrix space and forms extensive invaginations called cristae. (Chapters 12, 14)

inner nuclear membrane One of two concentric membranes comprising the nuclear envelope; contains specific proteins as anchoring sites for chromatin and the nuclear lamina. (Chapter 12)

inositol 1,4,5-trisphosphate (**IP**₃) Small intracellular signaling molecule produced during activation of the inositol phospholipid signaling pathway. Acts to release Ca^{2+} from the endoplasmic reticulum. (Chapter 15) (Figures 15–29 and 15–30)

inositol phospholipid signaling pathway Intracellular signaling pathway that starts with the activation of phospholipase C and the generation of IP₃ and diacylglycerol (DAG) from inositol phospholipids in the plasma membrane. The DAG helps to activate protein kinase C. (Chapter 15) (Figures 15–29 and 15–30)

integrin Transmembrane adhesion protein that is involved in the attachment of cells to the extracellular matrix and to each other. (Chapter 19) (Figure 19–3 and Table 19–1, p. 1107)

interaction domain Compact protein module, found in many intracellular signaling proteins, that binds to a particular structural motif (for example, a short peptide sequence, a covalent modification, or another protein domain) in another protein or lipid. (Chapter 15)

interferon- α (IFN α) and interferon- β (IFN β) Cytokines (type I interferons) produced by mammalian cells as a general response to a viral infection. (Chapter 24)

intermembrane space The compartment in a mitochondrion between the outer and inner mitochondrial membranes. (Chapters 12, 14)

internal ribosome entry site (IRES) Specific site in a eukaryotic mRNA, other than at the 5' end, at which translation can be initiated. (Chapter 7) (Figure 7–72)

interphase Long period of the cell cycle between one mitosis and the next. Includes G_1 phase, S phase, and G_2 phase. (Chapter 17) (Figure 17–4)

intestinal epithelium The single cell layer of polarized epithelial cells that makes up the lining of the small and large intestine, where it acts as a barrier to the lumen of the gut and mediates absorption of nutrients. (Chapter 22)

intracellular pathogens Pathogens, including all viruses and many bacteria and protozoa, that enter and replicate inside host cells to cause disease. (Chapter 23)

intrinsic pathway (mitochondrial pathway) Pathway of apoptosis activated from inside the cell in response to stress or developmental signals; depends on the release into the cytosol of mitochondrial proteins normally resident in the mitochondrial intermembrane space. (Chapter 18)

intron Noncoding region of a eukaryotic gene that is transcribed into an RNA molecule but is then excised by RNA splicing during production of the mRNA or other functional RNA. (Chapters 4, 6) (Figure 4–15)

invadopodia Actin-rich protrusions extending in three dimensions that are important for cells to cross tissue barriers by degrading the extracellular matrix. (Chapter 16)

ion channel Transmembrane protein complex that forms a water-filled channel across the lipid bilayer through which specific inorganic ions can diffuse down their electrochemical gradients. (Chapter 11) (Figure 11–22)

ion-sensitive indicators Molecules whose light emission reflects the local concentration of a particular ion; some are luminescent (emitting light spontaneously) while others are fluorescent (emitting light on exposure to light). (Figure 9–21)

ionotropic receptor (transmitter-gated ion channel) lon channel found at chemical synapses in the postsynaptic plasma membranes of nerve and muscle cells. Opens only in response to the binding of a specific extracellular neurotransmitter. The resulting inflow of ions leads to the generation of a local electrical signal in the postsynaptic cell. (Figures 11–38 and 15–6)

IP₃ receptor (**IP**₃-gated **Ca**²⁺-release channel) Gated Ca²⁺ channel in the ER membrane that opens on binding cytosolic IP₃, releasing stored Ca²⁺ into the cytosol. (Chapter 15) (Figure 15–30)

iron–sulfur cluster Electron-transporting group consisting of either two or four iron atoms bound to an equal number of sulfur atoms, found in a class of electron-transport proteins. (Figure 14–16)

iron–sulfur protein A protein that contains one or more iron–sulfur clusters, typically using those cofactors for electron transport. (Chapter 14)

J gene segment Short DNA sequence that encodes part of the variable region of light and heavy immunoglobulin chains and of α and β chains of T cell receptors. (Chapter 24) (Figures 24–28 and 24–29)

JAK-STAT signaling pathway Signaling pathway activated by cytokines and some hormones, providing a rapid route from the plasma membrane to the nucleus to alter gene transcription. Involves cytoplasmic Janus kinases (JAKs), and signal transducers and activators of transcription (STATs). (Chapter 15)

Janus kinases (**JAKs**) Cytoplasmic tyrosine kinases associated with cytokine receptors, which phosphorylate and activate transcription regulators called STATs. (Chapter 15)

junctional diversification The random loss and gain of nucleotides at joining sites during V(D)J recombination that occurs during B and T cell development when the cells are assembling the gene segments that encode their antigen receptors. It enormously increases the diversity of V-region coding sequences. (Chapter 24)

K⁺ **leak channel** K⁺-transporting ion channel in the plasma membrane of animal cells that remains open even in a "resting" cell. (Chapter 11)

 \textit{K}_{m} The Michaelis constant, equal to the concentration of an enzyme's substrate that allows that enzyme to produce product at one-half of its maximum rate. (Chapter 3)

karyotype Display of the full set of chromosomes of a cell, arranged with respect to size, shape, and number. (Chapter 4)

keratin Type of intermediate filament, commonly produced by epithelial cells. (Chapter 16)

kinase cascade Intracellular signaling pathway in which one protein kinase, activated by phosphorylation, phosphorylates the next protein kinase in the sequence, and so on, relaying the signal onward. (Chapter 15)

kinesin Member of one of the two main classes of motor proteins that use the energy of ATP hydrolysis to move along microtubules. (Chapter 16) (Figure 16–51)

kinesin-1 Motor protein associated with microtubules that transports cargo within the cell; also called "conventional kinesin." (Chapter 16)

kinetic proofreading A principle for increasing the specificity of catalysis. In the synthesis of DNA, RNA, and proteins, it refers to a time delay that begins with an irreversible step (such as ATP or GTP hydrolysis) and during which incorrect base pairs are more likely to dissociate than correct pairs. (Chapter 6)

kinetochore Large protein complex that connects the centromere of a chromosome to microtubules of the mitotic spindle. (Chapter 17) (Figure 17–33)

kinetochore microtubule In the mitotic or meiotic spindle, a microtubule that connects the spindle pole to the kinetochore of a chromosome. (Chapter 17)

lagging strand One of the two newly synthesized strands of DNA found at a replication fork. The lagging strand is made in discontinuous lengths that are later joined covalently. (Chapter 5) (Figure 5–7)

lamellipodium (plural **lamellipodia**) Flattened, sheetlike protrusion supported by a meshwork of actin filaments, which is extended at the leading edge of a crawling animal cell. (Chapter 16) (Figures 16–18 and 16–19)

laminin Extracellular matrix fibrous protein found in basal laminae, where it forms a sheetlike network. (Chapter 19) (Figures 19–53 and 19–54)

lampbrush chromosome Huge chromosome paired in preparation for meiosis, found in immature amphibian eggs; consisting of large loops of chromatin extending out from a linear central axis. (Chapter 4) (Figure 4–45)

late endosome Compartment formed from a bulbous, vacuolar portion of early endosomes by a process called endosome maturation; late endosomes fuse with one another and with lysosomes to form endolysosomes that degrade their contents. (Chapter 13)

LDL-receptor-related protein (LRP) Co-receptor bound by Wnt proteins in the regulation of β -catenin proteolysis. (Chapter 15)

leading strand One of the two newly synthesized strands of DNA found at a replication fork. The leading strand is made by continuous synthesis in the 5'-to-3' direction. (Chapter 5) (Figure 5–7)

lectin Protein that binds tightly to a specific sugar. Abundant lectins from plant seeds are used as affinity reagents to purify glycoproteins or to detect them on the surface of cells. (Chapter 10)

Legionnaires' disease Type of pneumonia resulting from infection with *Legionella pneumophila*, a bacterial parasite of freshwater amoebae that is spread to humans by airconditioning systems that harbor infected amoebae. (Chapter 23)

lethal factor One of the subunits of anthrax toxin; a protease that cleaves several activated members of the MAP kinase kinase family and causes a large fall in blood pressure and death on entry into the bloodstream of an animal. (Chapter 23)

leucine-rich repeat (LRR) receptor kinases Common type of receptor serine/threonine kinase in plants that contains

a tandem array of leucine-rich repeat sequences in its extracellular portion. (Chapter 15)

leukemia Cancer of white blood cells. (Chapter 20)

leukocyte General name for all the nucleated blood cells lacking hemoglobin. Also called white blood cells. Includes lymphocytes, granulocytes, and monocytes. (Chapter 22) (Figure 22–11)

ligand Any molecule that binds to a specific site on a protein or other molecule. From Latin *ligare*, "to bind." (Chapter 3)

light microscope One of a class of microscopes that uses visible light to create the image. (Chapter 9)

lignin Network of cross-linked phenolic compounds that forms a supporting network throughout the cell walls of xylem and woody tissue in plants. (Chapter 19)

limit of resolution In microscopy, the smallest distance apart at which two point objects can be resolved as separate. Just under 0.2 μ m for conventional light microscopy, a limit determined by the wavelength of light. (Chapter 9)

linkage In ligand binding, the conformational coupling between two separate ligand-binding sites on a protein, such that a conformational change in the protein induced by binding of one ligand affects the binding of a second ligand. (Chapter 3)

lipid bilayer (**phospholipid bilayer**) Thin double sheet of phospholipid molecules that forms the core structure of all cell membranes. The two layers of lipid molecules are packed with their hydrophobic tails pointing inward and their hydrophilic heads outward, exposed to water. (Chapter 10) (Figure 10–1 and Panel 2–5, pp. 102–103)

lipid droplets Storage form in cells for excess lipids; composed of a single monolayer of phospholipids and proteins that surrounds neutral lipids that can be retrieved from droplets as required by the cell. (Chapter 10)

lipid raft Small region of a membrane enriched in sphingolipids and cholesterol. (Chapter 10) (Figure 10–13)

liposome Artificial phospholipid bilayer vesicle formed from an aqueous suspension of phospholipid molecules. (Chapter 10) (Figure 10–9)

local mediator Extracellular signal molecule that acts on neighboring cells. (Chapter 15)

long noncoding RNA (IncRNA) One of a large group (~5000 in humans) of RNAs longer than 200 nucleotides and not coding for protein. The functions, if any, of most IncRNAs are unknown, but individual IncRNAs are known to play important roles in the cell; for example, in telomerase function and genomic imprinting. In a general sense, IncRNAs are believed to act as scaffolds, holding together proteins and nucleic acids to speed up a wide variety of reactions in the cell. (Chapter 7)

long-term depression (LTD) A long-lasting (hours or more) decrease in the sensitivity of certain synapses in the brain triggered by NMDA-receptor activation. As the opposing process to long-term potentiation, it is thought to be involved in learning and memory. (Chapter 11)

long-term potentiation (LTP) Long-lasting increase (days to weeks) in the sensitivity of certain synapses in the brain, induced by a short burst of repetitive firing in the presynaptic neurons. (Chapter 11) (Figure 11–46)

loss of heterozygosity The result of errant homologous recombination that uses the homolog from the other parent instead of the sister chromatid as the template, converting the

G:20 Glossary

sequence of the repaired DNA to that of the other homolog. (Chapter 5)

low-density lipoprotein (LDL) Large complex composed of a single protein molecule and many esterified cholesterol molecules, together with other lipids. The form in which cholesterol is transported in the blood and taken up into cells. (Chapter 13) (Figure 13–53)

lumen The space inside a hollow structure. In cells: the cavity enclosed by an organelle membrane. In tissues: the cavity enclosed by a sheet of cells. (Chapters 10, 12)

lymphocyte White blood cell responsible for the specificity of adaptive immune responses. Two main types: B cells, which produce antibody, and T cells, which interact directly with other effector cells of the immune system and with infected cells. T cells develop in the thymus and are responsible for cell-mediated immunity. B cells develop in the bone marrow in mammals and are responsible for the production of circulating antibodies. (Chapter 24)

lymphoid cells Immune cells including B and T lymphocytes and natural killer cells. (Chapter 22)

lymphoid organ An organ containing large numbers of lymphocytes. Lymphocytes are produced in central (or primary) lymphoid organs and respond to antigen in peripheral (or secondary) lymphoid organs. (Chapter 24) (Figure 24–12)

lymphoma Cancer of lymphocytes, in which the cancer cells are mainly found in lymphoid organs (rather than in the blood, as in leukemias). (Chapter 20)

lysosomal storage diseases Genetic diseases resulting from defects in or a lack of one or more functional hydrolases in lysosomes of some cells, leading to accumulation of undigested substrates in lysosomes and consequent cell pathology. (Chapter 13)

lysosome Membrane-enclosed organelle in eukaryotic cells containing digestive enzymes, which are typically most active at the acid pH found in the lumen of lysosomes. (Chapter 13) (Figure 13–62)

lysozyme Enzyme that catalyzes the cutting of polysaccharide chains in the cell walls of bacteria. (Chapter 3)

M-Cdk (M-phase Cdk) Cyclin-Cdk complex formed in vertebrate cells by an M-cyclin and the corresponding cyclin-dependent kinase (Cdk). (Chapter 17) (Figure 17-10 and Table 17-1, p. 1034)

M-cyclin A cyclin found in all eukaryotic cells that promotes the events of mitosis. (Chapter 17) (Figure 17–10)

M6P receptor proteins Transmembrane receptor proteins present in the *trans* Golgi network that recognize the mannose 6-phosphate (M6P) groups added exclusively to lysosomal enzymes, marking the enzymes for packaging and delivery to early endosomes. (Chapter 13)

macromolecule Polymers constructed of long chains of covalently linked, small organic (carbon-containing) molecules. The principal building blocks from which a cell is constructed and the components that confer the most distinctive properties of living things. (Chapter 2)

macrophage Phagocytic cell derived from blood monocytes, resident in most tissues but able to roam. It has both scavenger and antigen-presenting functions in immune responses. (Chapter 13)

macropinocytosis Clathrin-independent, dedicated degradative endocytic pathway induced in most cell types

by cell-surface receptor activation by specific cargoes. (Chapter 13)

malaria Protozoal disease caused by any one of four species of *Plasmodium*, which are transmitted to humans by the bite of the female *Anopheles* mosquito. (Chapter 23)

malignant Of tumors and tumor cells: invasive and/or able to undergo metastasis. A malignant tumor is a cancer. (Chapter 20) (Figure 20–3)

MAP kinase module (mitogen-activated protein kinase module) An intracellular signaling module composed of three protein kinases, acting in sequence, with MAP kinase as the third. Typically activated by a Ras protein in response to extracellular signals. (Chapter 15) (Figure 15–50)

master transcription regulator A transcription regulator specifically required for formation of a particular cell type. Artificial expression of master transcription regulators (alone or in combination with others) can often convert one cell type into another. (Chapter 7)

maternal inheritance A form of inheritance observed in animals and plants, caused by the fact that mitochondrial DNA is inherited only through the female germ line. (Chapter 14)

maternal effect Describes a gene that acts in the mother to specify maternal mRNAs and proteins in the egg (that is, maternal-effect gene). Maternal-effect mutations affect the development of the embryo even if the embryo itself has not inherited the mutated gene. (Chapter 21)

maternal-zygotic transition (MZT) Event in animal development where the embryo's own genome largely takes over control of development from maternally deposited macromolecules. (Chapter 21)

matrix metalloprotease Ca^{2+} - or Zn^{2+} -dependent proteolytic enzyme present in the extracellular matrix that degrades matrix proteins. Includes the collagenases. (Chapter 19)

matrix space The large internal compartment of the mitochondrion. (Chapter 12)

Mcm helicase Six-subunit protein complex that serves as the replicative helicase in eukaryotic DNA replication, unwinding the DNA to enable DNA synthesis. (Chapters 5, 17)

mechanosensitive channels Transmembrane ion channels that open in response to a mechanical stress on the lipid bilayer in which they are embedded. (Chapter 11)

megakaryocyte Large myeloid cell with a multilobed nucleus that remains in the bone marrow when mature. Buds off platelets from long cytoplasmic processes. (Chapter 22)

meiosis I The first of two rounds of chromosome segregation after meiotic chromosome duplication; segregates the homologs, each composed of a tightly linked pair of sister chromatids. (Chapter 17)

meiosis II The second of two rounds of chromosome segregation after meiotic chromosome duplication; segregates the sister chromatids of each homolog. (Chapter 17)

membrane-associated protein Membrane protein not extending into the hydrophobic interior of the lipid bilayer but bound to either face of the membrane by noncovalent interactions with other membrane proteins. (Chapter 10) (Figure 10–17)

membrane-bending proteins Attach to specific membrane regions as needed, where they act to control local membrane

curvature and thus confer on these regions their threedimensional shapes. (Chapter 10)

membrane-bound ribosome Ribosome attached to the cytosolic face of the endoplasmic reticulum. The site of synthesis of proteins that enter the endoplasmic reticulum. (Chapter 12) (Figure 12–21)

membrane potential Voltage difference across a membrane due to a slight excess of positive ions on one side and of negative ions on the other. A typical membrane potential for an animal cell plasma membrane is –60 mV (inside negative relative to the surrounding fluid). (Chapter 11) (Figure 11–23)

membrane protein Amphiphilic protein of diverse structure and function that associates with the lipid bilayer of cell membranes. (Chapter 10) (Figure 10–17)

membrane transport protein Membrane protein that mediates the passage of ions or molecules across a membrane. The two main classes are transporters (also called carriers or permeases) and channels. (Chapter 11) (Figure 11–3)

membraneless organelle An assembly of specific proteins held together by multivalent, low-affinity interactions. Also referred to as a *biomolecular condensate*. (Chapter 12)

memory cell In immunology: a T or B lymphocyte generated after antigen stimulation that is more easily and more quickly induced to become an effector cell or another memory cell by a later encounter with the same antigen. (Chapter 24) (Figure 24–17)

mesenchymal cell migration A mode of cell locomotion typical of fibroblasts that is characterized by protrusion of actin-rich lamellipodia at the leading edge, formation of integrin-based attachments to the underlying substratum, and actomyosin-based contraction at the rear of the cell. (Chapter 16)

mesoderm Embryonic tissue that is the precursor to muscle, connective tissue, skeleton, and many of the internal organs. (Chapter 21) (Figure 21–3)

messenger RNA (mRNA) RNA molecule that specifies the amino acid sequence of a protein. Produced in eukaryotes by processing of an RNA molecule made by RNA polymerase as a complementary copy of DNA. It is translated into protein in a process catalyzed by ribosomes. (Chapter 6) (Figure 6–21)

metabolism The sum total of the chemical processes that take place in living cells. All of catabolism plus anabolism. (Chapter 2) (Figure 2–14)

metabotropic receptors Neurotransmitter receptors that regulate ion channels indirectly through the activation of second-messenger molecules. (Chapter 11)

metaphase The stage of mitosis when all the chromosomes have been moved to the center of the cell, having been positioned there by the mitotic spindle. Metaphase follows prophase and prometaphase; it is succeeded by anaphase. (Chapter 17)

metaphase plate Imaginary plane at right angles to the mitotic spindle and midway between the spindle poles; the plane in which chromosomes are positioned at metaphase. (Chapter 17) (Panel 17–1, pp. 1048–1049)

metaphase-to-anaphase transition Transition in the eukaryotic cell cycle preceding sister-chromatid separation at anaphase. If the cell is not ready to proceed to anaphase, the cell cycle is halted at this point. (Chapter 17) (Figure 17–8 and Panel 17–1, pp. 1048–1049)

metastases Secondary tumors, at sites in the body additional to that of the primary tumor; they result from cancer cells

breaking loose, entering blood or lymphatic vessels, and colonizing separate environments. (Chapter 20)

metastasis The spread of cancer cells from their site of origin to other sites in the body. (Chapter 20) (Figures 20–1 and 20–20)

MHC genes Cluster of genes in one vertebrate chromosome (chromosome 6 in humans) that code for a set of highly polymorphic cell-surface glycoproteins (MHC proteins). (Figure 24–37)

MHC protein Cell-surface glycoprotein encoded within the major histocompatibility complex (MHC) of genes. The proteins are highly polymorphic and exist in two main classes—class I and class II MHC proteins, both of which function to present fragments of foreign proteins on the surface of antigen-presenting cells to T cells. (Chapter 24)

microbiome The combined genomes of the various species of a defined microbiota. (Chapter 23)

microbiota The collective of microorganisms that reside in or on an organism. (Chapter 23)

microelectrode A piece of fine glass tubing, pulled to an even finer tip, that is used to inject electric current into cells or to study the intracellular concentrations of common inorganic ions (such as H⁺, Na⁺, K⁺, Cl⁻, and Ca²⁺) in a single living cell by insertion of its tip directly into the cell interior through the plasma membrane. (Figure 11–36)

microRNAs (**miRNAs**) Short (~21 nucleotide) eukaryotic RNAs, produced by the processing of specialized RNA transcripts coded in the genome, that regulate gene expression through base-pairing with mRNA. (Chapters 7, 21) (Figure 7–78)

microsome Small vesicle derived from endoplasmic reticulum that is produced by fragmentation when cells are homogenized. (Chapter 12) (Figure 12–17)

microtubule flux Movement of individual tubulin molecules in the microtubules of the spindle toward the poles by loss of tubulin at their minus ends. Helps to generate the poleward movement of sister chromatids after they separate in anaphase. (Chapter 17) (Figure 17–37)

microtubule-associated protein (MAP) Any protein that binds to microtubules and modifies their properties. Many different kinds have been found, including structural proteins, such as MAP2, and motor proteins, such as dynein. [Not to be confused with the "MAP" (mitogen-activated protein) of "MAP kinase."] (Chapter 16)

microtubule-organizing center (MTOC) Region in a cell, such as a centrosome or a basal body, from which microtubules grow. (Chapter 16)

midbody Structure formed at the end of cleavage that can persist for some time as a tether between the two daughter cells in animals. (Chapter 17) (Figure 17–44)

mitochondrial hsp70 Part of a multisubunit protein assembly bound to the matrix side of the TIM23 complex that acts as a motor to pull mitochondrial precursor proteins into the matrix space. (Chapter 12)

mitochondrial matrix Large internal compartment of the mitochondrion. The corresponding compartment in a chloroplast is known as the stroma. (Chapter 14)

mitochondrial outer membrane permeabilization (MOMP) The change in the outer mitochondrial membrane that releases cytochrome *c* and other soluble proteins from the

G:22 Glossary

intermembrane space into the cytosol—a critical step in the intrinsic pathway of apoptosis. (Chapter 18)

mitochondrial precursor proteins Proteins that are first fully synthesized in the cytosol and then translocated into mitochondrial subcompartments, as directed by one or more signal sequences. (Chapter 12)

mitochondrion (plural **mitochondria**) Membrane-bounded organelle, about the size of a bacterium, that carries out oxidative phosphorylation and produces most of the ATP in eukaryotic cells. (Chapters 12, 14) (Figure 1–25)

mitogen Extracellular signal molecule that stimulates cells to proliferate. (Chapter 17)

mitotic chromosome Highly condensed duplicated chromosome as seen at mitosis, consisting of two sister chromatids held together at the centromere. (Chapter 4)

mitotic spindle Bipolar array of microtubules and associated molecules that forms in a eukaryotic cell during mitosis; it serves to position duplicated chromosomes and then segregate their sister chromatids to opposite spindle poles. (Chapter 17) (Figure 17–26 and Panel 17–1, pp. 1048–1049)

model organism A species that has been studied intensively over a long period and thus serves as a "model" for deriving fundamental biological principles. (Chapter 1)

molecular chaperone (**chaperone**) Protein that helps guide the proper folding of other proteins or helps them avoid misfolding. Includes heat-shock proteins. (Chapter 6)

monoallelic gene expression Expression of only one of the two copies of a gene in a diploid genome, occurring, for example, as a result of imprinting or X-inactivation. (Chapter 7)

monoclonal antibody Antibody secreted by a hybridoma cell line. Because the hybridoma is generated by the fusion of a single B cell with a single tumor cell, each hybridoma produces antibodies that are all identical. (Chapters 4, 8)

monocyte Type of white blood cell that leaves the bloodstream and matures into a macrophage in tissues. (Chapter 22) (Figure 22–11)

monomeric GTPase A single-subunit enzyme that converts GTP to GDP (also called monomeric GTP-binding protein). Cycles between an active GTP-bound form and an inactive GDP-bound form and frequently acts as a molecular switch in intracellular signaling pathways. (Chapter 15)

morphogen Diffusible signal molecule that can impose a pattern on a field of cells by causing cells in different places to adopt different fates. (Chapter 21) (Figure 21–8)

morphogenesis Developmental process in which cells undergo movements and deformations in order to assemble into tissues and organs with specific shapes and sizes. (Chapter 21)

motor protein Protein that uses energy derived from nucleoside triphosphate hydrolysis to propel itself along a linear track (protein filament or other polymeric molecule). (Chapter 16)

mRNA degradation control Cell regulation of gene expression by selectively preserving or destroying certain mRNA molecules in the cytoplasm. (Chapter 7)

mTOR The mammalian version of the large protein kinase called TOR, involved in cell signaling; mTOR exists in two functionally distinct multiprotein complexes. (Chapter 15)

multidrug resistance An observed phenomenon in which cells exposed to one anticancer drug evolve a resistance not

only to that drug but also to other drugs to which they have never been exposed. (Chapter 20)

multidrug resistance (MDR) protein Type of ABC transporter protein that can pump hydrophobic drugs (such as some anticancer drugs) out of the cytoplasm of eukaryotic cells. (Chapter 11)

multipass transmembrane protein Membrane protein in which the polypeptide chain crosses the lipid bilayer more than once. (Chapter 10) (Figure 10–17)

multivesicular bodies Intermediates in the endosome maturation process; early endosomes that are on their way to becoming late endosomes. (Chapter 13)

mutation Heritable change in the nucleotide sequence of a chromosome. (Chapter 1) (Panel 8–1, pp. 520–521)

mutation rate The rate at which changes (mutations) occur in DNA sequences. (Chapter 5)

mutualism Ecologic relationship between microbes and their host in which both the microbe and host benefit. (Chapter 23)

Myc Transcription regulatory protein that is activated when a cell is stimulated to grow and divide by extracellular signals. It activates the transcription of many genes, including those that stimulate cell growth. (Chapter 17) (Figure 17–59)

myelin sheath Insulating layer of specialized cell membrane wrapped around vertebrate axons. Produced by oligodendrocytes in the central nervous system and by Schwann cells in the peripheral nervous system. (Chapter 11) (Figure 11–35)

myeloid cell Any white blood cell other than a lymphocyte. (Chapter 22) (Figure 22–12)

myeloma Cancer of antibody-producing (B) cells found in bone marrow. (Chapter 20)

myoblast Mononucleated, undifferentiated muscle precursor cell. A skeletal muscle cell is formed by the fusion of multiple myoblasts. (Chapter 22)

myofibril Long, highly organized bundle of actin, myosin, and other proteins in the cytoplasm of muscle cells that contracts by a sliding filament mechanism. (Chapter 16)

myosin Type of motor protein that uses the energy of ATP hydrolysis to move along actin filaments. (Chapter 16)

Na+-K+ pump (Na+-K+ ATPase) Transmembrane carrier protein found in the plasma membrane of most animal cells that pumps Na+ out of and K+ into the cell, using energy derived from ATP hydrolysis. (Chapter 11) (Figure 11–15)

NAD+/NADH (nicotinamide adenine dinucleotide/reduced nicotinamide adenine dinucleotide) Electron carrier system that participates in oxidation-reduction reactions, such as the oxidation of food molecules. NAD+ accepts the equivalent of a hydride ion (H-, a proton plus two electrons) to become the activated carrier NADH. The NADH formed donates its high-energy electrons to the ATP-generating process of oxidative phosphorylation. (Chapter 2) (Figure 2–36)

NADH dehydrogenase complex First of the three electrondriven proton pumps in the mitochondrial respiratory chain, also known as Complex I. It accepts electrons from NADH and passes them to a quinone. (Chapter 14) (Figure 14–18)

NADP+/NADPH (nicotinamide adenine dinucleotide phosphate/reduced nicotinamide adenine dinucleotide phosphate) Electron carrier system closely related to

NAD+/NADH, but used almost exclusively in reductive biosynthetic, rather than catabolic, pathways. (Chapter 2) (Figure 2–36)

naïve cell In immunology: a T or B lymphocyte that proliferates and differentiates into an effector cell or memory cell when it encounters its specific foreign antigen for the first time. (Chapter 24) (Figure 24–17)

natural killer cell (NK cell) Cytotoxic cell of the innate immune system that can kill virus-infected cells and some cancer cells. (Chapter 24)

natural regulatory T cell (natural T_{reg} cell) A regulatory T cell (T_{reg} cell) that develops in the thymus and helps maintain self-tolerance. (Chapter 24)

negative selection Process by which thymocytes expressing a T cell receptor with high affinity for a self peptide bound to a self MHC protein are eliminated by undergoing apoptosis. (Chapter 24)

negative staining A technique in electron microscopy enabling fine detail of isolated macromolecules to be seen. Samples are prepared such that a very thin film of heavy-metal salt covers everywhere except where excluded by the presence of macromolecules, which allow electrons to pass through, creating a reverse or negative image of the molecule. (Chapter 9)

Nernst equation Equation that relates the equilibrium electrical potential (membrane potential in volts) to differences in ion concentrations across a membrane. (Chapter 11)

neural crest Collection of cells located along the line where the neural tube pinches off from the surrounding epidermis in the vertebrate embryo. Neural crest cells migrate to give rise to a variety of tissues, including neurons and glia of the peripheral nervous system, pigment cells of the skin, and the bones of the face and jaws. (Chapter 21) (Figure 19–8)

neural tube Tube of ectoderm that will form the brain and spinal cord in a vertebrate embryo. (Chapter 21)

neurofilament Type of intermediate filament found in nerve cells. (Chapter 16) (Figure 16–64)

neuromuscular junction Specialized chemical synapse between an axon terminal of a motor neuron and a skeletal muscle cell. (Chapter 11) (Figure 11–39)

neuron (nerve cell) Impulse-conducting cell of the nervous system, with extensive processes specialized to receive, conduct, and transmit signals. (Chapter 11) (Figure 11–29)

neurotransmitter Small signal molecule secreted by the presynaptic nerve cell at a chemical synapse to relay the signal to the postsynaptic cell. Examples include acetylcholine, glutamate, GABA, glycine, and many neuropeptides. (Chapters 11, 15)

neutrophil White blood cell that is specialized for the uptake of particulate material by phagocytosis. Enters tissues that become infected or inflamed. (Chapter 13) (Figure 24–5)

NFκB protein Latent transcription regulator that is activated by various intracellular signaling pathways when cells are stimulated during immune, inflammatory, or stress responses. Also has important roles in animal development. (Chapter 15) (Figure 15–63)

nitric oxide (NO) Gaseous signal molecule that is widely used in cell-cell communication in both animals and plants. (Chapter 15) (Figure 15–41)

 $\begin{array}{ll} \textbf{nitrogen fixation} & \text{Biochemical process carried out by certain} \\ \text{bacteria that reduces atmospheric nitrogen } (N_2) \text{ to ammonia,} \\ \end{array}$

leading eventually to various nitrogen-containing metabolites. (Chapter 2)

NMDA receptor Subclass of glutamate-gated ion channel in the mammalian central nervous system critical for long-term potentiation and long-term depression. NMDA-receptor channels are doubly gated, opening only when glutamate is bound to the receptor and, simultaneously, the membrane is strongly depolarized. (Chapter 11)

NO synthase (NOS) Enzyme that synthesizes nitric oxide (NO) by the deamination of arginine. (Chapter 15) (Figure 15–41B)

NOD-like receptors (NLRs) Large family of pattern recognition receptors (PRRs) with leucine-rich repeat motifs; they are exclusively cytoplasmic and recognize a distinct set of microbial molecules. (Chapter 24)

nonclassical cadherins Large family of cadherins that are more distantly related in sequence than classical cadherins and include proteins involved in adhesion (including protocadherins, desmocollins, and desmogleins) and signaling. (Chapter 19)

noncoding RNA An RNA molecule that is the final product of a gene and does not code for protein. These RNAs serve as enzymatic, structural, and regulatory components for a wide variety of processes in the cell. (Chapter 6)

noncovalent bond Weak bonds that require multiple sets to hold two molecules together. Includes hydrogen bonds, electrostatic attractions, and van der Waals attractions. (Chapter 2)

nondisjunction Event occurring occasionally during meiosis in which a pair of homologous chromosomes fails to separate so that the resulting germ cell has either too many or too few chromosomes. (Chapter 17)

nonenveloped virus Virus consisting of a nucleic acid core and a protein capsid only. (Chapter 23) (Figure 23–19C and D)

nonhomologous end joining A DNA repair mechanism for rejoining the ends at double-strand breaks in which the two broken ends of DNA are brought together and rejoined by DNA ligation, generally with the loss of one or more nucleotides at the site of joining. (Chapter 5)

non-kinetochore microtubule In the mitotic or meiotic spindle, a microtubule that forms between the spindle poles and is not attached directly to kinetochores; it can cross-link at the spindle equator with an antiparallel microtubule from the other pole. Also called interpolar microtubule. (Chapter 17)

nonretroviral retrotransposon A type of transposable element that moves by being first transcribed into an RNA copy that is converted to DNA by reverse transcriptase and then inserted elsewhere in the genome. Its mechanism of insertion differs from that of the retroviral-like transposons. (Chapter 5) (Table 5–4, p. 308)

nonsense-mediated mRNA decay Mechanism for degrading aberrant mRNAs containing in-frame internal stop codons before they can be translated into protein. (Chapter 6) (Figure 6–80)

Notch Transmembrane receptor protein (and latent transcription regulator) involved in many cell-fate choices in animal development, for example in the specification of nerve cells from ectodermal epithelium. Its ligands are cell-surface proteins such as Delta and Serrate. (Chapter 15) (Figure 15–60)

NSF Hexameric ATPase that disassembles a complex of a v-SNARE and a t-SNARE. (Chapter 13) (Figure 13–21)

G:24 Glossary

nuclear envelope The double membrane (two bilayers) surrounding the nucleus. Consists of an outer and inner membrane and is perforated by nuclear pores. The outer membrane is continuous with the endoplasmic reticulum. (Chapter 12) (Figures 4–10 and 12–54)

nuclear export receptors Proteins that bind to both the export signal and nuclear pore complex proteins, so as to guide their cargo through the nuclear pore complex to the cytosol. (Chapter 12)

nuclear export signal Sorting signal contained in the structure of those protein molecules and RNA–protein complexes that are to be transported from the nucleus to the cytosol through nuclear pore complexes; includes nuclear RNPs and new ribosomal subunits. (Chapter 12) (Figure 12–61)

nuclear import receptors Proteins that recognize nuclear localization signals to initiate the nuclear import of proteins containing the appropriate nuclear localization signal. (Chapter 12)

nuclear lamin Protein subunit of the intermediate filaments that form the nuclear lamina. (Chapter 12)

nuclear lamina Fibrous meshwork of proteins on the inner surface of the inner nuclear membrane. It is made up of a network of intermediate filaments formed from nuclear lamins. (Chapter 12)

nuclear localization signal (NLS) Signal sequence or signal patch found in proteins destined for the nucleus that enables their selective transport into the nucleus from the cytosol through the nuclear pore complexes. (Chapter 12) (Figures 12–56 and 12–61)

nuclear magnetic resonance (NMR) spectroscopy NMR is the resonant absorption of electromagnetic radiation at a specific frequency by atomic nuclei in a magnetic field, due to flipping of the orientation of their magnetic dipole moments. The NMR spectrum provides information about the chemical environment of the nuclei. NMR is used widely to determine the three-dimensional structure of small proteins and other small molecules. The principles of NMR are also used for medical diagnostic purposes in magnetic resonance imaging (MRI). (Chapter 8) (Figure 8–21)

nuclear pore complex (NPC) Large multiprotein structure forming an aqueous channel (the nuclear pore) through the nuclear envelope; it allows selected molecules to move between nucleus and cytoplasm. (Chapters 6, 12) (Figure 12–55)

nuclear receptor superfamily Intracellular receptors for hydrophobic signal molecules such as steroid and thyroid hormones and retinoic acid. The receptor–ligand complex acts as a transcription factor in the nucleus. (Chapter 15) (Figure 15–66)

nuclear transport The process by which cargo molecules are moved into and out of the nucleus through nuclear pore complexes. (Chapter 12)

nuclear transport receptor (karyopherin) Protein that escorts macromolecules either into or out of the nucleus: nuclear import receptor or nuclear export receptor. (Chapter 12) (Figure 12–61)

nucleolus A prominent structure in the nucleus where rRNA is transcribed and ribosomal subunits are assembled. (Figures 6–44 and 6–46)

nucleoporin Any of a number of different proteins that make up nuclear pore complexes. (Chapter 12)

nucleosome Beadlike structure in eukaryotic chromatin, composed of a short length of DNA wrapped around an octameric core of histone proteins. The fundamental structural unit of chromatin. (Chapter 4) (Figures 4–22 and 4–23)

nucleotide Nucleoside with a phosphate group joined in ester linkage to the sugar moiety. DNA and RNA are polymers of nucleotides. (Chapter 1) (Panel 2–6, pp. 104–105)

nucleotide excision repair Type of DNA repair that corrects irreversible damage of the DNA double helix, such as that caused by certain chemicals or UV light, by cutting out the damaged region on one strand and resynthesizing it using the undamaged strand as template. *Compare* **base excision repair**. (Chapter 5) (Figure 5–41)

O-linked glycosylation Addition of one or more sugars to a hydroxyl group on a protein. (Chapter 13)

obligate pathogens Bacteria that can only replicate inside their host. (Chapter 23)

olfactory receptors G-protein-coupled receptors on the modified cilia of olfactory receptor neurons that recognize odors. The receptors activate adenylyl cyclase via an olfactory-specific G protein (Golf), and resultant increases in cAMP open cyclic-AMP-gated cation channels, allowing Na⁺ influx and depolarization and initiation of a nerve impulse. (Chapter 15)

oligodendrocyte Glial cell in the vertebrate central nervous system that forms a myelin sheath around axons. *Compare* **Schwann cell**. (Chapter 11)

oligosaccharyl transferase Endoplasmic reticulum (ER) enzyme complex that transfers core oligosaccharides from dolichol lipid anchors to selected asparagine side chains in newly synthesized proteins as they enter the ER lumen. (Chapter 12)

oncogene An altered gene whose product can act in a dominant fashion to help make a cell cancerous. Typically, an oncogene is a mutant form of a normal gene (proto-oncogene) involved in the control of cell growth or division. (Chapter 20) (Figure 20–21)

open reading frame (ORF) A continuous nucleotide sequence free from stop codons in at least one of the three reading frames (and thus with the potential to code for protein). (Chapters 7, 8)

opportunistic pathogens Microbes of the normal flora that can cause disease only if the immune systems are weakened or if they gain access to a normally sterile part of the body. (Chapter 23)

optogenetics Use of genetically engineered channelrhodopsin and other light-responsive ion channels and transporters to modulate neuron function and hence analyze the neurons and circuits underlying complex functions, including behaviors in whole animals. (Chapter 11) (Figure 11–47)

organelle Subcellular compartment or large macromolecular complex, often but not always membrane-enclosed, that has a distinct structure, composition, and function. Examples of membrane-enclosed organelles are the nucleus, mitochondrion, ER, and Golgi apparatus; examples of organelles that form as biomolecular condensates and lack a membrane are the nucleolus and centrosomes. (Chapters 1, 12) (Figure 1–21)

organelle contact site Region of contact between two organelles stabilized by specific tethering proteins. (Chapter 12)

Organizer Specialized tissue at the dorsal lip of the blastopore in an amphibian embryo; a source of signals that

help to orchestrate formation of the embryonic body axis. (Chapter 21)

organoid A miniaturized and simplified organ produced in three-dimensional cell culture that possesses realistic microanatomy. (Chapter 22)

origin recognition complex (ORC) Large protein complex that is bound to the DNA at origins of replication in eukaryotic chromosomes throughout the cell cycle. (Chapters 5, 17) (Figure 5–31)

orthologs Genes or proteins from different species that are similar in sequence because they are descendants of the same gene in the last common ancestor of those species; orthologs often have the same or a very similar function in each organism. *Compare* **paralogs**. (Chapter 1) (Figure 1–20)

outer mitochondrial membrane The mitochondrial membrane that separates the organelle from the cytosol; surrounds the inner mitochondrial membrane. (Chapters 12, 14)

outer nuclear membrane One of two concentric membranes comprising the nuclear envelope; surrounds the inner nuclear membrane and is continuous with the inner nuclear membrane and the membrane of the endoplasmic reticulum. (Chapter 12)

OXA complex Protein translocator in the inner mitochondrial membrane that mediates insertion of inner membrane proteins. (Chapter 12)

oxidation (verb **oxidize**) Loss of electrons from an atom, as occurs during the addition of oxygen to a molecule or when a hydrogen is removed. Opposite of reduction. (Chapter 2) (Figure 2–20)

oxidative phosphorylation Process in bacteria and mitochondria in which ATP formation is driven by the transfer of electrons through an electron-transport chain to molecular oxygen. Involves the intermediate generation of an electrochemical proton gradient across a membrane and a chemiosmotic coupling of that gradient to drive ATP production by the ATP synthase. (Chapters 2, 14) (Figure 14–12)

P-type pumps A class of ATP-driven pumps comprising structurally and functionally related multipass transmembrane proteins that phosphorylate themselves during the pumping cycle. The class includes many of the ion pumps responsible for setting up and maintaining gradients of Na⁺, K⁺, H⁺, and Ca²⁺ across cell membranes. (Chapter 11) (Figure 11–12)

p53 A transcription regulatory protein that is activated by damage to DNA and is involved in blocking further progression through the cell cycle until the damage can be repaired. The *p53* gene is a tumor suppressor gene that is mutated in about half of human cancers. (Chapters 17, 20) (Figure 20–31)

pair-rule gene In *Drosophila* development, a gene expressed in a series of regular transverse stripes along the body of the embryo and which helps to determine its segments. (Chapter 21) (Figure 21–18)

pairing In meiosis, the lining up of the two homologous chromosomes along their length. (Chapter 17) (Figure 17–53)

pancreatic β cell Insulin-secreting cells of the pancreas. (Chapter 22)

papillomaviruses Class of viruses responsible for human warts and a prime example of DNA tumor viruses, being a cause of cancer of the uterine cervix. (Chapter 20)

paracrine signaling Short-range cell-cell communication via secreted signal molecules that act on neighboring cells. (Chapter 15) (Figure 15–2)

paralogs Genes or proteins that are similar in sequence because they are the result of a gene duplication event occurring in an ancestral organism. Those in two different organisms are less likely to have the same function than are orthologs. *Compare* **orthologs**. (Chapter 1) (Figure 1–20)

parasitism Ecologic relationship between microbes and their host in which the microbe benefits to the detriment of the host, as is often the case for pathogens. (Chapter 23)

passenger mutations Mutations that have occurred in the same cell as driver mutations, but which are irrelevant to the development of the cancer. (Chapter 20)

passive transport (facilitated diffusion) Transport of a solute across a membrane down its concentration gradient or its electrochemical gradient, using only the energy stored in the gradient. (Chapter 11) (Figure 11–4)

patch-clamp recording Electrophysiological technique in which a tiny electrode tip is sealed onto a patch of cell membrane, thereby making it possible to record the flow of current through individual ion channels in the patch. (Chapter 11) (Figure 11–36)

Patched Transmembrane protein predicted to cross the plasma membrane 12 times; located both in intracellular vesicles and on the cell surface where it binds the Hedgehog protein. (Chapter 15)

pathogen (adjective **pathogenic**) An organism, cell, virus, or prion that causes disease. (Chapters 23, 24)

pathogen-associated molecular patterns (PAMPs) Microbe-associated molecules, either not present or kept sequestered in the host organism, that often occur in a repeating pattern that is recognized by pattern recognition receptors (PRRs) of the innate immune system. PAMPs can be present in various microbial molecules, including nucleic acids, lipids, polysaccharides, and proteins. (Chapter 24)

pattern recognition receptor (PRR) Receptor present on or in cells of the innate immune system that recognizes and is activated by microbial pathogen-associated molecular patterns (PAMPs). (Chapter 24)

PDZ domain Protein-binding domain present in many scaffold proteins and often used as a docking site for the intracellular tails of transmembrane proteins. (Chapter 19) (Figure 19–22)

pectin Mixture of polysaccharides rich in galacturonic acid that forms a highly hydrated matrix in which cellulose is embedded in plant cell walls. (Chapter 19) (Figure 19–64)

peripheral (**secondary**) **lymphoid organ** Lymphoid organ in which T cells and B cells interact and respond to foreign antigens. Examples are spleen, lymph nodes, and mucosal-associated lymphoid organs. (Chapter 24) (Figure 24–12)

peroxins The proteins that form a protein translocator that participates in the import of proteins into peroxisomes. (Chapter 12)

peroxisome Small membrane-bounded organelle that uses molecular oxygen to oxidize organic molecules. Contains some enzymes that produce and others that degrade hydrogen peroxide (H₂O₂). (Chapter 12) (Figure 12–43)

pH scale Common measure of the acidity of a solution: "p" refers to power of 10, "H" to hydrogen. Defined as the negative logarithm of the hydrogen ion concentration in moles per liter (M). $pH = -log[H^+]$. Thus a solution of pH 3 will contain 10^{-3} M hydrogen ions. pH less than 7 is acidic and pH greater than 7 is alkaline. (Chapter 2)

phagocytosis Process by which unwanted cells, debris, and other bulky particulate material is endocytosed ("eaten") by a cell. Prominent in carnivorous cells, such as *Amoeba proteus*, and in vertebrate macrophages and neutrophils. From Greek *phagein*, "to eat." (Chapter 13)

phagosome Large intracellular membrane-enclosed vesicle that is formed as a result of phagocytosis. Contains ingested extracellular material. (Chapter 13) (Figure 13–70)

phase-contrast microscope Type of light microscope that exploits the interference effects that occur when light passes through material of different refractive indices. Used to view living cells. (Chapter 9) (Figure 9–6)

phase variation The random switching of phenotype of an infectious agent that is caused by changes in expression of proteins at frequencies much higher than mutation rates. (Chapter 5)

phenotype The observable character (including both physical appearance and behavior) of a cell or organism. (Chapter 8) (Panel 8–1, pp. 520–521)

phosphatidylinositol 4,5-bisphosphate [Pl(4,5)P₂, PIP₂] Membrane inositol phospholipid (a phosphoinositide) that is cleaved by phospholipase C into IP₃ and diacylglycerol at the beginning of the inositol phospholipid signaling pathway. It can also be phosphorylated by Pl 3-kinase to produce PIP₃ docking sites for signaling proteins in the Pl-3-kinase–Akt signaling pathway. (Chapter 15) (Figures 15–28 and 15–54)

phosphatidylserine Negatively charged phospholipid that is normally confined to the cytosolic leaflet of the lipid bilayer of the plasma membrane; in apoptotic cells, it accumulates in the outer leaflet, where it serves as an "eat me" signal to neighboring phagocytic cells. (Chapter 18)

phosphoinositide A lipid containing a phosphorylated inositol derivative. Minor component of the plasma membrane, but important in demarking different membranes and for intracellular signal transduction in eukaryotic cells. (Chapter 15) (Figure 15–53)

phosphoinositide 3-kinase (PI 3-kinase) Membrane-bound enzyme that is a component of the PI-3-kinase–Akt intracellular signaling pathway. It phosphorylates phosphatidylinositol 4,5-bisphosphate at the 3 position on the inositol ring to produce PIP₃ docking sites in the membrane for other intracellular signaling proteins. (Chapter 15) (Figure 15–54)

phosphoinositides (phosphatidylinositol phosphates, or PIPs) A lipid containing a phosphorylated inositol derivative. Minor component of the plasma membrane, but important in demarking different membranes and for intracellular signal transduction in eukaryotic cells. (Chapter 13) (Figure 13–10)

phospholipase C (PLC) Membrane-bound enzyme that cleaves inositol phospholipids to produce IP $_3$ and diacylglycerol in the inositol phospholipid signaling pathway. PLC $_3$ is activated by GPCRs via specific G proteins, while PLC $_3$ is activated by RTKs. (Chapter 15) (Figure 15–56)

phospholipid The main category of lipids used to construct biomembranes. Generally composed of two fatty acids linked through glycerol (or sphingosine) phosphate to one of a variety of polar groups. (Chapter 10) (Figure 10–3 and Panel 2–5, pp. 102–103)

phosphorylation Reaction in which a phosphate group is covalently coupled to another molecule. (Chapters 2, 3, 15)

photoactivation Technique for studying intracellular processes in which an inactive form of a molecule of interest

is introduced into the cell and is then activated by a focused beam of light at a precise spot in the cell. (Chapter 9)

photochemical reaction center The part of a photosystem that converts light energy into chemical energy in photosynthesis. (Chapter 14) (Figure 14–46)

photorespiration A wasteful form of metabolism conducted by photosynthetic plants in low CO_2 environments that consumes O_2 and liberates CO_2 , but does not result in the production of an energy carrier useful to the plant. (Chapter 14)

photosynthetic electron-transfer reactions Light-driven reactions in photosynthesis in which electrons move along an electron-transport chain in a membrane, generating ATP and NADPH. (Chapter 14)

photosystem Multiprotein complex involved in photosynthesis that captures the energy of sunlight and converts it to useful forms of energy: a reaction center plus an antenna (Chapter 14) (Figure 14–46)

phototropin Photoprotein associated with the plant plasma membrane that senses blue light and is partly responsible for phototropism. (Chapter 15)

phragmoplast Structure made of microtubules and actin filaments that forms in the prospective plane of division of a plant cell and guides formation of the cell plate. (Chapter 17) (Figure 17–48)

phytochrome Plant photoprotein that senses light via a covalently attached light-absorbing chromophore, which changes its shape in response to light and then induces a change in the protein's conformation. Plant phytochromes are cytoplasmic serine/threonine kinases, which respond differentially and reversibly to red and far-red light to alter cell behavior. (Chapter 15)

PI-3-kinase–Akt pathway Intracellular signaling pathway that stimulates animal cells to survive and grow. (Chapter 15) (Figure 15–54)

pinocytosis Literally, "cell drinking." Type of endocytosis in which soluble materials are continually taken up from the environment in small vesicles and moved into endosomes along with the membrane-bound molecules. *Compare* **phagocytosis**. (Chapter 13) (Figure 13–51)

piRNAs (**piwi-interacting RNAs**) A class of small noncoding RNAs made in the germ line that, in complex with Piwi proteins, keep the movement of transposable elements in check by transcriptionally silencing transposon genes and destroying RNAs produced by them. (Chapter 7)

planar cell polarity Type of cellular asymmetry seen in some epithelia, such that each cell has a polarity vector oriented in the plane of the epithelium. (Chapter 21) (Figure 21–50)

plant growth regulator (**plant hormone**) Signal molecule that helps coordinate growth and development. Examples are ethylene, auxins, gibberellins, cytokinins, abscisic acid, and the brassinosteroids. (Chapter 15)

plasma membrane The membrane that surrounds a living cell. (Chapters 1, 10) (Figure 10–1)

plasmid vector Small, circular molecules of double-stranded DNA that have been derived from plasmids that occur naturally in bacterial cells; widely used for gene cloning. (Chapter 8)

plasmodesma (plural **plasmodesmata**) Plant equivalent of a gap junction. Communicating cell–cell junction in plants in which a channel of cytoplasm lined by plasma membrane

connects two adjacent cells through a small pore in their cell walls. (Chapter 19)

platelet Cell fragment, lacking a nucleus, that breaks off from a megakaryocyte in the bone marrow and is found in large numbers in the bloodstream. Helps initiate blood clotting when blood vessels are injured. (Figure 22–12)

pleckstrin homology domain (**PH domain**) Protein domain found in some intracellular signaling proteins. Some PH domains in intracellular signaling proteins bind to phosphatidylinositol 3,4,5-trisphosphate produced by PI 3-kinase, bringing the signaling protein to the plasma membrane when PI 3-kinase is activated. (Chapter 15)

pluripotent Describes a cell that has the potential to give rise to all or almost all of the cell types of the adult body. (Chapters 21, 22)

podosomes Actin-rich protrusive and adhesive structures on the cell surface important for crossing tissue barriers. (Chapter 16)

point spread function The distribution of light intensity within the three-dimensional, blurred image that is formed when a single point source of light is brought to a focus with a lens. (Chapter 9)

polarized In epithelia, the fact that the basal end of a cell, adherent to the basal lamina below, differs from the apical end, exposed to the medium above; thus, all epithelia and their individual cells are structurally polarized. (Chapter 19)

Polycomb group Set of proteins critical for cell memory for some genes. They form complexes as part of the chromatin of the *Hox* complex, where they maintain a repressed state in cells where *Hox* genes have not been activated. (Chapters 4, 21) (Figure 4–40)

polymerase chain reaction (PCR) Technique for amplifying specific regions of DNA by the use of sequence-specific primers and multiple cycles of DNA synthesis, each cycle being followed by a brief heat treatment to separate complementary strands. (Chapter 8) (Figure 8–34)

polymorphisms Describes genome sequences that coexist as two or more sequence variants at high frequency in a population. (Chapter 8)

polypeptide Linear polymer of amino acids. Proteins are large polypeptides, and the two terms can be used interchangeably. (Figure 3–1)

 $\begin{array}{ll} \textbf{polypeptide backbone} & \text{Repeating sequence of atoms along} \\ \text{the core of the polypeptide chain. (Figure 3-1)} \end{array}$

 ${\bf polyribosome}\ \ {\rm mRNA}\ {\rm engaged}\ {\rm with}\ {\rm multiple}\ {\rm ribosomes}\ {\rm in}\ {\rm the}$ act of translation. (Figure 6–77)

polytene chromosome Giant chromosome in which the DNA has undergone repeated replication and the many copies have stayed together in precise alignment. (Chapter 4) (Figures 4–47 and 4–48)

porins Channel-forming proteins of the outer membranes of bacteria, mitochondria, and chloroplasts. (Chapter 12)

position effect variegation Alteration in gene expression resulting from a change in the position of the gene on a chromosome, caused by the spread of neighboring heterochromatic domains. When an active gene is placed next to heterochromatin, the inactivating influence of the heterochromatin can spread to affect the gene to a variable degree, giving rise to a variegated phenotype. (Figure 4–32)

positional value A cell's internal record of its positional information in a multicellular organism; an intrinsic character that differs according to a cell's location. (Chapter 21)

positive feedback Control mechanism whereby the end product of a reaction or pathway stimulates its own production or activation. (Figure 7–42)

positive selection In immunology: a process of thymocyte maturation in which thymocytes expressing a T cell receptor with appropriate affinity for a self peptide bound to a self MHC protein is signaled to survive and continue development. (Chapter 24)

post-transcriptional controls Any control on gene expression that is exerted at a stage after transcription has begun. (Chapter 7) (Figure 7–57)

post-translational Occurring after completion of translation, thus after the completion of protein synthesis. (Chapter 12)

preprophase band Circumferential band of microtubules and actin filaments that forms around a plant cell under the plasma membrane prior to mitosis and cell division. (Chapter 17) (Figure 17–48)

primary cell wall The first cell wall produced by a developing plant cell; it is thin and flexible, allowing room for cell growth. (Chapter 19) (Figure 19–64)

primary cilium Short, single, nonmotile cilium lacking dynein that arises from a centriole and projects from the surface of many animal cell types. Involved in cell signaling, with some signaling proteins being concentrated in these (Chapter 15) (Figure 15–39)

primary Ig repertoire The billions of IgM and IgD immunoglobulin molecules made by the B cells of an adaptive immune system in the absence of antigen stimulation. (Chapter 24)

primary immune response Adaptive immune response to an antigen that is made on first encounter with that antigen. (Chapter 24) (Figure 24–16)

primary pathogens Pathogens that can cause overt disease in most healthy people. Some cause acute, life-threatening epidemic infections and spread rapidly between hosts; other potential primary pathogens may persistently infect a single individual for years without causing overt disease, the host often being unaware of being infected. (Chapter 23)

primary structure Linear sequence of monomer units in a polymer, such as the amino acid sequence of a protein. (Chapter 3)

primary tumor Tumor at the original site at which a cancer first arose. Secondary tumors develop elsewhere by metastasis. (Chapter 20)

prion disease Transmissible spongiform encephalopathy—such as kuru and Creutzfeldt–Jakob disease (CJD) in humans, scrapie in sheep, and bovine spongiform encephalopathy (BSE, or "mad cow disease") in cows—that is caused and transmitted by an infectious, abnormally folded protein (prion). (Figure 3–33)

pro-apoptotic Bcl2 family effectors Pro-apoptotic proteins of the intrinsic pathway of apoptosis that in response to an apoptotic stimulus become activated and aggregate to form oligomers in the mitochondrial outer membrane, inducing the release of cytochrome *c* and other intermembrane proteins. Bax and Bak are the main effector Bcl2 family proteins in mammalian cells. (Chapter 18)

pro-inflammatory cytokine Any cytokine that stimulates an inflammatory response. (Chapter 24)

prokaryote Single-celled microorganism whose cells lack a well-defined, membrane-enclosed nucleus. Either a bacterium or an archaeon. (Chapter 1) (Figure 1–9)

promoter Nucleotide sequence in DNA to which RNA polymerase binds to begin transcription. (Chapters 6, 7) (Figure 6–11)

prophase The initial stage of mitosis, during which the chromosomes condense and the mitotic spindle begins to assemble outside of the nucleus. It is followed by prometaphase—where the nuclear envelope disassembles, and the microtubules from each spindle pole engage with the chromosomes. (Panel 17–1, pp. 1048–1049)

proteasome Large protein complex in the cytosol with proteolytic activity that is responsible for degrading proteins that have been marked for destruction by ubiquitylation or by some other means. (Chapter 6) (Figures 6–86 and 6–87)

protein The major macromolecular constituent of cells. A linear polymer of amino acids linked together by peptide bonds in a specific sequence. (Chapters 1, 3) (Figure 3–1)

protein activity control The selective activation, inactivation, degradation, or compartmentalization of specific proteins after they have been made. One of the means by which a cell controls which proteins are active at a given time or location in the cell. (Chapter 7)

protein degradation control The means by which the concentration of a protein in the cell can be reduced by selectively degrading it in response to external signals or to stages of the cell division cycle. (Chapter 7)

protein domain See domain. (Chapter 3)

protein glycosylation The process of transferring either a single saccharide or a preformed precursor oligosaccharide to proteins. (Chapter 12)

protein kinase Enzyme that transfers the terminal phosphate group of ATP to one or more specific amino acids (serine, threonine, or tyrosine) of a target protein. (Chapters 3, 15)

protein kinase C (PKC) Ca²⁺-dependent protein kinase that, when activated by diacylglycerol and an increase in the concentration of cytosolic Ca²⁺, phosphorylates target proteins on specific serine and threonine residues. (Chapter 15) (Figure 15–30)

protein phosphatase Enzyme that catalyzes phosphate removal from amino acids of a target protein. (Chapters 3, 15)

protein phosphatase 2A (PP2A) Protein phosphatase, composed of three subunits, that dephosphorylates Cdk substrates and thereby helps to govern cell-cycle progression. (Chapter 17)

protein phosphorylation The covalent addition of a phosphate group to a serine, threonine, or tyrosine side chain of a protein. (Chapter 3)

protein subunit An individual protein chain in a protein composed of more than one chain. (Chapter 3)

protein translocation The process of moving a protein across a membrane. (Chapter 12)

protein translocator Any membrane-bound protein that mediates the transport of another protein across a membrane. (Chapter 12) (Figure 12–48)

protein tyrosine phosphatase Enzyme that removes phosphate groups from phosphorylated tyrosine residues on proteins. (Chapter 15)

proteoglycan Molecule consisting of one or more glycosaminoglycan chains attached to a core protein. (Chapters 13, 19) (Figure 19–36)

proto-oncogene Normal gene, usually concerned with the regulation of cell proliferation, that can be converted into a cancer-promoting oncogene by mutation. (Chapter 20)

protofilament Linear string of subunits joined end to end; multiple protofilaments associate with one another laterally to construct and provide strength and adaptability to microtubules. (Chapter 16)

proton (H⁺) Positively charged subatomic particle that forms part of an atomic nucleus. Hydrogen has a nucleus composed of a single proton (H⁺). (Chapter 2)

proton-motive force The force exerted by the electrochemical proton gradient that moves protons across a membrane. (Chapter 14)

protozoan parasite Parasitic, nonphotosynthetic, singlecelled, motile eukaryotic organism; for example, *Plasmodium*. (Chapter 23)

pseudogene Nucleotide sequence of DNA that has accumulated multiple mutations that have rendered an ancestral gene inactive and nonfunctional. (Chapter 4)

pseudopodia Three-dimensional actin-based protrusions at the leading edge of rapidly migrating cells. (Chapter 16)

purified cell-free system Fractionated cell homogenate that retains a particular biological function of the intact cell, and in which biochemical reactions and cell processes can be most easily studied. (Chapter 8)

purifying selection Natural selection operating in a population to slow genome changes and reduce divergence by eliminating individuals carrying deleterious mutations. (Chapter 4)

Q cycle The cyclic series of reactions that allow the quinone (Q) electron carrier to transfer an electron to the cytochrome *c* reductase complex and then recapture it, in order to pump two rather than one proton per electron across the membrane in a respiratory system; a similar Q cycle occurs as part of the electron transfers critical for photosynthesis. (Figure 14–23)

quantitative RT-PCR (reverse transcription–polymerase chain reaction) Technique in which a population of mRNAs is converted into cDNAs via reverse transcription, and the cDNAs are then amplified by PCR. The quantitative part relies on a direct relationship between the rate at which the PCR product is generated and the original concentration of the mRNA species of interest. Widely used for detecting viral infection. (Chapter 8)

quaternary structure Three-dimensional relationship of the different polypeptide chains in a multisubunit protein or protein complex. (Chapter 3)

quinone (Q) Small, lipid-soluble, mobile electron carrier molecule found in the respiratory and photosynthetic electron-transport chains. (Chapter 14) (Figure 14–17)

Rab cascade An ordered recruitment of sequentially acting Rab proteins into Rab domains on membranes, which changes the identity of an organelle and determines membrane dynamics. (Chapter 13)

Rab effectors Molecules that bind activated, membranebound Rab proteins and act as downstream mediators of vesicle transport, membrane tethering, and fusion. (Chapter 13)

Rab proteins Monomeric GTPases in the Ras superfamily present in plasma and organelle membranes in their

GTP-bound state and as soluble cytosolic proteins in their GDP-bound state. Involved in conferring specificity on vesicle docking. (Chapter 13) (Table 15–5, p. 915)

Rac (Rac protein) Member of the Rho family of monomeric GTPases that regulate the actin and microtubule cytoskeletons, cell-cycle progression, gene transcription, and membrane transport. (Chapter 15)

Rad51 protein Eukaryotic protein that catalyzes the pairing of homologous DNA strands during recombination and repair processes . Analogous to the RecA protein in *E. coli* and other bacteria. (Chapter 5)

Ran (Ran protein) Monomeric GTPase of the Ras superfamily present in both cytosol and nucleus. It is required for the active transport of macromolecules into and out of the nucleus through nuclear pore complexes. (Chapter 12) (Table 15–5, p. 915)

rapidly inactivating K $^+$ **channel** Neuronal voltage-gated K $^+$ channel, open when the membrane is depolarized, with a specific voltage sensitivity and kinetics of inactivation that induce a reduced rate of action potential firing at levels of stimulation only just above the threshold required, thereby resulting in a firing rate proportional to the strength of the depolarizing stimulus. (Chapter 11)

Ras A small family of proto-oncogenes that are frequently mutated in cancers, each of which produces a Ras monomeric GTPase. (Chapter 20)

Ras (Ras protein) Monomeric GTPase of the Ras superfamily that helps to relay signals from cell-surface receptor tyrosine kinase receptors to the nucleus, frequently in response to signals that stimulate cell division. Named for the *Ras* gene, first identified in viruses that cause rat sarcomas. (Chapters 3, 15, 17) (Figure 3–64)

Ras GAPs Ras GTPase-activating proteins; increase the rate of hydrolysis of bound GTP by Ras, thereby inactivating Ras. (Chapter 15)

Ras GEFs Ras guanine nucleotide exchange factors; stimulate the dissociation of GDP and the subsequent uptake of GTP from the cytosol, thereby activating Ras. (Chapter 15)

Ras–MAP-kinase signaling pathway Intracellular signaling pathway that relays signals from activated receptor tyrosine kinases to effector proteins in the cell, including transcription regulators in the nucleus. (Chapter 15)

Ras superfamily Large superfamily of monomeric GTPases (also called small GTP-binding proteins) of which Ras is the prototypical member. (Chapter 15) (Table 15–5, p. 915)

Rb A cell-cycle control protein that inhibits E2F transcription regulatory proteins and entry into S phase of the cell cycle. The *Rb* gene is a tumor suppressor that is defective in both copies in individuals with retinoblastoma. (Chapter 20) (Figures 17–59 and 20–24)

reading frame The phase in which nucleotides are read in sets of three to encode a protein. An mRNA molecule can be read in any one of three reading frames, only one of which will give the required protein. (Chapter 6) (Figure 6–53)

RecA protein Prototype for a ubiquitous class of DNA-binding proteins that catalyze synapsis of DNA strands during genetic recombination in bacteria; analogous to Rad51 protein in eukaryotes. (Chapter 5) (Figure 5–48)

receptor Any protein that binds a specific signal molecule (ligand) and initiates a response in the cell. Some are on the

cell surface, while others are inside the cell. (Chapter 15) (Figure 15–3)

receptor editing Process by which a developing B cell that recognizes a self molecule changes its antigen receptors so that the cell no longer does so. (Chapter 24)

receptor-mediated endocytosis Internalization of receptor-ligand complexes from the plasma membrane by endocytosis, a type of receptor down-regulation. (Chapter 13) (Figure 13–54)

receptor serine/threonine kinase Cell-surface receptor with an extracellular ligand-binding domain and an intracellular kinase domain that phosphorylates signaling proteins on serine or threonine residues in response to ligand binding. The TGF receptor is an example. (Chapter 15) (Figure 15–58)

receptor tyrosine kinase (RTK) Cell-surface receptor with an extracellular ligand-binding domain and an intracellular kinase domain that phosphorylates signaling proteins on tyrosine residues in response to ligand binding. (Chapter 15) (Figure 15–44 and Table 15–4, p. 911)

recombinant DNA technology Collection of techniques by which DNA segments from different sources are combined to make a new DNA, often called a recombinant DNA. Recombinant DNAs are widely used in the cloning of genes, in the genetic modification of organisms, and in the production of large amounts of rare proteins. (Chapter 8)

recycling endosome Organelle that provides an intermediate stage on the passage of recycled receptors back to the cell membrane. Regulates plasma membrane insertion of some proteins. (Chapter 13) (Figure 13–56)

red blood cell Small hemoglobin-containing blood cell of vertebrates that transports oxygen to, and carbon dioxide from, tissues. Also called an erythrocyte. (Figures 22–11 and 22–12)

redox pair Pair of molecules in which one acts as an electron donor and one as an electron acceptor in an oxidation–reduction reaction; for example, NADH (electron donor) and NAD⁺ (electron acceptor). (Panel 14–1, p. 825)

redox potential The affinity of a redox pair for electrons, generally measured as the voltage difference between an equimolar mixture of the pair and a standard reference. NADH/ NAD $^+$ has a low redox potential, and O $_2$ /H $_2$ has a high redox potential (high affinity for electrons). (Panel 14–1, p. 825)

redox reaction Reaction in which one component becomes oxidized and the other reduced; an oxidation–reduction reaction. (Chapter 14) (Panel 14–1, p. 825)

reduction (verb **reduce**) Addition of electrons to an atom, as occurs during the addition of hydrogen to a biological molecule or the removal of oxygen from it. Opposite of oxidation. (Chapter 2) (Figure 2–20)

regulated secretory pathway A secretory pathway found mainly in cells specialized for secreting products rapidly on demand—such as hormones, neurotransmitters, or digestive enzymes—in which soluble proteins and other substances are initially stored in secretory vesicles for later release. (Chapter 13) (Figure 13–38)

regulator of G protein signaling (RGS) A type of GAP protein that binds to a trimeric G protein and enhances its GTPase activity, thus helping to limit G-protein-mediated signaling. (Chapter 15) (Figure 15–8)

regulatory site Region of an enzyme surface to which a regulatory molecule binds and thereby influences the catalytic events at the separate active site. (Chapter 3)

regulatory T cell (T_{reg}) A type of T cell that suppresses the development, activation, or function of other immune cells via secreted cytokines or cell-surface inhibitory proteins. (Chapter 24)

replication fork Y-shaped region of a replicating DNA molecule; the point at which the two strands of the parent DNA helix are being separated and the daughter strands are being formed. (Chapter 5) (Figures 5-7 and 5-18)

replication origin A location on a DNA molecule at which duplication of the DNA begins by the formation of replication forks. (Chapters 4, 5) (Figures 4-19 and 5-24)

replicative cell senescence Phenomenon observed in primary cell cultures in which cell proliferation slows down and finally irreversibly halts. (Chapters 17, 20)

respiratory chain (electron-transport chain) Electrontransport chain present in the inner mitochondrial membrane that generates an electrochemical proton gradient across the membrane: this gradient is used to drive ATP synthesis by ATP synthase. (Chapter 14) (Figures 14-4 and 14-10)

resting membrane potential Electrical potential across the plasma membrane of a cell at rest; that is, a cell that has not been stimulated to open additional ion channels beyond those that are normally open. (Chapter 11)

restriction nuclease One of a large number of nucleases that can cleave a DNA molecule at any site where a specific short sequence of nucleotides occurs. Extensively used in recombinant DNA technology. (Chapter 8) (Figure 8-23)

restriction point Important transition at the end of G₁ in the eukaryotic cell cycle; passage past this point commits the cell to enter S phase. The term was originally used for this transition in the mammalian cell cycle; in this book we use the term "Start." (Chapter 17) (Figure 17-8)

retinoblastoma A rare type of human cancer arising from cells in the retina of the eye that are converted to a cancerous state by an unusually small number of mutations. Studies of retinoblastoma led to the discovery of the first tumor suppressor gene. (Chapter 20)

retinoblastoma protein (Rb protein) Tumor suppressor protein involved in the regulation of cell division. Mutated in the cancer retinoblastoma, as well as in many other tumors. Its normal activity is to regulate the eukaryotic cell cycle by binding to and inhibiting the E2F proteins, thus blocking progression to DNA replication and cell division. (Chapter 17) (Figure 17–59)

retroviral-like retrotransposons A large family of transposons that move themselves in and out of chromosomes by a mechanism similar to that used by retroviruses, being first transcribed into an RNA copy that is converted to DNA by reverse transcriptase then inserted elsewhere in the genome. (Chapter 5) (Table 5-4, p. 308)

retrovirus RNA-containing virus that replicates in a cell by first making an RNA-DNA intermediate and then a double-strand DNA molecule that becomes integrated into the cell's DNA. (Chapters 5, 20) (Figure 5-61)

reverse genetics Approach to discovering gene function that starts from the DNA (gene) and its protein product and then creates mutants to analyze the gene's function. (Chapter 8)

reverse transcriptase Enzyme first discovered in retroviruses that makes a double-strand DNA copy from a single-strand RNA template molecule. (Chapter 5)

Reynolds number A dimensionless number that represents the ratio of inertial forces to viscous forces acting on an object moving through a fluid. The inertial force or momentum relates to the size of an object and its speed, while viscous forces depend on the properties of the fluid. (Chapter 16)

RGD sequence Tripeptide sequence of arginine-glycineaspartic acid that forms a binding site for integrins; present in fibronectin and some other extracellular proteins. (Chapter 19) (Figure 19-48C)

Rho family Family of monomeric GTPases within the Ras superfamily involved in signaling the rearrangement of the cytoskeleton. Includes Rho, Rac, and Cdc42. (Chapters 15, 16) (Table 15-5, p. 915)

Rho protein Member of the Rho family of monomeric GTPases that regulate the actin and microtubule cytoskeletons, cell-cycle progression, gene transcription, and membrane transport. (Chapter 15)

rhodopsin Seven-span membrane protein of the GPCR family that acts as a light sensor in rod photoreceptor cells in the vertebrate retina. Contains the light-sensitive prosthetic group retinol. (Chapter 15) (Figure 15–40)

ribonucleic acid See RNA. (Chapter 1)

ribosomal RNA (rRNA) Any one of a number of specific RNA molecules that form part of the structure of a ribosome and participate in the synthesis of proteins. Often distinguished by their sedimentation coefficient (for example, 28S rRNA, 5S rRNA). (Chapter 6)

ribosome Particle composed of rRNAs and ribosomal proteins that catalyzes the synthesis of protein using information provided by mRNA. (Chapter 6) (Figure 6-68)

ribozyme An RNA molecule with catalytic activity. (Chapter 6)

RNA (ribonucleic acid) Polymer formed from covalently linked ribonucleotide monomers. See also messenger RNA, ribosomal RNA, transfer RNA. (Chapter 1) (Figures 6-4 and 6-7)

RNA editing Type of RNA processing that alters the nucleotide sequence of an RNA transcript after it is synthesized by inserting, deleting, or altering individual nucleotides. (Chapter 7)

RNA exosome Large protein complex with an interior rich in 3'-to-5' RNA exonucleases; degrades RNA molecules to produce ribonucleotides. (Chapter 6)

RNA interference (RNAi) As originally described, mechanism by which an experimentally introduced double-stranded RNA induces sequence-specific destruction of complementary mRNAs. The term RNAi is often used to include the inhibition of gene expression by microRNAs (miRNAs) and piwi-interacting RNAs (piRNAs), which are encoded in the cell's own genome. (Chapter 7)

RNA polymerase Enzyme that catalyzes the synthesis of an RNA molecule on a DNA template from ribonucleoside triphosphate precursors. (Chapter 6) (Figure 6-9)

RNA primer Short stretch of RNA synthesized on a DNA template. It is required by DNA polymerases to start their DNA synthesis. (Chapter 5)

RNA-processing control Regulation by a cell of gene expression by controlling the processing of RNA transcripts, which includes their splicing. (Chapter 7)

RNA splicing Process in which intron sequences are excised from RNA transcripts. A major process in the nucleus of eukaryotic cells leading to formation of messenger RNAs (mRNAs). (Chapter 6)

RNA transport and localization control Regulation by a cell of gene expression by selecting which completed mRNAs are exported from the nucleus to the cytosol and determining where in the cytosol they are localized. (Chapter 7)

RNA world Hypothesis that early life on Earth was based primarily on RNA molecules that both stored genetic information and catalyzed biochemical reactions. (Chapter 6)

RNA-seq Sequencing the entire repertoire of RNA from a cell or tissue; also known as deep RNA sequencing. (Chapter 8)

robustness The ability of biological regulatory systems to function normally in the face of perturbations such as exposure to frequent and/or extreme variations in external conditions or the concentrations or activities of key components. (Chapter 8)

rod photoreceptor (rod) Photoreceptor cell in the vertebrate retina that is responsible for noncolor vision in dim light. (Chapter 15)

rough ER (**rough endoplasmic reticulum**) Endoplasmic reticulum with ribosomes on its cytosolic surface. Involved in the synthesis of secreted and membrane-bound proteins. (Chapter 12) (Figure 12–15)

rRNA gene Gene that specifies a ribosomal RNA (rRNA). (Chapter 6)

ryanodine receptor A regulated Ca²⁺ channel in the ER membrane that opens in response to rising Ca²⁺ levels and thus amplifies a Ca²⁺ signal. (Chapter 15)

SAM complex Protein translocator that helps β -barrel proteins to fold properly in the outer mitochondrial membrane. (Chapter 12)

Sanger sequencing See dideoxy sequencing. (Chapter 8)

Sar1 protein (Sar1 GEF) Monomeric GTPase responsible for regulating COPII coat assembly at the endoplasmic reticulum membrane. (Chapter 13)

sarcoma Cancer of connective tissue. (Chapter 20)

scaffold protein Protein that binds groups of intracellular proteins into a complex, often anchoring the complex at a specific location in the cell. (Chapters 3, 15) (Figures 3–76 and 15–10)

scanning electron microscope (**SEM**) Type of electron microscope that produces an image of the surface of an object. (Chapter 9) (Figure 9–45)

S-Cdk Cyclin–Cdk complex formed in vertebrate cells by an S-cyclin and the corresponding cyclin-dependent kinase (Cdk). (Chapter 17) (Figure 17–10 and Table 17–1, p. 1034)

SCF Family of ubiquitin ligases formed as a complex of several different proteins. One is involved in regulating the eukaryotic cell cycle, directing the destruction of inhibitors of S-Cdks in late G_1 and thus promoting the activation of S-Cdks and DNA replication. (Chapters 3, 17) (Figure 3–67)

Schwann cell Glial cell responsible for forming myelin sheaths in the peripheral nervous system. *Compare* **oligodendrocyte**. (Chapter 11) (Figure 11–35)

S-cyclin Member of a class of cyclins that accumulate during late G_1 phase and bind Cdks soon after progression through Start; they help stimulate DNA replication and chromosome duplication. Levels remain high until late mitosis, after which these cyclins are destroyed. (Chapter 17) (Figure 17–10)

Sec61 complex Three-subunit core of the protein translocator that transfers polypeptide chains across the endoplasmic reticulum membrane. (Chapter 12)

second messenger (**small intracellular mediator**) Small intracellular signaling molecule that is formed or released for action in response to an extracellular signal and helps to relay the signal within the cell. Examples include cyclic AMP, cyclic GMP, IP₃, Ca²⁺, and diacylglycerol. (Chapter 15)

secondary cell wall Permanent rigid cell wall that is laid down underneath the thin primary cell wall in certain plant cells that have completed their growth. (Chapter 19)

secondary Ig repertoire Immunoglobulins produced by B cells after somatic hypermutation and class switching induced by antigen and helper T cells. Compared to the primary Ig repertoire, these Igs have a greatly increased diversity of both Ig classes and antigen-binding sites and have increased affinity for antigen. (Chapter 24)

secondary immune response The adaptive immune response that occurs in response to a second or subsequent exposure to an antigen. The response is more rapid in onset and stronger than the primary immune response. (Chapter 24) (Figure 24–16)

secondary structure Regular local folding pattern of a polymeric molecule; in proteins, α helices and β sheets. (Chapter 3)

secretory vesicle Membrane-enclosed organelle in which molecules destined for secretion are stored prior to release. Sometimes called secretory granule because darkly staining contents make the organelle visible as a small solid object. (Chapter 13) (Figure 13–43)

securin Protein that binds to the protease separase and thereby prevents its cleavage of the protein linkages that hold sister chromatids together in early mitosis. Securin is destroyed at the metaphase-to-anaphase transition. (Chapter 17) (Figure 17–39)

segment Divisions of an insect body along its anteroposterior axis, each forming highly specialized structures, but all built according to a similar fundamental plan. (Chapter 21)

segment-polarity gene In *Drosophila* development, a gene involved in specifying the anteroposterior organization of each body segment. (Chapter 21) (Figure 21–18)

segmentation clock The gene expression oscillator controlling regular segmentation during vertebrate embryonic development. (Chapter 21)

segmentation genes Genes expressed by subsets of cells in the embryo that refine the pattern of gene expression so as to define the boundaries and ground plan of the individual body segments. (Chapter 21)

selectin Member of a family of cell-surface carbohydrate-binding proteins that mediate transient, Ca²⁺-dependent cell-cell adhesion in the bloodstream; for example, between white blood cells and the endothelium of the blood vessel wall. (Chapter 19) (Figure 19–28)

selectivity filter The part of an ion channel structure that determines which ions it can transport. (Chapter 11) (Figures 11–24 and 11–25)

sensory bristles Miniature sense organs present on most exposed surfaces of *Drosophila*, consisting of a sensory neuron and supporting cells and responding to chemical or mechanical stimuli. (Chapter 21)

separase Protease that cleaves the cohesin protein linkages that hold sister chromatids together. Acts at anaphase, enabling chromatid separation and segregation. (Chapter 17) (Figure 17–39)

septum Structure formed during bacterial cell division by the inward growth of the cell wall and plasma membrane; it divides the cell into two. (Chapter 16)

sequential induction Development process that generates a progressively more complicated pattern. A series of local inductions whereby one of two cell types present in a developing tissue can produce a signal to induce neighboring cells to specialize in a third way; the third cell type can then signal back to the other two cell types nearby to generate a fourth and a fifth cell type, and so on. (Figure 21–12)

serine protease A type of protease that has a reactive serine in the active site. (Chapters 3, 19) (Figures 3–13 and 3–37)

serine/threonine kinase Enzyme that uses ATP to phosphorylate specific proteins on serine or threonines. (Chapter 15)

SH2 domain Src homology region 2, a protein domain present in many signaling proteins. Binds a short amino acid sequence containing a phosphotyrosine. (Chapter 15) (Panel 3–2, pp. 150–151)

side chain The part of an amino acid that differs between amino acid types. The side chains give each type of amino acid its unique physical and chemical properties. (Chapter 3) (Panel 3–1, pp. 118–119)

signal patch Protein-sorting signal that consists of a specific three-dimensional arrangement of amino acids on the folded protein's surface. (Chapter 12) (Figure 13–41)

signal peptidase Enzyme that removes a terminal signal sequence from a protein once the sorting process is complete. (Figures 12–27 and 12–49)

signal sequence Short continuous sequence of amino acids that determines the eventual location of a protein in the cell. An example is the N-terminal sequence of 20 or so amino acids that directs nascent secretory and transmembrane proteins to the endoplasmic reticulum. (Chapter 12) (Figure 12–13)

signal-recognition particle (SRP) Ribonucleoprotein particle that binds an ER signal sequence on a partially synthesized polypeptide chain and directs the polypeptide and its attached ribosome to the endoplasmic reticulum. (Chapter 12) (Figure 12–19)

signaling center Cluster of specialized cells in developing tissues that serves as a source of developmental signals; for example, for the generation of a morphogen gradient. (Chapter 21)

single-molecule localization microscopy (SMLM) Any one of a number of superresolution microscopy techniques for the visualization of biological systems with an optical resolution measured in the tens of nanometers. These methods, which include PALM and STORM, allow the accurate localization of single fluorescently labeled molecules by imaging sufficient photons, and then calculating the center of the resulting point spread functions. (Chapter 9)

single-nucleotide polymorphism (SNP) A variation between individuals in a population due to a relatively common difference in a specific nucleotide at a defined point in the DNA sequence. (Chapter 8)

single-particle reconstruction Computational procedure in electron microscopy in which images of many identical molecules are obtained and digitally combined to produce an averaged three-dimensional image, thereby revealing structural details that are hidden by noise in the original images; critical for attaining atomic-level resolution by cryo-electron microscopy (Chapter 9) (Panel 9–1, p. 594)

single-pass transmembrane protein Membrane protein in which the polypeptide chain crosses the lipid bilayer only once. (Chapter 10) (Figure 10–24)

single-strand DNA-binding (SSB) protein Protein that binds to the single strands of the opened-up DNA double helix, preventing helical structures from re-forming while the DNA is being replicated. (Chapter 5) (Figure 5–15)

sister chromatids Tightly linked pair of chromosomes that arise from chromosome duplication during S phase. They separate during M phase and segregate into different daughter cells. (Chapter 17) (Figures 4–18 and 17–24)

skeletal muscle Body muscles made up of myofibrilcontaining striated muscle fibers that are under the voluntary control of the somatic nervous system. (Chapter 22)

sliding clamp Ring-shaped protein complex that holds the DNA polymerase on DNA during DNA replication. (Chapter 5) (Figure 5–17)

Smad family Latent transcription regulators that are phosphorylated and activated by receptor serine/threonine kinases to carry a signal from the cell surface to the nucleus. (Chapter 15) (Figure 15–58)

small interfering RNAs (**siRNAs**) Short (21–26 nucleotide) double-stranded RNAs that inhibit gene expression by directing destruction of complementary mRNAs. Production of siRNAs is usually triggered by exogenously introduced double-stranded RNA. (Chapter 7) (Figure 7–80)

small nuclear RNA (**snRNA**) Small RNA molecules that are complexed with proteins to form the ribonucleoprotein particles (small nuclear ribonucleoproteins; snRNPs) involved in RNA splicing. (Chapter 6) (Figures 6–29 and 6–30)

small nucleolar RNA (**snoRNA**) Small RNAs found in the nucleolus, with various functions, including guiding the modifications of precursor rRNA. (Chapter 6) (Table 6–1, p. 327, and Figure 6–43)

SMC protein complex A large ring-shaped protein complex that uses ATP hydrolysis energy to produce the looped domains that organize chromosomes; includes the eukaryotic cohesion and condensin proteins (Figures 4–56, 4–57, and 17–25)

smooth ER (**smooth endoplasmic reticulum**) Region of the endoplasmic reticulum not associated with ribosomes. Involved in detoxification reactions, Ca²⁺ storage, and lipid synthesis. (Chapter 12) (Figure 12–15)

Smoothened Seven-pass transmembrane protein with a structure very similar to a GPCR; it is controlled by the Patched and iHog proteins. (Chapter 15)

SNARE proteins (SNAREs) Members of a large family of transmembrane proteins present in organelle membranes and the vesicles derived from them. SNAREs catalyze the many membrane fusion events in cells. They exist in pairs—a v-SNARE in the vesicle membrane that binds specifically to a complementary t-SNARE in the target membrane. (Chapter 13)

sodium dodecyl sulfate polyacrylamide-gel electrophoresis (SDS-PAGE) Type of electrophoresis used to separate proteins by size. The protein mixture to be separated is first treated with a powerful negatively charged detergent (SDS) and with a reducing agent (β-mercaptoethanol), before being run through a polyacrylamide gel. The detergent and reducing agent unfold the proteins, free them from association with other molecules, and separate any polypeptide subunits. (Chapter 8)

somatic cell Any cell of a plant or animal other than cells of the germ line. From Greek *soma*, "body." (Chapter 5)

somatic hypermutation In immunology: the targeted accumulation of point mutations in the assembled variable-region coding sequences of immunoglobulin genes that occurs when B cells are activated to form memory cells. Results in the production of antibodies with altered antigen-binding sites, some of which bind antigen with increased affinity; it is important for affinity maturation in antibody responses. (Chapter 24)

somatic mutations In cancer, one or more detectable abnormalities in the DNA sequence of tumor cells that distinguish them from the normal somatic cells from which the tumor was derived. (Chapter 20)

somite One of a series of paired blocks of mesoderm that form during early development and lie on either side of the notochord in a vertebrate embryo. They give rise to the segments of the body axis, including the vertebrae, muscles, and associated connective tissue. (Chapter 21) (Figure 21–38)

sorting receptors Proteins involved in binding signal sequences or cargo proteins and bringing them to specific sites in the cell where cargo proteins are released. Sorting receptors pick up and deliver cargo proteins repeatedly. (Chapter 12)

sorting signal Signal sequence or signal patch that directs the delivery of a protein to a specific location, such as to a particular intracellular compartment. (Chapter 12)

spectrin Abundant protein associated with the cytosolic side of the plasma membrane in red blood cells, forming a network that supports the membrane. Also present in other cells. (Chapters 10, 16) (Figure 10–38)

S phase The period of a eukaryotic cell cycle in which DNA is synthesized. (Chapter 5) (Figure 17–4)

spindle assembly checkpoint Regulatory system that operates during mitosis to ensure that all chromosomes are properly attached to the spindle before sister-chromatid separation starts. (Chapter 17) (Figure 17–20 and Panel 17–1, pp. 1048–1049)

spliceosome Large assembly of RNA and protein molecules that performs pre-mRNA splicing in eukaryotic cells. (Chapter 6)

Src (**Src protein family**) Family of cytoplasmic tyrosine kinases (pronounced "sark") that associate with the cytoplasmic domains of some enzyme-linked cell-surface receptors that lack intrinsic tyrosine kinase activity. They transmit a signal onward by phosphorylating the receptor itself and specific intracellular signaling proteins on tyrosines. (Figures 3–61 and 24–46)

SRP (signal-recognition particle) receptor Component in the endoplasmic reticulum (ER) membrane that guides the signal-recognition particle to the ER membrane. (Chapter 12)

standard free-energy change (ΔG°) The change in free energy under a standard condition, defined as that where the concentrations of all the reactants are set to the same fixed value of 1 mole/liter. (Chapter 2)

starch Polysaccharide composed exclusively of glucose units, used as an energy-storage material in plant cells. (Figure 2–53)

Start (restriction point) Important transition at the end of G_1 in the eukaryotic cell cycle. Passage through Start commits the cell to enter S phase. The term was originally used for this point in the yeast cell cycle only; the equivalent point in the mammalian cell cycle was called the restriction point. In this book we use Start for both. (Chapter 17) (Figure 17–8)

STAT (signal transducer and activator of transcription)
Latent transcription regulator that is activated by phosphorylation
by Janus kinases (JAKs) and enters the nucleus in response

by Janus kinases (JAKs) and enters the nucleus in response to signaling from receptors of the cytokine receptor family. (Figure 15–57)

stem cell Undifferentiated cell that can continue dividing indefinitely, throwing off daughter cells that can either commit to differentiation or remain a stem cell (in the process of self-renewal). (Chapter 22) (Figure 22–2)

stem-cell niche The specialized microenvironment in a tissue in which self-renewing stem cells can be maintained. (Chapter 22)

steroid hormones Hormones, including cortisol, estrogen, and testosterone, that are hydrophobic lipid molecules derived from cholesterol that activate intracellular nuclear receptors. (Chapter 15)

stimulatory G protein (G_s) G protein that, when activated, activates the enzyme adenylyl cyclase and thus stimulates the production of cyclic AMP. See also **G protein**. (Chapter 15) (Table 15–3, p. 907)

stochastic Random. Involving chance, probability, or random variables. (Chapter 8)

strand exchange Reaction in which a single-strand 3' end from one duplex DNA molecule penetrates another duplex and finds a homologous sequence through base-pairing. Also called strand invasion. (Chapter 5)

strand-directed mismatch repair A proofreading system that removes DNA replication errors missed by the DNA polymerase proofreading exonuclease. It detects the DNA helix distortion from noncomplementary base pairs and then excises the mismatch in the newly synthesized strand specifically; the excised DNA segment is then replaced using the old strand as a template. (Chapter 5)

stress fibers Cortical fibers of contractile actin–myosin II bundles that connect the cell to the extracellular matrix or adjacent cells through focal adhesions or a circumferential belt and adherens junctions. (Chapter 16)

stroma (1) "Bedding": the connective tissue in which a glandular or other epithelium is embedded. Stromal cells provide the environment necessary for the development of other cells within the tissue. (2) The large interior space of a chloroplast, containing enzymes that incorporate CO₂ into sugars. (Chapters 12, 14, 20) (Figures 14–38 and 20–19)

substrate Molecule on which an enzyme acts. (Chapters 2, 3)

superresolution Describes several approaches in light microscopy that bypass the limit imposed by the diffraction of light and successfully allow objects as small as 10 nm to be imaged and clearly resolved. (Chapter 9)

survival factor Extracellular signal that promotes cell survival by inhibiting apoptosis. (Chapter 18) (Figure 18–12)

symporter Carrier protein that transports two types of solute across the membrane in the same direction. (Chapter 11) (Figure 11–8)

synapse Communicating cell–cell junction that allows signals to pass from a nerve cell to another cell. In a chemical synapse, the signal is carried by a diffusible neurotransmitter. In an electrical synapse, a direct connection is made between the cytoplasms of the two cells via gap junctions. (Figures 11–38 and 19–23)

synaptic plasticity Changes in the strength with which a chemical synapse transmits a signal. It is thought to be

G:34 Glossary

important in memory formation, where concentrations of postsynaptic AMPA receptor are modulated in response to a synapse's activity. (Chapter 11)

synaptic signaling Intercellular signaling performed by neurons that transmit signals electrically along their axons and release neurotransmitters at synapses, which are often located far away from the neuronal cell body. (Chapter 15)

synaptic vesicle Small neurotransmitter-filled secretory vesicle found at the axon terminals of nerve cells. Its contents are released into the synaptic cleft by exocytosis when an action potential reaches the axon terminal. (Chapter 13)

synaptonemal complex Structure that holds paired homologous chromosomes tightly together in pachytene of prophase I in meiosis and promotes the final steps of crossing-over. (Chapter 17) (Figures 17–54 and 17–55)

syncytium Mass of cytoplasm containing many nuclei enclosed by a single plasma membrane. Typically the result either of cell fusion or of a series of incomplete division cycles in which the nuclei divide but the cell does not. (Chapters 17, 21)

T cell receptor (TCR) Transmembrane receptor for antigen on the surface of T lymphocytes, consisting of an immunoglobulin-like heterodimer. (Chapter 24) (Figure 24–32)

T cell-mediated immune response Any adaptive immune response mediated by antigen-specific T cells. (Chapter 24)

tail-anchored protein Protein containing a transmembrane segment very close to its C-terminus. (Chapter 12)

TATA box Sequence in the promoter region of many eukaryotic genes that binds a general transcription factor (TFIID) and hence specifies the position at which transcription is initiated. (Chapter 6) (Figure 6–15)

telomerase Enzyme that elongates the telomere sequences in DNA, which occur at the ends of eukaryotic chromosomes. (Chapters 5, 17) (Figure 5–33)

telomere End of a chromosome, associated with a characteristic DNA sequence that is replicated in a special way. Counteracts the tendency of the chromosome otherwise to shorten with each round of replication. From Greek *telos*, "end," and *meros*, "portion." (Chapters 4, 17)

telophase Final stage of mitosis in which the two sets of separated chromosomes decondense and become enclosed by nuclear envelopes. (Chapter 17) (Panel 17–1, pp. 1048–1049)

template Single strand of DNA or RNA whose nucleotide sequence acts as a guide for the synthesis of a complementary strand. (Chapter 4) (Figure 1–3)

terminal differentiation The limit of cell determination when a cell forms one of the highly specialized cell types of the adult body. (Chapter 21)

terminally differentiated A cell at the limit of cell determination, being one of the highly specialized cell types of the adult body. (Chapter 21)

terminator Signal in bacterial DNA that halts transcription; in eukaryotes, transcription terminates after cleavage and polyadenylation of the newly synthesized RNA. (Chapter 6)

tertiary structure Complex three-dimensional form of a folded polymer chain, especially a protein or RNA molecule. (Chapter 3)

T_{FH} cell See follicular helper T cell. (Chapter 24)

 $T_{H}1\ cell$ A type of effector helper T cell that secretes IFN $_{Y}$ to help activate macrophages and induces B cells to switch the class of antibody they make. (Chapter 24) (Figure 24–44)

T_H17 cell A type of effector helper T cell that secretes IL17, which recruits neutrophils and stimulates an inflammatory response. (Chapter 24) (Figure 24–44)

 T_{H2} cell A type of effector helper T cell that helps activate B cells to produce antibodies, to undergo somatic hypermutation, and switch the class of immunoglobulin produced. (Chapter 24) (Figure 24–44)

thylakoid Flattened sac of membrane inside a chloroplast that contains chlorophyll and other pigments and carries out the light-trapping reactions of photosynthesis. Stacks of thylakoids form the grana of chloroplasts. (Chapters 12, 14) (Figures 14–37 and 14–38)

thylakoid membrane Chloroplast membrane system that contains the large membrane protein complexes for photosynthesis and photophosphorylation. (Chapter 14)

thymocytes Developing T cells in the thymus. (Chapter 24)

tight junction Cell-cell junction that seals adjacent epithelial cells together, preventing the passage of most dissolved molecules from one side of the epithelial sheet to the other. (Chapter 19) (Figures 19–2 and 19–21)

TIM complexes Protein translocators in the mitochondrial inner membrane. The TIM23 complex mediates the transport of proteins into the matrix and the insertion of some proteins into the inner membrane; the TIM22 complex mediates the insertion of a subgroup of proteins into the inner membrane. (Chapter 12) (Figure 12–48)

tissue-specific stem cells (or **adult stem cells)** Stem cells that replenish the differentiated cell types of a particular tissue. They are found in small numbers and produce only a subset of cell types compared to embryonic stem cells. (Chapter 22)

Toll A transmembrane receptor protein. On the ventral side of the *Drosophila* egg membrane, its activation controls the distribution of Dorsal, a transcription regulator of the NF κ B family. (Chapter 21)

Toll-like receptors (TLRs) Family of pattern recognition receptors (PRRs) on or in cells of the innate immune system. They recognize pathogen-associated immunostimulants (that is, PAMPs) associated with microbes. (Chapter 24) (Figure 24–4)

TOM complex Multisubunit protein complex that transports proteins across the mitochondrial outer membrane. (Chapter 12) (Figure 12–48)

TOR Large serine/threonine protein kinase that is activated by the Pl-3-kinase–Akt signaling pathway and promotes cell growth. (Chapter 15)

totipotent Describes a cell that is able to give rise to all the different cell types in an organism. (Chapters 21, 22)

trans face Face on the other (far) side. (Chapter 13)

trans Golgi network (TGN) Network of interconnected tubular and cisternal structures closely associated with the *trans* face of the Golgi apparatus and the compartment from which proteins and lipids exit the Golgi, bound for the cell surface or another compartment. (Chapter 13)

transcellular transport Transport of solutes, such as nutrients, across an epithelium, by means of membrane transport proteins in the apical and basal faces of the epithelial cells. (Chapter 11) (Figure 11–11)

transcription (**DNA transcription**) Copying of one strand of DNA into a complementary RNA sequence by the enzyme RNA polymerase. (Chapters 1, 6) (Figures 6–1 and 6–8)

transcription regulators General name for any protein that binds to a specific DNA sequence (known as a *cis*-regulatory sequence) to influence the transcription of a gene. (Chapter 7)

transcriptional control Regulation by a cell of gene expression by controlling when and how often a given gene is transcribed. (Chapter 7)

transcytosis Uptake of material at one face of a cell by endocytosis, its transfer across a cell in vesicles, and discharge from another face by exocytosis. (Chapter 13) (Figure 13–56)

transfer RNA (**tRNA**) Set of small RNA molecules used in protein synthesis as an interface (adaptor) between mRNA and amino acids. Each type of tRNA molecule is covalently linked to a particular amino acid. (Chapter 6) (Figure 6–54)

transferrin receptor Cell-surface receptor for transferrin (a soluble protein that carries iron); delivers iron to the cell interior via receptor-mediated endocytosis and recycling of the receptor-transferrin complex. (Chapter 13)

transformed A cell with an altered phenotype that behaves in many ways like a cancer cell (that is, unregulated proliferation, anchorage-independent growth in culture). (Chapter 20)

transforming growth factor- β superfamily (TGF β superfamily) Large family of structurally related secreted proteins that act as hormones and local mediators to control a wide range of functions in animals, including during development. It includes the TGF β /activin and bone morphogenetic protein (BMP) subfamilies. (Chapter 15) (Figure 15–58)

transgene The foreign or modified gene that has been added to create a transgenic organism. (Chapter 8)

transgenic organism Plant or animal that has stably incorporated one or more genes from another cell or organism (through insertion, deletion, and/or replacement) and can pass them on to successive generations. (Chapter 8) (Figures 8–55 and 8–71)

transit amplifying cell Cell derived from a stem cell that divides a limited number of times before terminally differentiating. (Figure 22–3)

transition state Structure that forms transiently in the course of a chemical reaction and has the highest free energy of any reaction intermediate. Its formation is a rate-limiting step in the reaction. (Chapter 3) (Figure 3–45)

translation (**RNA translation**) Process by which the sequence of nucleotides in an mRNA molecule directs the incorporation of amino acids into protein. Occurs on a ribosome. (Chapters 1, 6) (Figures 6–1 and 6–68)

translational control Regulation by a cell of gene expression by selecting which mRNAs in the cytoplasm are translated by ribosomes. (Chapter 7)

transmembrane adhesion proteins Transmembrane proteins with one end linking to the cytoskeleton inside the cell and the other end linking to other structures outside the cell. (Chapter 19)

transmembrane protein Membrane protein that extends through the lipid bilayer, with part of its mass on either side of the membrane. (Chapter 10) (Figure 10–17)

transmembrane segment The region of a transmembrane protein that spans the lipid bilayer, often as an α helix. (Chapter 12)

transmitter-gated ion channel (ionotropic receptor) Ion channel found at chemical synapses in the postsynaptic plasma

membranes of nerve and muscle cells. Opens only in response to the binding of a specific extracellular neurotransmitter. The resulting inflow of ions leads to the generation of a local electrical signal in the postsynaptic cell. (Chapter 11) (Figures 11–38 and 15–6)

transport vesicle Membrane-enclosed transport containers that bud from specialized coated regions of a donor membrane and pass from one cell compartment to another as part of the cell's membrane transport processes; vesicles can be spherical, tubular, or irregularly shaped. (Chapter 13)

transporter (carrier protein, permease) Membrane transport protein that binds to a solute and transports it across the membrane by undergoing a series of conformational changes. Transporters can either transport ions or molecules passively down an electrochemical gradient or they can link the conformational changes to a source of metabolic energy such as ATP hydrolysis to drive active transport. *Compare* channel. See also membrane transport protein. (Chapter 11) (Figure 11–3)

transposable element (transposon) Segment of DNA that can move from one chromosomal position to another by transposition. (Chapter 5) (Table 5–4, p. 308)

transposition (transpositional recombination) Movement of a DNA sequence from one chromosomal site to another. (Chapter 5) (Table 5–4, p. 308)

transposon See transposable element. (Chapter 5)

treadmilling Process by which a polymeric protein filament is maintained at constant length by addition of protein subunits at one end and loss of subunits at the other. (Panel 16–2, pp. 960–961)

Trithorax group Set of proteins critical for cell memory that maintains the transcription of *Hox* genes in cells where transcription has already been switched on. (Chapter 21)

t-SNAREs Transmembrane SNARE protein, usually composed of three proteins and found on target membranes where it interacts with v-SNAREs on vesicle membranes. (Chapter 13)

tubulin The protein subunit of microtubules. (Chapter 16) (Panel 16–1, p. 950, and Figure 16–36)

 γ -tubulin ring complex (γ -TuRC) Protein complex containing γ -tubulin and other proteins that is an efficient nucleator of microtubule formation; it caps microtubule minus ends. (Chapter 16)

tumor progression Process by which an initial mildly disordered cell behavior gradually evolves into a full-blown cancer by the selection for cell proliferation. (Chapter 20) (Figures 20–8 and 20–9)

tumor suppressor gene Gene that appears to help prevent formation of a cancer. Loss-of-function mutations in such genes favor the development of cancer. (Chapter 20) (Figure 20–21)

tumor virus Virus that can help make the cell it infects cancerous. (Chapter 20)

turgor pressure Large hydrostatic pressure developed inside a plant cell as the result of the intake of water by osmosis; it is the force driving cell expansion in plant growth and it maintains the rigidity of plant stems and leaves. (Chapter 19)

two-dimensional gel electrophoresis Technique combining two different separation procedures—separation by charge (isoelectric focusing) in the first dimension, then separation by size in a direction at a right angle to that of the first step—to

G:36 Glossary

resolve up to 2000 proteins in the form of a two-dimensional protein map. (Chapter 8)

type III fibronectin repeat The major repeat domain in fibronectin, it is about 90 amino acids long and occurs at least 15 times in each subunit. The repeat is among the most common of all protein domains in vertebrates. (Chapter 19)

type III secretion system One of several secretion systems in Gram-negative bacteria; delivers effector proteins into host cells in a contact-dependent manner. (Chapter 23) (Figure 23–7)

type IV collagen An essential component of mature basal laminae consisting of three long protein chains twisted into a rope-like superhelix with multiple bends. Separate molecules assemble into a flexible, felt-like network that gives the basal lamina tensile strength. (Chapter 19)

tyrosine kinase Enzyme that phosphorylates specific proteins on tyrosines. See also **cytoplasmic tyrosine kinase**, **receptor tyrosine kinase** (**RTK**). (Chapter 15)

tyrosine-kinase-associated receptor Cell-surface receptor that functions similarly to receptor tyrosine kinases (RTKs), except that the kinase domain is encoded by a separate gene and is noncovalently associated with the receptor polypeptide chain. (Chapter 15)

ubiquitin Small, highly conserved protein present in all eukaryotic cells that can be covalently attached to lysines of other proteins. Attachment of a short chain of ubiquitins to such a lysine can tag a protein for intracellular proteolytic destruction by a proteasome. (Chapter 3) (Figure 3–65)

ubiquitin ligase Any one of a large number of enzymes that attach ubiquitin to a protein, often marking it for destruction in a proteasome. The process catalyzed by a ubiquitin ligase is called ubiquitylation. (Chapter 3) (Figure 3–67)

unfolded protein response The cellular response triggered by an accumulation of misfolded proteins in the endoplasmic reticulum. It causes an expansion of the ER and increased transcription of genes that code for endoplasmic reticulum chaperones and degradative enzymes, as well as other changes. (Chapter 12) (Figure 12–36)

uniporter Carrier protein that transports a single solute from one side of the membrane to the other. (Chapter 11) (Figure 11–8)

V gene segment A DNA sequence encoding most of the variable region of an immunoglobulin or T cell receptor polypeptide chain. There are many different *V* gene segments, one of which becomes joined to a *D* or *J* gene segment by somatic recombination when an individual lymphoid progenitor cell begins to differentiate into a B or T lymphocyte. (Chapter 24) (Figure 24–28)

vaccination The process of injecting a substance (called an antigen) into an animal in order to elicit an adaptive immune response that protects the animal against pathogens containing the antigen; critical for combating the COVID-19 pandemic. (Chapter 24)

vacuole Large fluid-filled compartment found in most plant and fungal cells, often occupying more than a third of the cell volume. (Chapter 13) (Figure 13–66)

van der Waals attraction Type of (individually weak) noncovalent bond that is formed at close range between nonpolar atoms. (Table 2–1, p. 51, and Panel 2–3, pp. 98–99)

variable region Region of an immunoglobulin or T cell receptor polypeptide chain that is the most variable and

contributes to the antigen-binding site. (Chapter 24) (Figures 24–25 and 24–32)

vascular endothelial growth factor (VEGF) Secreted protein that stimulates the growth of blood vessels. (Table 15–4, p. 911)

V(D)J recombination Somatic recombination process by which gene segments are brought together to form a functional gene for a polypeptide chain of an immunoglobulin or T cell receptor. (Chapter 24) (Figure 24–28)

vesicular transport The transport of proteins from one cell compartment to another by means of membrane-bounded intermediaries, such as vesicles or organelle fragments. (Chapter 12)

virulence factor Protein, encoded by a virulence gene, that contributes to an organism's ability to cause disease. (Chapter 23)

virulence gene Gene that contributes to an organism's ability to cause disease. (Chapter 23)

virus Particle consisting of nucleic acid (RNA or DNA) enclosed in a protein coat and capable of replicating within a host cell and spreading from cell to cell. (Chapters 1, 23) (Figure 23–11)

virus receptor Molecule on the host-cell surface to which virus surface proteins bind to enable the binding of virus to the cell and its subsequent entry into the cytoplasm. (Chapter 23)

voltage-gated cation channel Type of ion channel found in the membranes of electrically excitable cells (such as nerve, endocrine, egg, and muscle cells). Opens in response to a shift in membrane potential past a threshold value. (Chapter 11)

voltage-gated K⁺ channel Ion channel in the membrane of nerve cells that opens in response to membrane depolarization, enabling K⁺ efflux and rapid restoration of the negative membrane potential. (Chapter 11)

voltage-gated Na⁺ channel Ion channel in the membrane of nerve and skeletal muscle cells that opens in response to a stimulus causing sufficient depolarization, allowing Na⁺ to enter the cell down its electrochemical gradient. (Chapter 11)

v-SNAREs Transmembrane SNARE protein, comprising a single polypeptide chain, usually found in vesicle membranes where it interacts with t-SNAREs in target membranes. (Chapter 13)

V-type pumps Turbine-like protein machines constructed from multiple different subunits that use the energy of ATP hydrolysis to drive transport across a membrane. A V-type proton pump transfers H⁺ into organelles such as lysosomes to acidify their interior. (Chapter 11) (Figure 11–12)

water channel See aquaporin. (Chapter 11)

Wee1 Protein kinase that inhibits Cdk activity by phosphorylating amino acids in the Cdk active site. Important for regulating entry into M phase of the cell cycle. (Chapter 17)

western blotting Technique by which proteins are separated by electrophoresis and immobilized on a paper sheet and then analyzed, usually by means of a labeled antibody. Also called immunoblotting. (Chapter 8)

white blood cell General name for all the nucleated blood cells lacking hemoglobin. Also called leukocytes. Includes lymphocytes, granulocytes, and monocytes. (Table 22–1, p. 1286)

Wnt protein Member of a family of secreted signal proteins that have many different roles in controlling cell differentiation,

proliferation, and gene expression in animal embryos and adult tissues. (Chapter 15)

Wnt/β-catenin pathway Signaling pathway activated by binding of a Wnt protein to its cell-surface receptors. The pathway has several branches. In the major (canonical) branch, activation causes increased amounts of β -catenin to enter the nucleus, where it regulates the transcription of genes controlling cell differentiation and proliferation. Overactivation of the Wnt/ β -catenin pathway can lead to cancer. (Chapter 15) (Figure 15–61)

XIAP An inhibitor of apoptosis protein (IAP) that is encoded on the X chromosome. (Chapter 18)

X-inactivation Inactivation of one copy of the X chromosome in the somatic cells of female mammals. (Chapter 7)

X-inactivation center (XIC) Site in an X chromosome at which inactivation is initiated and spreads outward. (Figure 7–55)

Xist A long (20,000 nucleotide) noncoding RNA responsible for inactivating one of the two X chromosomes in female mammals. (Chapter 7)

x-ray crystallography Technique for determining the threedimensional arrangement of atoms in a molecule on the basis of the diffraction pattern of x-rays passing through a crystal of the molecule. (Chapter 8) (Figure 8–20)

zygote Diploid cell produced by fusion of a male and female gamete. A fertilized egg. (Chapter 21)

	-cell adnesion (continued)	phosphorylation and 1033, 1034–1036,	Overview 603-604
	immunoglobulins in 1125, 1126–1127	1037–1038, 1039–1040, 1041T	proportion of protein 615
	mediation by glycolipids and	regulatory proteins 1041T	relative amounts in cell, by
	glycoproteins 621	resetting 1045	types 685T
	tissue remodeling 1108, 1114–1116	Start (restriction point)	see also lipid bilayers; membrane
	vertebrate embryo patterning 1250	transition 1029, 1032–1033,	proteins; membrane structure;
	-cell contact	1034, 1038, 1041, 1081	plasma membranes
	contact-dependent signaling	transcriptional regulation in 1040	cell memory
	874–875, 928	cell-cycle network, negative	CaM-kinase II as molecular memory
	desmosomes 1009	feedback 550	device 902, 903-904
	immunological synapses 1391, 1392F	cell death, programmed see apoptosis	and chromatin structure 203
	lateral inhibition dependent on 928	cell determination 1220	defined 431
	Rac and Rho in actin organization	see also differentiation	and differentiation 423, 427F, 431-433,
	at 1021, 1022F	cell division	443–444, 1220, 1221–1222
cell	-cell junctions 1108-1127	asymmetric cell division 1069-1070,	in embryonic development 427F,
	anchoring junctions 1106F,	1124, 1244–1245	1220, 1221–1222, 1235–1236
	1107–1108, 1124	contribution to body size 1269F	Hox complexes and 1235–1236
	cadherin mediation 1107, 1259	control of cell growth and 1077–1084	and inductive signaling in
	focal adhesions 924	coordination of cell growth and 1084	patterning 1221–1222
	intermediate filaments and 950P	cytoskeleton in 951, 952F	
			intracellular signaling pathways 889,
	major forms 1106–1107	limits, for human cells 1082,	904F
	microtubules 995	1173–1174	overriding with cell
	repulsive interactions 1259-1260	mitogens in 1078	reprogramming 1300–1301
	see also cell-matrix junctions; gap	see also cell cycle; meiosis; mitosis	and positive feedback 432, 433,
	junctions; tight junctions	cell doctrine 563	443–444, 553, 889
cell	coats 621	cell-fate determinants 1070, 1244-1245,	reinforcement mechanisms
cell	cortex	1293	435–445
	actin filaments in 631-632, 951, 967,	cell-free systems 486-487, 701-702	see also epigenetic inheritance
	971–972, 973	cell growth	cell migration
	cortical cytoskeleton 630-632	contribution to body size 1269F	amoeboid cell migration 973F, 974
	ERM proteins and 969	control and the PI-3-kinase-Akt	attachment to surfaces 973F, 974
cell	cycle 1027-1088	pathway 921-922	blebbing cell migration 973F, 974, 1267
	accessory proteins and 956	control of, in plants 1157-1158	in cancer 973
	changes in the nucleolus 354, 355F	control of cell division and 1077-1084	cell sorting in 1259-1260
	endocycle (endoreduplication)	coordination of cell division and 1084	chain migration 1268
	1029–1030	dependent on growth factors 1083	chemotaxis and 1022, 1023F,
	in eukaryotes 195–196, 276F,	distinguished from cell	1266–1267
	1028–1030	proliferation 1078	clustered migration 1268

210–211, 212F, 214F, 215, 216F,	hsp70 381–382, 708, 713, 728F, 729, 731, 756	hemidesmosomes 1009, 1010F, 1106F,
226, 421, 465	hsp90 382, 383F	1107, 1117F, 1133, 1148 hemoglobin
H3K27me3 class of	as molecular chaperones 380–382, 717	α - and β-globin subunits 131, 189F,
heterochromatin 204F, 210-211,	Hedgehog genes 1231F, 1232	241
212F, 216F, 217, 226, 421	Hedgehog pathway 1221, 1225, 1232	cooperative allosteric transition
HaelII nuclease 499, 502F	Hedgehog proteins 932–933, 1232, 1291	241
Haemanthus 1061F	see also Sonic hedgehog (Shh) protein	expression in red blood cells 399
hair cells, auditory	helicase loaders 273	fetal hemoglobin 241-242
differentiation 1242	helices	gene duplications and evolution
mechanically gated ion channels 659	actin filaments 950P, 955, 958, 970F	241–242
myosins in 986	collagen triple helix 132-133, 1132	heme groups in 154–155
planar cell polarity 1262–1263	DNA, hairpin helices 262, 263F	see also α-globin; β-globin
stereocilia 951, 953, 969, 986, 1262	handedness 132, 133F	hemophilia 314, 322–323F, 340F, 526
hairpin helices, DNA 262, 263F hairpin helices, RNA 328F, 329, 330, 349,	microtubules 988, 992F	heparan sulfate 1129F, 1132, 1139F,
390F, 451	reasons for abundance 132	1145–1146, 1223, 1329
Hairy protein (<i>Drosophila</i>) 455F	recognition helix 404P	heparin 1129F, 1139F
Haiti, cholera outbreak 1313, 1318	RNA, hairpin helices 328F, 329, 330, 349, 390F, 451	hepatitis-B and -C viruses 1201, 1202T, 1203, 1323T
half-lives	S4 helix 663, 664F	hepatocytes
connexins 1123	superhelices, collagen 1132, 1143	derivation from megakaryocytes
extracellular, of nitric oxide (NO) 908	see also α helices; coiled-coils; DNA	1070
messenger RNA 459	supercoiling; double helix	gene expression during
and time to steady state 887	Helicobacter pylori 1201F, 1203, 1313,	development 437F
Halobacterium salinarum 626, 629, 630F,	1327–1328	homeostatic control 1289
646	helitrons 309, 310F	I-cell disease 779-780
halteres 1233, 1234F	hellebore pollen 592F	lipoprotein particle production 699
handedness of helices 132, 133F	helper T cells (T _H cells)	relative amounts of membrane
haploid cells, defined 1071	B cell activation 1371, 1373, 1374,	types 685T
haploid-diploid cycle 36–37, 520P	1379, 1382, 1393	relative volumes of intracellular
haplotype blocks 525–526	CD4 expression on 1389, 1390, 1391	compartments in 684T
HARs (human accelerated regions) 238 HATs (histone acetyl transferases) 206,	class switch recombination 1380 co-stimulatory proteins/signals 1371,	smooth ER in 699 Her genes 1250F
418F	1393, 1395, 1396F	Her2 (human epidermal growth factor
HDACs (histone deacetylase	cytokines produced 1379, 1393F	receptor 2) protein 1209
complexes) 206, 212, 421F,	dendritic cell activation 1382	Herceptin (trastuzumab) 1209
1306F	effector helper T cells 1382, 1384,	herd immunity 1399, 1401
HDL (high-density lipoproteins) in	1391, 1392–1394, 1396F	hereditary cancers 269, 1182, 1183F
nanodiscs 625	follicular helper T cells (T _{FH}	hereditary nonpolyposis colorectal cancer
heart attacks	cells) 1393, 1395, 1396F, 1399F	(HNPCC) 269, 1195-1196
apoptosis and 1100	HIV invasion of 1389	heredity
muscle replacement by scar	inducing cytokines 1393	as characteristic of life 2
tissue 1296	macrophage activation 1382,	DNA and the mechanism of 184,
muscle replacement by	1393–1394	187–189
transdifferentiation 1309	possible differentiation 1393–1394	see also epigenetic inheritance
heart muscle	recognition of peptide–MHC	hermaphroditism, <i>C. elegans</i> 38F, 443,
actin and myosin isoforms 984	complexes 1384, 1387–1388,	1270
adherens junctions in 1114	1396F	herpes simplex virus 1323T, 1329
contraction 978, 984, 1122	T _H 1 cells 1393, 1395	herpesvirus family 1202T, 1323F, 1324,
desmin filaments 1116 effects of acetylcholine 904–905	T _H 2 cells 1393, 1394 T _H 17 cells 1393, 1394	1337F, 1338, 1339 Hes genes 1250-1251
GINGOLO DI AUGLYIULIUIILE 304-303	1417 65115 1030, 1034	1169 AGUES 1490-1491

heterochromatin	and nucleosome core particle	homeobox-containing genes 571F, 1234
amount in human genome 211	structure 199F, 200	see also Hox complex; Hox genes
around centromeres 421, 466	in nucleosome stacking 202	homeodomain 127, 128F, 404P, 406F,
condensed DNA in 204-205	side chain modifications 206-208,	1234
constitutive heterochromatin 204F,	418	homeodomain family of proteins 127,
205, 211, 214F, 465	histone variants	128F, 404P, 406
defined 204, 1045	CENP-A (centromere protein-A)	homeostasis
distribution in the nucleus 220-221,	variant 208F, 213-214, 215	growth and body size control 1270,
225–227	chromatin structure variety and 200	1272–1273
facultative heterochromatin 204F,	fibroblast reprogramming and 1305,	hepatocyte numbers 1289
205, 211	1306F	neuron firing behavior control 668
gene expression restricted in	structures 208F	river analogy 1279–1280, 1281
204–205, 421	histones	telomeres, control mechanism 282,
and gene silencing 205, 211, 215	covalent modifications, effect on	283F
H3K9me3 class 204F, 210–211, 212F,	function 208–210	vacuoles as homeostatic device 800
214F, 215, 216F, 226, 421, 465	covalent modifications,	homeotic mutations 1234
H3K27me3 class 204F, 210–211,	nomenclature 210	homeotic selector see Hox genes
212F, 216F, 217, 226, 421	covalent modifications of side	homing receptors 1369
inheritance of 206, 207, 215, 216F	chains 206–208	Homo sapiens
oncohistone mutations 216–217 pericentric heterochromatin 214F	DNA compaction in chromosomes 55 evolutionary conservation 200, 202,	conserved DNA 18F, 230 genome size 13, 29T, 40, 44

as treatments for human	233F, 234–236, 314–315	multipass transmembrane proteins
diseases 479–480	genome size 29T germ-free mice 1348	association with lipid bilayers 615F defined 618, 639
monocytes 1286T, 1287F, 1288, 1357 monomeric GTPases	hematopoietic stem cell	hydrophobic transmembrane
cell-surface receptors and 880	transplantation 1286–1288,	segments 710–711
Ras proteins as 162, 163F, 166, 915	1291, 1294–1296	ion-channel-coupled receptors
in Rho family 904, 1016	Hox gene effects 1242F	as 878
monosaccharides	immunological self-tolerance in 1370	KDEL receptor as 768
aldoses and ketoses 100P	imprinting in 438–439	membrane transport proteins as 616,
α and β links 101P	intestinal epithelial cell lifetimes 1282	625, 639, 732
derivatives 101P	iPS cell incorporation 1304	rhodopsin/bacteriorhodopsin as
isomers 100P	liver 1274F	625–627
ring and complex formation 100-101P	macrophage 803F	seven-pass transmembrane
structures and properties 54, 100-101P	as model organism 29T, 38, 41-42,	proteins 892, 893F, 911, 930
monoubiquitylation 163F, 795	531, 1220	structure 620-621
morphogenesis	myosin gene mutation effects 984F	see also transmembrane proteins
branching morphogenesis 1264-1265	olfactory bulb neurons 1299	multiphoton imaging 580
defined 1217	optogenetic control of aggression	multiple sclerosis 666
in embryonic development	neurons 679F	multispecies conserved sequences 230,
1129–1130, 1257–1269	transposons in genome 314–315	237–238
folding of epithelial sheets 1115, 1258	X-inactivation in 442F, 443F	multiubiquitylation 163F, 795
hyaluronan role in tissue	mouse, transgenic	multivesicular bodies 788F, 796–797, 807
morphogenesis 1129–1130	knockout mice 529, 530F	muntjac deer 193F
lung development 1264–1265	oncogene collaboration 1190–1192	Mus musculus see mouse
in plants 541, 577	premature aging 283, 530F	muscarinic acetylcholine receptors
tissue morphogenesis 1129–1130	procedures for making gene	904–905, 908F
see also development of multicellular	replacements in 529F, 541	muscle cells Ca ²⁺ pump in SR 647, 648F, 674, 700
organisms	RNA interference in 533–534 telomere studies 283	in culture 477
morphogens Bicoid as 1231	mouse–human hybrid cells 627–628	localization of mitochondria 813
	•	myoblast migration 1266–1267
concentration gradients 1222–1223, 1229, 1236–1238	moving junctions 1333 Mre11 285T, 298, 301F, 302, 303F	myotendinous junctions 1148
diffusion 1222–1223, 1225	MreB protein 1014	neuromuscular junctions 671
Dorsal as 1237	mRNAs see messenger RNA	muscle contraction
Dpp 1272F	mRNPs (messenger	actin and myosin in 977–981
graded effects 926, 1222–1223	ribonucleoproteins) 742	calcium (Ca ²⁺) ions in 981–984
range 1225	MRSA (methicillin-resistant	smooth muscle 978, 983–984
response timing 885	Staphylococcus aureus) 1326	speed of 980

muscle specific homeobox gene 571F	fibroblast reprogramming 1304	N-terminal histone tails see histone tails,
muscular dystrophy 1011, 1144, 1149,	p53 response 1190	N-terminal
1286	see also OSKM factors	N-terminus
mutagenesis	Mycobacterium tuberculosis 1315, 1331,	acetylation and degradation 387
Ames test for 1119	1334F, 1335	anchoring Src kinases 118P
carcinogenesis link to 1166	Mycoplasma genitalium 10, 177, 532	cadherin linking 1110F
chemical and radiation	myelin membrane 615	polypeptide backbone 116F, 118P,
mutagenesis 519	myelin sheath 666, 724F	122F, 124F
insertional mutagenesis 519, 524 random mutagenesis 519	myelination of neurons 666, 724 myeloid cells 1288	propeptides on protein precursors 781, 1134–1135
site-directed mutagenesis 511,	myelomas 1165	protein structure and 116F
573–574	myoblasts 477F, 763, 979F, 1266–1267,	signal sequences at 695–696, 712,
mutations	1273, 1285–1286	725–726, 727, 729, 732, 734
classical genetics approaches 519,	MyoD transcription regulator 428, 429,	N-WASp protein 1338, 1339F
520-521P, 522	1241–1242, 1303, 1307	Na ⁺ -Ca ²⁺ exchanger 647, 900
complementation tests 521P, 523	myofibrils 979, 980, 981–982, 1004	Na+-driven Cl ⁻ HCO ³⁻ exchanger 644
conditional mutations 521P, 522	myosin	Na ⁺ gradients 642–643, 644–645, 648,
<i>de novo</i> mutations 245–246, 247, 254, 527	access to actin bundles 969, 974	842 Na ⁺ –H ⁺ antiporter (exchanger) 644, 842
deducing gene function from 30F,	actin and, in muscle contraction 977–981	Na ⁺ -independent Cl ⁻ HCO ₃ ⁻
32–33, 519, 522, 524, 527–528,	in actin arrowheads 958, 959F	exchanger 644–645
529–530	ATP hydrolysis by 977, 978F	Na+-K+ pump (Na+-K+ ATPase) 624F,
defined 253	in the contractile ring 951, 984, 1012,	648–649, 655, 657
deletion mutations 521P, 522F	1065	Na+-linked symporters 642-643, 645, 673
disease risk and 379, 526, 527, 539	lever arm 977, 978F, 986F	NAD+ (nicotinamide adenine dinucleotide)
driver mutations 1178, 1186–1187,	as motor protein 55, 167, 168F, 951,	as activated carrier 73–75
1188, 1192, 1193F, 1210	976–977, 1258	as electron carrier 73, 812, 818–819, 824
effects of mitochondrial DNA mutations 866–867	in non-muscle cells 984–986	as reducing agent 75
fixation of 243–244	see also cytoskeleton myosin gene mutations 984, 986	regeneration 81, 819
in germ cells and somatic cells 254	myosin I 985, 986	NADH (reduced nicotinamide adenine
heterochronic mutants 1253, 1254F	myosin II	dinucleotide)
identification through DNA	adherens junction links 984,	as activated carrier 70, 73-75, 76, 80
analysis 524	1112–1114	in catabolic reactions 74–75, 81
intragenic mutation, defined 16	bipolar thick filaments 976–977,	as electron donor 81, 89, 90, 812,
inversion mutations 521P lethal mutations 254, 441, 521P, 522,	979–980, 981, 985F	824 electron transfer through respiratory-
529	in cell motility 974, 1021 heavy chains 976, 984, 985, 1022F	chain complexes 827–828
libraries of 531–533	light chains 976, 977, 984, 985F,	in electron-transport chain 81, 90,
mobile genetic elements and 307,	1021, 1022F	827–828
308, 314–315	movement cycle of myosin II 977,	production by glycolysis 81, 82F, 83,
molnupiravir and 313	978F	108–109P
multiple mutations in cancer	sliding along actin fibers in muscle	production in the citric acid cycle
development 254, 1166–1167 mutation rates, overview 253–254	contraction 977–981	88–90, 110–111P, 817–818 respiratory-chain complexes
neutral mutations 18, 243–244	stress fibers and 969 structure 976	and 827–828
oncohistone mutations 216–217	myosin superfamily 976–977, 985F	shuttle system for electrons 820
passenger mutations 1178, 1180,	myosin V 168F, 986, 1018F	NADH dehydrogenase complex (Complex
1186, 1193F, 1210	myosin VI 985–986	I) 827, 828–829, 830F, 831,
and RNA splicing patterns 347	myostatin 1273	834F, 835F, 860F
silent mutations 254	myotendinous junctions 1148	NADP+ (nicotinamide adenine dinucleotide
somatic mutations in cancer	myotonia 668	phosphate)
cells 254, 1166, 1178, 1184, 1186, 1210F	myotonic dystrophy 347	as activated carrier 73–75 cap on mRNA 339
suppressor mutations 521P	myristic acid 616, 617F MZT (maternal–zygotic transition) 1219,	as electron carrier 73–75
temperature-sensitive	1254–1255	regeneration 74
mutations 521P, 522	1204 1200	NADPH (reduced nicotinamide adenine
types of 521P, 1179	N	dinucleotide phosphate)

About the Covers

Front cover: The determination of molecular structures by cryo-electron microscopy is a major new advance, highlighted in this Seventh Edition, and it has been chosen as the basis for our cover design. One of the main benefits of the technique has been the ability to determine the structure of integral membrane protein complexes that are either hard or impossible to crystallize. Richard Henderson at the MRC Laboratory of Molecular Biology in Cambridge, England (who shared the Nobel Prize in Chemistry in 2017 for cryoEM), suggested six recent atomic structures, all determined by cryoEM, all integral membrane proteins, and all resolved to better than 0.4 nm. Simple images of each of these molecules, which contain multiple subunits, have been drawn to scale and inserted as graphic elements in their "silver" membranes. The six molecular structures (together with their corresponding PDB codes) are as follows, starting clockwise from top left:

- 1. The voltage-gated sodium channel (see Figure 11–30) from the desert bush spider, a target for many neurotoxins including puffer fish toxin. (PDB code: 6A95.)
- 2. The human calcitonin-gene-related peptide (CGRP) receptor in complex with its G-protein-coupled receptor (GPCR). (PDB code: 6E3Y.)
- 3. The light-harvesting reaction center complex (LH1-RC) from the purple bacterium *Blastochloris viridis*. Unusually, it absorbs infrared light. In addition to the reaction center and multiple cofactors, the light-harvesting ring contains 17 alpha, 17 beta, and 16 gamma polypeptides. (PDB code: 6ET5.)
- 4. The six connexins in the hemichannel of a human connexin assembly; see Figure 19–25. (PDB code: 6L3T.)
- 5. The fungal class D GPCR from *Saccharomyces cerevisiae* in complex with the dimeric pheromone receptor, Ste2. (PDB code: 7AD3.)
- 6. The ubiquinol oxidase complex from *Escherichia coli*. (PDB code: 6WTI.)

Back cover: Instead of the more conventional pictures of the book's authors that appeared on the back covers in the past, we have chosen for the Seventh Edition to play with the idea of a "genetic portrait of each author." Issues around the public disclosure of personal health information mean that we cannot use our own individual DNA sequences, so instead we have chosen a short 1000-base-pair region of the human genome that contains common, naturally occurring, combinatorial variants and have presented them as if each might have come from one of the authors. The sequence chosen comes from an enhancer for a gene that codes for one of the subunits of the exocyst complex. This complex mediates the tethering of secretory vesicles to the plasma membrane prior to fusion (see Figure 13-21). Each of the four nucleotides in the DNA sequence has been color coded as shown in Figure 4-5, and each author's 1-kb sequence (100 lines of 10 bases per line) can be read from top left. The seven variants shown include a five-nucleotide deletion (white box) and several singlenucleotide exchanges nearer the end of the sequence (outlined in black). We thank Sai Zhang and Michael Snyder for kindly providing the seven sequences.
